**FIGURE 96-7** Modification of the pull-through procedure with the use of stapling devices. **A,** Note the stapling of the submucosal tube just above the dentate line with a linear stapling device. **B,** Insertion of an end-to-end anastomosing (EEA) stapler transanally and connection with the J pouch via the abdomen. As with an open procedure, great care is taken to ensure the J pouch is appropriately oriented during this process. **C,** Appearance of the anastomosis after firing of the EEA stapler.

Two recent comparisons between open versus laparoscopic techniques demonstrated similar outcomes between these two groups,[137,138] suggesting that laparoscopy is a viable and safe approach. Conversion rates are fairly small and were reported at 7% in a recent pediatric series.[139]

An initial umbilical port, followed by three to four 5-mm ports, are placed as shown in Figure 96-8. The umbilical port initially contains the camera with a 30-degree telescope. This is followed by an epigastric port and then left and right lateral ports. The colon, from the terminal ileum to the midrectum, is mobilized and released from the peritoneal attachments and the splenic and hepatic flexures. Initial mobilization of the lateral attachments is assisted by "air-planing" the patient to the contralateral side, with traction on the colon using a blunt bowel grasper through either the epigastric or the contralateral trocar sites, and using a cautery scissors via the remaining trocar site. The ureters are identified early during this dissection. Depending on the site of mobilization, the camera and operating ports will vary.

The more time-consuming aspect of the dissection is the mobilization of the omentum off the transverse colon—a particular challenge in more obese or high-dose steroid-dependent children. A pair of 5-mm ultrasonic scissors or the use of an endoscopic stapling device will help at this point of the dissection. Care is taken to identify and ligate the middle colic vessels, which will greatly help bring the transverse colon down to the pelvis. Alternatively, the omentum may be spared by retracting it superiorly and using electrocautery dissection between the stomach and colon.

Once the colon is fully mobilized, a low transverse, suprapubic incision is made, predominantly on the left side of the midline (see Fig. 96-8). The operating surgeon pulls the entire colon out through this incision and sequentially ligates remaining mesenteric vessels. The ileum is divided, and an ileal pouch is then created. The endorectal dissection is then performed as described earlier.

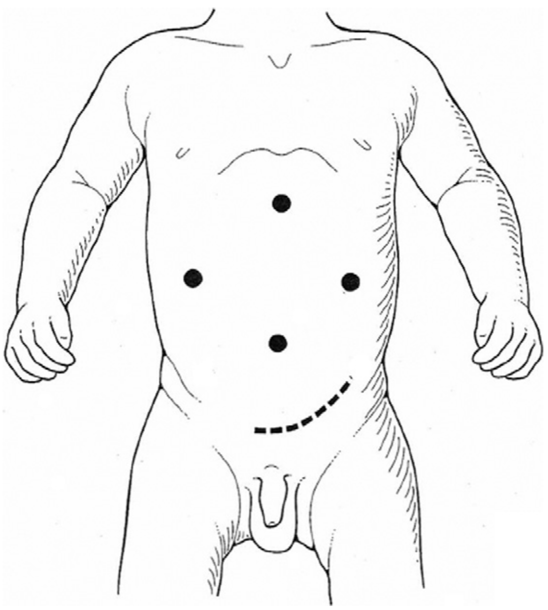

FIGURE 96-8 Suggested port sites for a laparoscopically assisted colectomy.

# Postoperative Care

Intravenous steroids are tapered after operation; oral prednisone can usually be discontinued within 3 to 4 weeks. Most children are discharged from the hospital by the sixth day after surgery. A water-soluble contrast enema is performed within 2 months to ensure that the ileal reservoir has no leaks or sinus tracts. Most children resume full physical activities within 3 weeks.

Approximately 2 to 3 months after the first operation, the patient is rehospitalized for ileostomy closure. The ileoanal anastomosis is dilated under anesthesia.

One to two digital dilations are performed in the clinic before ostomy closure to prevent narrowing of the anastomosis.

# Additional Surgical Considerations

## PROTECTIVE ILEOSTOMY

The early experience with pull-through operations demonstrated that a protecting ileostomy that completely diverts the fecal stream for approximately 2 to 3 months minimizes the risk of pouch leak and pelvic infection. Leaks from the ileal pouch when not used in conjunction with an ileostomy have been reported to be more than twice as frequent as when an ileostomy is used.[121] On the other hand, the one-stage pull-through operation has been performed successfully for many years on patients with polyposis coli. Patients with chronic UC who receive long-term steroids or other medications are often malnourished and frequently have a suppressed immune response. Such children would probably be at high risk from a primary procedure. However, patients with UC who may be considered for the one-stage pull-through procedure would include those in good general health and adequately nourished, those taking only low-dose steroids and minimal immunosuppressive drugs, those who have minimal rectal inflammation, and those who are not obese.[122] Considerable judgment must be given when deciding whether to perform a protective ileostomy. High-dose steroids, weight loss, urgent surgery, or recent (within 3 months) anti-TNF therapy should provide strong consideration for the performance of a protective ostomy.

### Stooling Patterns Post Pull-Through

In general stooling patterns become one of the key outcome measures in children after a pull-through. Stooling always takes considerable adjustment. First, nocturnal incontinence is strikingly common in the first few months, and patients and families need to be educated about this fact. This appears to be most common in younger, preadolescent patients and decreases with the age of the patient and time from surgery. Frequency of bowel movements may range widely from 6 to 15 motions per day immediately after ostomy closure. Stooling frequencies decrease over the first 2 to 3 years following ostomy closure. This is another important factor in the education of patients. Generally, after the first 3 years, further reduction in stooling frequency will not occur.

### Straight Versus J Pouch

The question as to whether children fare better or worse with a straight versus a J pouch reconstruction remains an important question. A meta-analysis comparing the two procedures in

pediatric patients showed a trend toward lower stool frequency in those children who underwent a pouch. Unfortunately, because of the nature of a meta-analysis review, there were limitations in being able to comparatively analyze patients between the selected papers in this meta-analysis.[140] A more recent multicenter series retrospectively examined stooling outcomes.[141] This study showed that rate of stooling was significantly higher in those undergoing a straight pull-through; however, rates in both groups progressively declined over time. In fact, by 24 months post-pull-through rates were fairly similar between the groups (nocturnal and during day time); however, children undergoing a J pouch had a fivefold higher rate of pouchitis compared with those with a straight pull-through (Fig. 96-9, *A* and *B*).

### Medical and Dietary Management of Stooling

Two strategies may be taken to modify the diet for reducing stool frequency. The first is an avoidance of highly spicy foods, chocolate, or acidic foods. Additionally, a bland diet with reduced simple carbohydrates may prove useful, as is a strategy of separating liquid intake from solids. One obstacle is that many children tend to lose weight after colectomy, and one needs to balance such dietary restrictions with the need to encourage good energy delivery to the child.[142]

Bulking agents (fiber) are occasionally helpful. Although they will not reduce the frequency of stooling, they will provide bulk, which may make stooling more manageable. Initiation of loperamide hydrochloride (Imodium) is often helpful in decreasing the frequency of stooling. In general this should not begin until approximately 2 weeks after ostomy closure but may need to be started earlier in some individuals. Starting doses should be 2 mg three times a day but may increase to 2 to 4 mg four times a day. Patients and their families need to be educated about the need to maintain good hydration and electrolyte intake.

## Complications and Outcomes

Although the mortality rate for children is strikingly low, morbidity is high. Complications following the ileoanal pouch procedure are reported to occur in 35% to 65% of patients.[119,126–128] The most common complications are discussed next.

### POUCHITIS

Pouchitis is the most frequent complication following a pull-through procedure, regardless of whether a straight or pouch reconstruction was performed, and may be observed in 10% to 50% of patients.[141,143] Pouchitis results in cramping lower abdominal pain and increased frequency of stooling, often with watery diarrhea. For cases that present in a nonspecific manner, the use of fecal calprotectin has been shown by several investigators to have a fairly high level of sensitivity in making the diagnosis.[144] With more systemic manifestations, one may observe fever, malaise, and occasional arthralgias.[129] Although pouchitis occurs more frequently within the first 2 years post pull-through, it may be persistent. The etiology of pouchitis has not been fully elucidated. What is particularly striking is that those children who undergo a pouch reconstruction for either multiple polyposis or Hirschsprung disease rarely develop pouchitis. This suggests that the ileum has an underlying abnormality that predisposes patients to pouchitis. One interesting observation is that those patients who received pre-pull-through calcineurin inhibitors had a low incidence of pouchitis[145]; however, this has not been

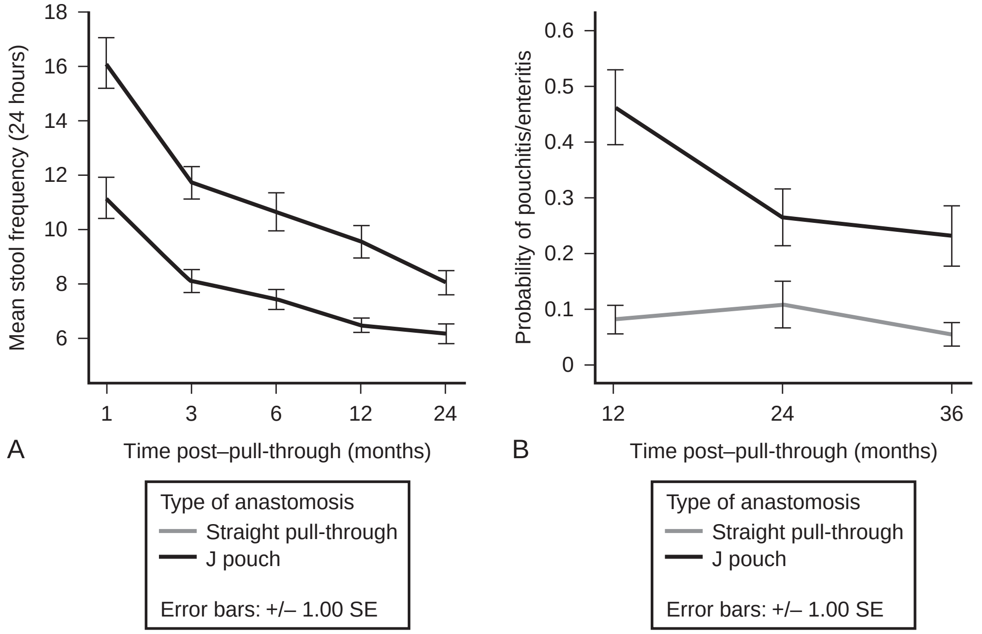

**FIGURE 96-9** **A,** Mean 24-hour stooling frequencies for children undergoing a straight and J pouch pull-through. Note the decrease in the frequencies over the first 2 years. **B,** Mean rates of pouchitis/enteritis for children undergoing a straight and J pouch pull-through. Note the rates are markedly higher in those undergoing a pouch reconstruction. (Modified from Seetharamaiah R, West B, Ignash S, et al: Outcomes in pediatric patients undergoing straight versus J-pouch ileoanal anastomosis: A multi-center analysis. J Pediatr Surg 2009;44:1410-1417.)

subsequently substantiated. Others have found an association of pouchitis with an abnormal intestinal microbiome, which is distinct from other patients without pouchitis, or those with familial adenomatous polyps. This suggests that alteration in the microbiome may be a causative factor and may allow future work to be directed at eliminating or treating this disorder.[146]

Treatment for pouchitis typically begins with a 2- to 4-week course of oral metronidazole and confirmation that the anastomosis is widely patent. More than 90% of children will respond to this approach. Should this fail, or recurrence occur, an alternative antimicrobial may be tried; in general ciprofloxacin is a good alternative. Should this fail, one should try the addition of daily pouch washouts with tap water or Rowasa (Solvay Pharmaceuticals, Inc., Marietta, Ga.) enemas. Once in remission, there is some evidence in adults that the implementation of probiotics may avoid or decrease the incidence of recurrence.[147]

For more persistent cases, oral mesalamine and hydrocortisone retention enemas may be added. When the disorder is recalcitrant, a diverting ileostomy may become necessary, particularly in children in whom chronic pouchitis may cause delayed growth and development. Several recent publications have shown that the use of probiotics can put patients into remission after antibiotics have resolved the acute pouchitis episode. Most of the recent data trends toward supporting the use of these probiotics[148] once the acute pouchitis has subsided.

## GASTROINTESTINAL OBSTRUCTION AND FISTULA FORMATION

Adhesive obstruction of the small intestine occurs in 10% to 30% of patients and remains one of the most common surgical complications.[25,30,117,149] Obstructions due to complications of the diverting ileostomy are also not uncommon and may be seen in up to 20% of cases. Not uncommonly these may be due to a tightening around the fascia or from a food bolus obstructing the lumen. One should always attempt to clear this obstruction using a large red rubber catheter through the proximal limb of the ostomy. Stricture formation at the ileo-anal anastomosis is common, particularly when an EEA type anastomosis is performed, or when a diverting ileostomy is placed. Stricture formations have been reported in 10% to 20% of cases.[25,141,143,149] Most of these strictures are readily dilatable, and once the ileostomy is closed, the passage of stool often keeps the passage open. However, if there is a devascularization of the ileum, dilations may not succeed. Fistula formation has been reported in most series.[149] In a recent multicenter study, 13% of those undergoing a straight and 5% of J pouch pull-throughs developed fistulas.[141] Fistula formation may occur to the vagina, skin, perineum, and other portions of the small bowel. In more than half of these patients, a temporary or permanent ileostomy will be necessary.[141] Miscellaneous complications include hemorrhage and hernia formation.

## CONTINENCE

One key aspect of continence is differentiation of daytime and nighttime continence. A large proportion of children will complain of nighttime accidents, with approximately 40% initially incontinent.[124] This is an important factor to educate patients and parents on ahead of the pull-through procedure. Nocturnal incontinence is most prevalent over the first 6 months after a pull-through but will often persist in preadolescent children because they typically sleep much more soundly than older patients. Daytime incontinence is far less common but has been reported in approximately 5% of all patients. However, depending on the stringency to which continence is graded, some degree of decreased continence may be found in up to 50% of children in some series.[150] In one large series of children, the occurrence of incontinence was reported at 6% and perioperative complications, particularly leakage at the anastomosis, were associated with the development of lower continence scores.[30]

## VENOUS THROMBOSIS

Postoperative mesenteric vein thrombosis with extension into the portal venous tree has been described in a number of adult series[151] and has also been reported in children.[152,153] The development of this complication may be due to excessive tension on the pull-through segment, as well as a proinflammatory state that predisposes IBD patients to the development of lower extremity deep vein thrombosis.[154] Strong consideration should be given to placing pneumatic compression stockings on children during the pull-through and prophylactic low-molecular-weight heparin.

### Pull-Through (Pouch) Failure

Approximately 15% to 45% of patients will require a repeat operation. Furthermore, anywhere from 6% to 25% will develop a pull-through failure, many of which will require removal of the pouch and construction of a permanent ileostomy.[25,124,141,155,] For approximately one third of patients who require pouch removal, the diagnosis will be found to be Crohn disease.[157] Other causes of failure include intractable stricture; leak; frequent stooling, which results in poor quality of life; and intractable pouchitis. In these cases a child should undergo an end ileostomy. Although consideration should be given to a completion proctectomy in cases of Crohn disease or intractable stricture, for those with frequent stooling or pouchitis, the pouch should be retained and an ileostomy performed, with closure 1 to 2 years after the patient has recovered from these symptoms. Interestingly, in a large meta-analysis of pediatric patients having a straight pull-through, there was a significantly higher rate of pull-through failure by almost twofold[140]; however, the cause of these failures was not identified. Another group that suffers from an increased risk of pouch failure is patients with a diagnosis of indeterminate colitis. This group of patients may make up between 5% and 25% of children.[158] In general they will present at a much younger age (some under 2 years), typically have a more severe diarrhea (often with blood), and have a more extensive pattern of ulcerations, usually with rectal sparing.[159] This group may well benefit from a total colectomy with ileostomy and retention of the distal rectum for future pull-through. Up to one third of patients with indeterminate colitis will go on to be subsequently diagnosed with either Crohn disease or UC.[158] Because of the future risk of Crohn disease, one may strongly consider waiting on the definitive pull-through until this can be determined. One way to help distinguish these patients is with the use of a gadolinium magnetic resonance imaging study. Another is with the use of serum antibodies. Those children who are

p-antineutrophil cytoplasmic antibodies (p-ANCA) positive and anti-*Saccharomyces cerevisiae* antibodies (ASCA) negative will reclassify to UC in 63.6%, whereas those who are pANCA negative and ASCA positive will reclassify to Crohn disease in 80%.[160] In contrast, another large study of children with pouch failures found a fairly high incidence of failures (15%) but was unable to attribute this to the diagnosis of indeterminate colitis.[157] In fact, these authors associated failure with female gender, perianal disease, Crohn disease, and early and late complications.

### Diagnosis of Crohn Disease After Pull-Through

As suggested in the previous paragraph, it is not uncommon to secondarily have the diagnosis of UC change to Crohn disease. In fact, between 5% and 10% of all children undergoing a proctocolectomy and pull-through will eventually be diagnosed with Crohn disease.[161] Many of these patients will initially have a diagnosis of indeterminate colitis; however, others would have little to no indication of Crohn disease at the time of pull-through. It is incumbent on the surgeon to make sure that outside pathology studies are read by their pediatric or gastrointestinal pathologist and a complete evaluation of the remainder of the gastrointestinal tract has been thoroughly evaluated before a pull-through procedure. Postoperative suspicion should arise if a child presents with any of the following: markedly increased stooling, bloody stools, frequent pouchitis, weight loss, or most importantly fistula formation (to perineum, bladder, or vagina). Although some patients with Crohn disease may remain stable with adequate medical therapy, up to one third of all pull-through failures are due to this diagnosis.[157]

### Risk of Postoperative Complications and Preoperative Medical Therapy

Complications are frequent, and a number of investigators have attributed some of these complications to the use of these therapies. Some authors have attributed the use of corticosteroids to increased infectious complications,[162] and others have demonstrated that the association of steroid use with poor preoperative nutrition is related to an increase in infectious complications.[163] Interestingly, others have failed to associate steroids, or other conventional therapies (azathioprine or 6-mercaptopurine) with the development of such complications.[164] Although conventional therapy has typically involved corticosteroids, recent therapies have included a number of additional immunosuppressive therapies including cyclosporine A and anti-TNF therapies. Tremendous controversy has arisen in the literature regarding the risk to secondary septic and leak complications postsurgery for both patients with Crohn disease and UC. Although a meta-analysis failed to show an increased risk,[165] more recent publications have identified an increased risk. Unfortunately, virtually all studies are retrospective and in part are lacking precise details regarding the length of time between last therapy and performance of surgery or are lacking details as to the disease severity of the IBD process.[166] For UC, two recent studies, one of which did stratify patients on the basis of their severity of disease, identified the use of infliximab as being associated with increased risk of postoperative complications.[167,168] Further, many who were on such therapy underwent a three-stage operation due to the surgeon's preference. Because virtually all levels of infliximab are out of a patient's circulation by 12 weeks, caution should be taken should a surgical procedure be undertaken before this time period; however, no data exist on whether there are longer-term immune-suppressive effects. Additionally, little to no data exist as to how the pediatric patient population might be affected by the use of these agents.

## QUALITY OF LIFE

Most patients have a remarkably poor quality of life (QOL) before their pull-through, so it is not surprising that most patients report a strikingly improved QOL after such a procedure.[169] Although large series have reported excellent results,[126] it is important to emphasize that QOL is not ideal after these procedures. Most patients have urgency, leakage, nocturnal incontinence, pouchitis, and occasionally sexual dysfunction. Each of these adverse events will significantly reduce QOL. Despite this, in two series on QOL in children, results showed that QOL was not significantly different from age-matched U.S. children, with little or no adverse effects from the surgery.[170,171] In fact, the surgical scar was noted to be a negative factor of significance in one series and chronic pouchitis was a factor associated with poorer QOL in the other.

## LONG-TERM FOLLOW-UP

Performance of a proctocolectomy and pull-through will require a child to be followed for the rest of his or her life. Although 99% of the colon and rectum are removed, a flexible or rigid sigmoidoscopy to monitor the small amount of remaining tissue above the dentate line must be done every 3 years to ensure that no secondary dysplastic or malignant changes develop. In addition, this close follow-up will allow the surgeon or gastroenterologist to screen for secondary complications, evaluate the patient's nutrition, and rule out extraintestinal manifestations.

# Conclusions

UC has a significant morbidity in pediatric patients. The disease process requires extensive expertise from the medical, nutritional, nursing, and surgical specialties. With comprehensive and aggressive care, excellent results may be obtained. Many patients in the pediatric age group will require surgical care. Although most children do well with a proctocolectomy and pull-through, realistic outcomes need to be emphasized to the family. More than half of all patients will encounter early or late complications after such surgery. With time, most patients will improve and their lives normalize; however, care following surgery requires patients to maintain continual follow-up with their medical providers throughout life.

# CHAPTER 97

# Primary Peritonitis

Robert Baird and Jean-Martin Laberge

Primary peritonitis (PP), also referred to as *idiopathic* or *spontaneous peritonitis*, has been defined as an infectious process involving the peritoneal cavity without an intra-abdominal source.[1–3] Such infection may seed the abdomen through hematogenous or lymphatic routes or by direct extension from the vagina. With the exception of the ends of the fallopian tubes, the peritoneal cavity is a completely closed space that can be penetrated by foreign bodies such as ventriculoperitoneal shunts and peritoneal dialysis catheters. In prepubertal and adolescent girls, retrograde spread of fluid out through the fallopian tubes may account for the presence of an ascending vulvovaginitis or "swimming pool peritonitis."[4–7]

By the early 1900s, up to 10% of abdominal operations in children fell into the category of PP and carried an associated mortality of up to 50%.[2] In 1964 Conn linked the presence of intra-abdominal ascites with the bacterial translocation of intestinal flora resulting in primary peritonitis.[8] Today, PP is a rare cause of peritonitis in children and represents less than 1% of all pediatric laparotomies because the diagnosis is often made and treatment frequently does not require an operation.[3] Most cases of PP in the pediatric age group are associated with nephrotic syndrome (NS) or chronic hepatic states in which ascites and/or cirrhosis is present. This group includes infants and children with biliary atresia, cystic fibrosis, hepatic fibrosis, and lupus erythematosus (Table 97-1).[9–11] Organisms isolated from the peritoneal cavity vary according to the associated conditions (Table 97-2). For instance, gram-positive organisms including *Streptococcus pneumoniae* and group A streptococci are most commonly found in patients with NS.[12–14] The same gram-positive groups are cultured in patients with underlying liver disease, but this patient population also demonstrates gram-negative isolates including *Escherichia coli, Klebsiella pneumoniae,* and *Pseudomonas* species.

## Clinical History, Laboratory Data, and Diagnostic Studies

Children with PP have acute abdominal pain associated with a febrile illness, nausea, vomiting, diarrhea, or other viral-like prodromes. The time course may be more protracted than that for secondary peritonitis, and diffuse rebound tenderness is often present. The absence of localized pain may result from irritation of visceral surfaces.[15–16] Diagnostic paracentesis may be helpful in the presence of ascites, as is sampling of the dialysate in children with renal failure on ambulatory peritoneal dialysis programs. The diagnosis of PP is made when the peritoneal fluid leukocyte count is higher than $500/mm^3$ and granulocytes predominate (lymphocytes are usually present in higher numbers in normal peritoneal fluid). Typical peritoneal fluid in PP also has a pH of less than 7.35 and an elevated lactate level.[17] If more than one organism is present on Gram stain, a perforated viscus should be suspected. Sending a minimum of 10 mL of fluid for Gram stain and culture analysis will increase the number of positive isolates, yet cultures may be negative in up to 60% of reported cases.[18] The isolation and sensitivity pattern of specific bacteria decreases the spectrum of antibiotics required and potentially eliminates the use of nephrotoxic drugs in patients with compromised renal function.[13] Samples of blood and urine should be sent for culture, and radiographs of the chest and abdomen should be obtained. These studies will help eliminate a perforated viscus or a pneumonic process as the cause of the abdominal pathology. Routine electrolytes and total protein levels should be investigated because low serum protein levels and concomitant decreased opsonins may contribute to the development of PP.[19]

Ultrasound studies and computed tomography (CT) of the abdomen have been used to differentiate primary from secondary peritonitis (caused by such common pediatric processes as appendicitis) when the clinical picture is confusing. Double-contrasted CT scan findings in PP include the presence of a patent appendiceal lumen, diffusely distributed peritoneal fluid, and secondary enhancement of the bowel wall.[9]

## Primary Peritonitis in Healthy Children

Gross reported 58 cases of PP in a group of previously healthy infants and toddlers (mean age, 2 years) who had a preexisting upper respiratory infection.[20] The complex of initial symptoms included vomiting, fever, irritability, abdominal distention, and tenderness. *S. pneumoniae* was the predominant organism isolated. A later series from the same facility

recorded 33 patients with a mean age of 5 years who were treated for PP over the next 30 years.[21,22] The decrease in number of affected children was considered the result of increased availability and use of oral antibiotics. Although multiple potential sources of infection have been implicated including hematogenous (dental procedures, bacteremia), lymphatic, gut translocation, and ascending gynecologic processes, the etiology remains unclear in most cases. In 1985 two previously healthy children with dehydration, abdominal distention, and group A streptococcal peritonitis were reported. At the time of laparotomy no source of infection was identified, although one of the children had a concomitant right-sided diaphragmatic hernia.[23] The literature has since identified a group of healthy children with idiopathic peritonitis and simultaneously positive cultures for group A streptococci from the trachea, pharynx, or tonsils.[24–26] *Haemophilus parainfluenzae* was recently isolated during an abdominal exploration when no intestinal pathology was identified.[27]

In prepubertal girls with gonococcal vaginitis, 6% may have evidence of peritonitis. Treatment with parenteral cephalosporins is indicated, and the presence of other associated simultaneous sexually transmitted diseases should be investigated.[6] In earlier reported series of PP, most of the patients were girls and the vagina was often implicated as the source of the infections. However, vaginitis was uncommon and the ultimate source of the infection remained obscure.[21] The prepubertal cervix lacks the endocervical glands that may harbor bacteria, so ascending infections in this age group would more likely be associated with some traumatic force that pushes the bacteria up through the vagina, as in sexual abuse cases or by jumping feet first into a swimming pool or lake water.[5] In more recent series the incidence of PP is equally distributed between boys and girls.[15,28,29] In some cases the same bacteria causing the peritoneal infection have also been cultured from the respiratory and urinary tracts, as well as from the oral cavity.[1]

In all instances of peritonitis without an overt source of infection, failure to improve with intravenous antibiotics is an indication for laparoscopy or laparotomy. An appendectomy can be done safely even in the presence of cloudy exudate, and the bowel surface can be inspected for secondary causes of the infection. After the surgical intervention, antibiotics should be continued until the leukocytosis normalizes and the ileus resolves.[2,16]

# Nephrotic Syndrome

PP has been reported in 3% to 17% of children with NS.[12,30–35] Before the availability of antibiotic therapy, PP was the leading cause of death in this group of patients. An increased susceptibility to infection in these patients may be influenced by impaired cellular immunity and chemotaxis, decreased opsonization, and reduced levels of circulating immunoglobulins. Complement proteins I and B are reduced in the serum but increased in the urine of patients with peritonitis and NS.[36] The episodes of peritonitis are recurrent in 15% to 26% of cases and have been associated with decreased levels of circulating IgG.[31,35]

Large reported series in children indicate that gram-negative organisms are isolated in 6% to 30% of patients with NS and peritonitis, whereas *S. pneumoniae* was cultured in 4% to 38%.[12,31,37] Even when the peritoneal fluid showed no bacterial isolates, children symptomatically responded to the systemic administration of intravenous penicillin.[10] Initial treatment of PP should include the administration of antibiotics to cover both gram-positive and gram-negative bacteria. In cases in which clinical improvement does not occur within 24 hours after the initiation of therapy, further diagnostic studies such as abdominal CT or diagnostic laparoscopy should be employed to eliminate other causes of peritonitis. Abdominal CT scans may not always successfully differentiate primary from secondary peritonitis. Laparoscopy and abdominal irrigation have been successfully used with medical management when the clinical course shows no improvement.

In almost 80% of children with NS in whom PP developed, either steroids were being used as treatment of the condition or a relapse of NS had occurred.[12,34,55] Pneumococcal vaccination (Pneumovax) has been recommended in this group of patients, yet peritonitis has occurred despite protective immunization.[37,38] In the context of the developing world, a recent report advocates immunization only for the small number of children who have steroid-dependent or steroid-resistant nephrotic syndrome.[39] Resistant organisms can develop in children treated with oral penicillin prophylaxis.[38]

# Peritonitis with Peritoneal Dialysis

In children maintained on chronic peritoneal dialysis (PD), peritonitis is the primary complication compromising survival. The problem has prompted formation of the International

Pediatric Peritonitis Registry, an Internet-based prospective registry of 47 pediatric centers across 14 countries.[35] Peritonitis (either bacterial or fungal) occurred at a rate of one episode per 11.1 to 13.2 patient-months in separate multi-institutional studies.[14,40–42] Gram-positive organisms were isolated in 44% to 49% of the cases (most commonly *S. aureus* and *S. epidermidis*). Gram-negative bacteria were in 21% to 25% of the cases, and fungi were in 1.8%. Of the symptomatic patients, 21% to 31% did not have positive cultures (Table 97-3).[35,40] Gonococcal peritonitis has been reported in a sexually active adolescent undergoing peritoneal dialysis.[7] Risk factors for the development of peritonitis in this group of children include contamination of the connectors during dialysate fluid exchange, exit site or tunnel infections, local trauma to the tunnel site, and nasal colonization with staphylococcal organisms.[40] Additional risk factors for the development of PD-related peritonitis include the duration of PD (longer than a year), chronologic age younger than 2 years, and decreased serum IgG levels.[43]

Clinical findings include abdominal pain, fever, and an elevated neutrophil count in the cloudy dialysate. Once suspected, the fluid should be cultured and both intravenous and intraperitoneal antibiotics should be instituted, with close monitoring of antibiotic levels. Because in vitro evaluation revealed 69% sensitivity of gram-positive organisms to a first-generation cephalosporin and 80% sensitivity of gram-negative organisms to a third-generation cephalosporin worldwide, current treatment guidelines for empiric therapy include either a first-generation cephalosporin and ceftazidime or a glycopeptide (vancomycin or teicoplanin) with ceftazidime.[44] Aminoglycosides may play a role in empiric therapy for high-risk patients, and antibiotic therapy should be tailored once culture and sensitivity results become available.

Symptoms should begin to improve within 24 to 36 hours after initiation of therapy.[45] Long-term multi-institutional longitudinal studies suggest that the PD catheter must be removed to eradicate the infection when *Pseudomonas, Candida,* or atypical mycobacterial species are involved.[14,40,43,46] There is also a risk of peritoneal membrane failure when these organisms are involved, thus precluding the continued use of PD. Peritonitis rates are decreased when a two-cuff system is used and when the exit site is directed downward.[29,40] Nonetheless, relapsing peritonitis remains a common clinical problem for these patients. Defined as recurrence of peritonitis with the same organism within 4 weeks after termination of antibiotic treatment, relapsing peritonitis was found to occur in 11% of PD patients experiencing an episode of peritonitis; it significantly decreased the rate of full functional recovery and increased the rate of necessitating permanent PD discontinuation.[47]

**TABLE 97-3**
**Organisms Involved in Peritonitis in Children Maintained on Chronic Ambulatory Peritoneal Dialysis***

| Other bacteria or fungi | 13.9 |
| No organisms found on culture | 13.9 |

*Data from 144 episodes of peritonitis in 66 children at J.W. Riley Hospital for Children, Indianapolis.

## Hepatic Dysfunction

In a child with impaired hepatic function, cirrhosis, and ascites, the PP that develops is characteristically associated with both gram-negative and gram-positive organisms.[19,48] The liver with its rich reticuloendothelial tissue normally filters the bacteria found in the portal circulation. As cirrhosis develops, portal venous flow is partially shunted away from the liver, thereby decreasing the clearance of bacteria and fungi from both the blood and lymphatic systems. This decreased clearance likely allows for the persistence of bacteria in ascitic fluid.[11,18,49–51] Children will have fever and abdominal pain in 50% of PP cases. Paracentesis fluid that has greater than 500 leukocytes/mm$^3$, bacteria on Gram stain, and a pH of less than 7.35 had 100% sensitivity and 96% specificity for active PP.[13] Patients with cystic fibrosis and hepatic dysfunction as a result of cirrhosis or impaired synthetic function are also at risk for episodic PP.[52] The treatment of choice for PP in this context is a third-generation cephalosporin in most pediatric patients. Children at risk should be maintained on trimethoprim-sulfamethoxazole for prophylaxis.[53] Long-term fluoroquinolone use in infants and young children is discouraged due to safety concerns regarding possible quinolone-induced arthralgia or cartilage toxicity.

## Ventriculoperitoneal Shunts

Spontaneous bacterial peritonitis has been described in children with indwelling ventriculoperitoneal (VP) shunts without evidence of cerebrospinal fluid infection.[54] Cultures from these patients have resulted in a variety of gram-positive organisms, and improvement in peritoneal irritation occurs with exteriorization of the shunt tubing. On the other hand, VP shunt infection from a readily identifiable source remains a common complication (see Chapter 128); a complete diagnostic workup is required including a shunt series, tapping of the shunt reservoir for culture and sensitivity, head CT scan, and abdominal imaging depending on presenting complaints. When shunt fluid appears sterile, Gram stain and culture of peritoneal fluid may help to differentiate PP or shunt infection from an intra-abdominal source. Common intra-abdominal infectious processes like appendicitis must be treated promptly, and shunt exteriorization strongly considered. In patients with indwelling VP shunts and recurrent episodes of PP, consideration should be made for elective appendectomy.

## Sterile Peritonitis

Although PP is traditionally defined as an infectious process, certain disease entities are associated with peritoneal inflammation without the presence of an offending organism.

## SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is a rheumatologic condition characterized by the formation of autoantibodies directed at self-antigens. The pathophysiology is multifactorial, and the presentation can vary greatly among patients. Serositis is a frequent manifestation of the disease, and PP has been described as the index presentation for SLE.[55] Peritoneal inflammation is not a consequence of bacterial contamination, but rather a reaction to antibody-antigen interaction. A recent review of pediatric-onset SLE demonstrated a 19% rate of abdominal involvement, most commonly due to pancreatitis or new-onset ascites. Three children in the series, one of whom was found to have acalculous cholecystitis, underwent laparotomies for peritonitis before the diagnosis of SLE.[56] For patients with known SLE, high-dose steroids usually prove effective as first-line therapy for acute abdominal pain once other surgical pathologies have been ruled out. This can sometimes prove difficult in immunodepressed children, in whom clinical signs of intra-abdominal perforation or ischemia may be masked. Clinical vigilance is required, and extensive investigations are frequently necessary.

## FAMILIAL MEDITERRANEAN FEVER

Familial Mediterranean fever (FMF, also known as *recurrent polyserositis*) is characterized by transient episodes of pleuritis, arthritis, and peritonitis and primarily affects Armenians, Turks, and Jews originating from the Mediterranean area. Its inheritance is generally recessive, although varying penetrance has been reported depending on the genetic mutation. Nonsense or missense mutations in the *MEFV* (Mediterranean fever) gene appear to cause the disease in many cases. *MEFV* causes the production of inflammatory proteins, pyrin (derived from the association with predominant fever) or marenostrin (derived from the phrase “our sea,” because of the Mediterranean heritage of most patients). Frequent episodes of inflammation of the peritoneum (85%), joints (50%), and pleura (33%) are associated with high fever and abdominal tenderness. A recent review has demonstrated that 31% of patients manifest symptoms by 2 years of age, although this young cohort is less likely to present with peritonitis.[57] In FMF, the abdominal symptoms begin to abate within 12 hours of onset, with resolution within 24 to 48 hours. If surgical intervention is undertaken, the bowel is characteristically coated with a sterile exudate containing fibrin. As in SLE, ascitic fluid is characteristically sterile in FMF; antibiotics do not play a role in the acute setting or as prophylaxis. The use of colchicine may decrease the severity of painful episodes and reduce the incidence of long-term adhesive small bowel disease.[58] Five to ten percent of patients have not responded to colchicine; anakinra (an interleukin-1 receptor antagonist) can control the acuity of febrile attacks in adolescents.[59] Once the diagnosis of FMF has been considered, a complete family history should be obtained and genetic testing promptly offered. Long-term complications include the development of adhesive small bowel obstruction in 3% of pediatric cases.[60]

CHAPTER 98

# Stomas of the Small and Large Intestine

Michael W. L. Gauderer

## Historical Note

The word *stoma* originates from the Greek *stomoun* (to provide with an opening or mouth). Intestinal stomas, considered basic surgical procedures, have a long and colorful history.[1–4] As a method of treating intestinal obstruction, colostomies date back to the latter part of the eighteenth century and some of the first survivors of this procedure were children with an imperforate anus.[5–7] Despite sporadic early successes, the use of stomas in the large intestine and later the small intestine in children evolved slowly. Surgeons were understandably reluctant and even strongly opposed to performing these drastic procedures, which were associated with major complications. However, as the experience of surgeons increased toward the end of the nineteenth century and beginning of the twentieth century, colostomies and occasionally jejunostomies were used to manage a few pediatric conditions. With the advent and the development of pediatric surgical practice in the mid to late 1900s and survival of children with conditions that were formerly likely to be fatal, the need for stomas increased. Enterostomal construction techniques, originally developed for adults,[8–12] were modified and adapted for use in children, particularly newborns with congenital intestinal obstruction.[13–18] New techniques that combined proximal decompression and distal feeding for neonates with atresia of the duodenum or high jejunum were introduced next.[19,20] In the past 3 decades, endoscopic, laparoscopic, and various image-guided approaches have been added to established open techniques continuously fostering the creation of feeding, venting, decompressing, irrigating, and special-purpose stomas. Understanding of stomal physiology and of specialized enteral and parenteral nutrition, as well as the diagnosis and management of stoma-related complications, have paralleled the advances in technique significantly improving outcome.

Several other factors have contributed to the safety, effectiveness, and ease of care of stomas in adults and children. Paramount among these is the advent of enterostomal therapy, which has evolved into a specialty in its own right.[21,22] Enterostomal therapists are now an integral part of health care teams in most medical institutions. Major national and international ostomy associations[23] foster the dialogue among professionals and provide a wealth of information through traditional and web-based material including publications for parents, caregivers, and teenage patients.[24,25]

Regional and local chapters are involved in establishing nonmedical support systems and guidance to access resources.[26] Greater awareness and acceptance of ostomates, as well as the recognition of their needs and rights among the lay population, has also helped to improve their quality of life. The knowledge and experience derived from enterostomal care has led to the creation of appliances in a wide variety of types and sizes, manufactured of well-tolerated biomaterials and complemented by numerous stoma care products.[27] Not surprisingly, at times, parents, caregivers, or ostomates contribute innovative ideas to the established management techniques.[28]

In the contemporary clinical setting, primarily because of earlier diagnosis of certain gastrointestinal anomalies such as Hirschsprung disease, improved surgical approaches, and perioperative care, pediatric surgeons were able to safely perform more single-stage procedures, thereby decreasing the need for preliminary decompressing enterostomies (ileostomies and colostomies).[29–33] Conversely, due to an ever-increasing number of children with a variety of complex surgical and nonsurgical pathologies, there has been a greater demand for upper gastrointestinal access for long-term enteral feeding (gastrostomies and jejunostomies),[34–38] as well as lower intestinal access for antegrade enemas (appendicostomies, tube cecostomies, and tube sigmoidostomies).[39–43] Often requiring a team approach, the creation, care, and closure of enterostomas continue to occupy a substantial portion of pediatric surgical practice.

## Child with a Stoma

An enterostoma in a child is a major disruption of normality and frequently leads to substantial psychologic trauma for the child and parents. However, most decompressing intestinal stomas in the pediatric age group are temporary and correction of the underlying problem often leads to closure of the diverting opening. Although pediatric surgeons continuously search for alternatives to intestinal exteriorization, an appropriately indicated, properly constructed temporary stoma is frequently unavoidable and lifesaving. Moreover, in several instances of noncorrectable and crippling pathologic conditions of the lower intestinal tract, a permanent, well-functioning stoma contributes to an improved quality of life.[44,45]

Despite many advances related to enterostomas, their placement, care, and closure are still associated with a surprisingly high rate of both early and late complications.[46–70] These facts present the surgeon, the enterostomal therapist, the nurses, the parents, and the child with major challenges. Therefore when the need for a stoma arises, the best results are achieved by carefully evaluating the child's pathologic condition and health status, weighing the pros and cons of diversion, planning ahead (for eventual closure) whenever possible, and considering both construction and takedown as major interventions.

In addition to the well-defined guidelines for stomal placement established for adult patients, pediatric factors including anatomic and physiologic differences, delicate structures, growth, and physical and emotional maturity, as well as preoperative preparation, whenever possible, need to be considered.[24,25,71] The surgeon and members of the surgical team must always keep in mind that the quality of life of a patient with a stoma is largely related to the quality of that stoma.

# Types of Enterostomas

The four basic types of enterostomas, primary purposes, and technique options are listed in Table 98-1. Examples of these methods are illustrated in Figures 98-1 to 98-3. Options for bringing the proximal stoma through the abdominal wall and handling the distal stoma are listed in Table 98-2. Examples are found in Figures 98-3 to 98-5.

**TABLE 98-1**
**Applications and Considerations for Enterostomas**

| |
|---|
| **Administration of Feedings, Medication, or Both** |
| Without entering the jejunal wall: nasojejunal tube, gastrostomy-jejunostomy tube[34] |
| Direct access through the jejunal wall: tunneled catheter,[9] needle catheter, T-tube,[82] button,[100] other |
| Isolated jejunal loop brought directly to abdominal wall: Roux-en-Y[108–110] |
| **Proximal Decompression and Distal Feedings** |
| Gastrostomy and distal feeding tube, same stoma or separately[20,34] |
| Double-lumen tube in dilated proximal jejunum with feeding end across an anastomosis[19]; or two single-lumen tubes inserted separately into divided, closed loops of small intestines[81] |
| Divided intestinal segments brought directly to skin level, with pouch applied to proximal stoma and feeding catheter inserted into distal one |
| **Access for Antegrade Irrigation** |
| Appendix or other intestinal conduit brought to abdominal wall for intermittent catheterization[5,52,85] |
| Catheter, T-tube, skin level device placed in intestinal lumen[37,41,81,88] |
| **Decompression, Diversion, or Evacuation** |
| End stoma, single opening[11] |
| Double-barrel stoma[10,17] |
| End stoma with an anastomosis below the abdominal wall[13,15] |
| Loop over a small rod or skin bridge[8,14] |
| Closed loop with catheter[81] or open loop with occluding valve-type device allowing controlled egress |
| Special stomas such as a catheterizable pouch[36,47] |

# Indications for Enterostomas in Children

Temporary and occasionally permanent stomas of the small and large intestine are used in the management of a wide variety of surgical and nonsurgical pathologic conditions in neonates, infants, and children. With the exception of feeding and antegrade enema access, more than one half of all stomas are placed in the neonatal period and another one fourth in infants younger than 1 year of age.[51,52,54,59]

## JEJUNOSTOMIES

Indirect access to the jejunum via naso-jejunal or gastro-jejunal route is adequate for short- or intermediate-length nutritional support.[36] Direct access to the proximal small bowel is most commonly used for long-term enteral alimentation as an alternative to a gastrostomy, which is the preferred route.[34,72] The majority of patients requiring a feeding jejunostomy are neurologically impaired children, usually with complex medical problems associated with foregut dysmotility. Some of these may require both a gastrostomy and a jejunostomy in their management. Jejunal access can also be useful in the care of patients with acute surgical problems benefiting from early enteral nutrition (e.g., major trauma or burn victims, children needing long-term supplemental feedings). Various types of exteriorized jejunal segments were once used in the management of infants with biliary atresia, in an attempt to reduce ascending cholangitis. However, this approach is no longer used, in part because of secondary problems such as bleeding from stomal varices associated with portal hypertension[50] and because the stoma adds complexity to a future liver transplantation.

On the other hand, the use of a segment of intestine or drainage device interposed between the gallbladder and the abdominal wall for partial drainage of bile has been helpful in the management of children with some types of genetic cholestatic syndromes.[73–76] As with other segments of the intestine, exteriorization[55,77–80] or tube decompression[81] is indicated following bowel resection when a primary anastomosis is unsafe or impossible (e.g., necrotizing enterocolitis, midgut volvulus).

## ILEOSTOMIES

These stomas are essential in the management of neonates with certain types of distal intestinal obstruction (e.g., long-segment Hirschsprung disease, complex meconium ileus, gastroschisis with atresia).[13,52,54,82] Ileostomies are commonly placed to divert bowel contents when reestablishing bowel continuity is precluded by peritonitis, ischemia, or hemodynamic instability ( e.g., neonatal necrotizing enterocolitis) (Figs. 98-6 and 98-7).[77–79,82] Ileal diversion has traditionally been used in the surgical approach to colonic pathology (e.g., ulcerative colitis, familial polyposis) as temporary, protective, or, at times, permanent stomas.[3,4,11,83,84] Less common indications include other forms of inflammatory bowel disease, rare manifestations of colonic dysmotility, and monitoring of the intestinal graft in patients with small bowel transplantation.

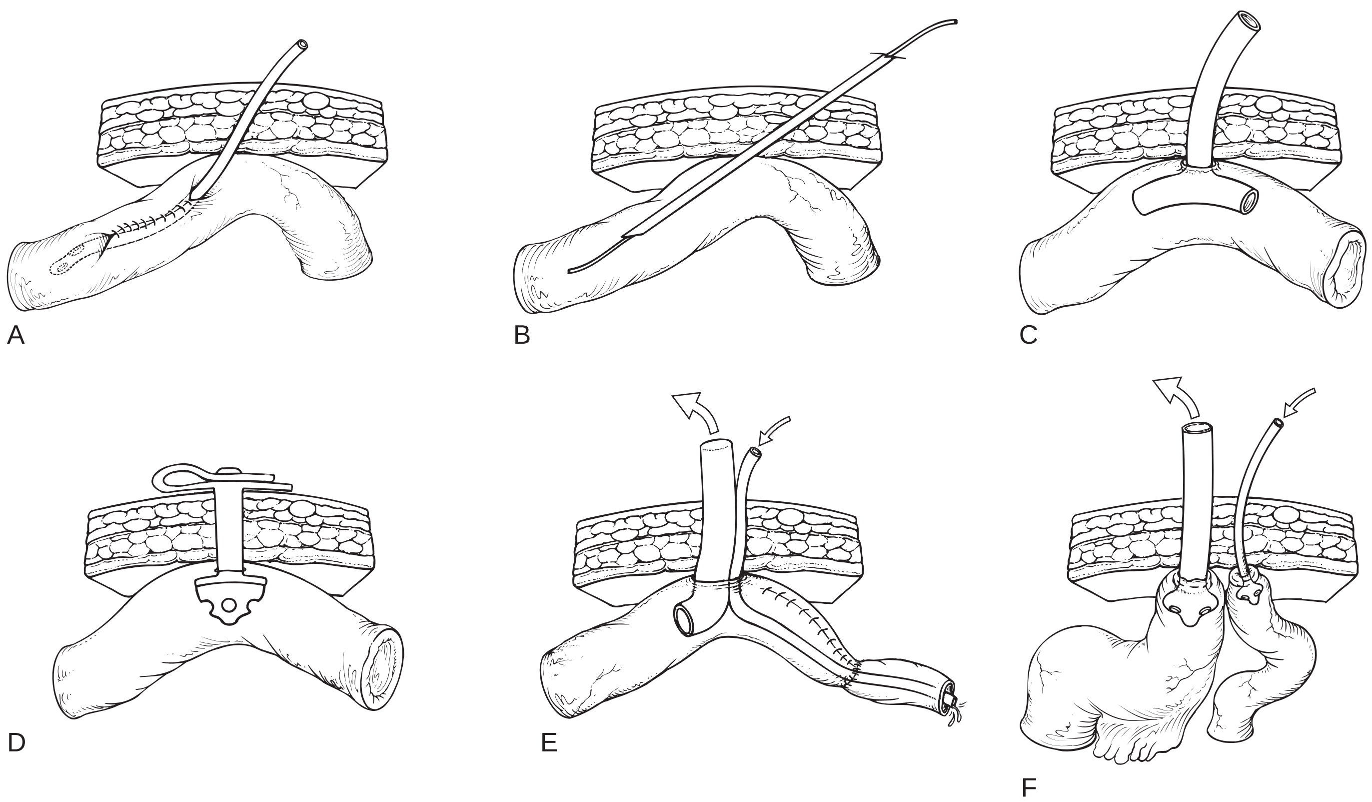

**FIGURE 98-1** Diagrams of select-feeding and decompressing-feeding jejunostomies. **A,** Tunneled catheter.[9] **B,** Needle catheter. **C,** T-tube.[82] **D,** Button.[100] **E,** Proximal decompression and distal feeding across an anastomosis.[19] **F,** Temporary decompression feeding using catheters when primary anastomosis is unsafe and intestinal exteriorization is undesirable or not possible.[81]

## APPENDICOSTOMIES, TUBE CECOSTOMIES, AND TUBE SIGMOIDOSTOMIES

The main indication for these interventions is to provide long-term access sites for antegrade intestinal irrigation in children with colonic motility, anal sphincter problems, and myelodysplasia.[39–42,85–91]

## COLOSTOMIES

Stomas of the large bowel have the longest history, and extensive experience with these enterostomies has accrued.[1–7] Diversion of fecal stream is essential in the treatment of several congenital hindgut pathologies (e.g., high forms of imperforate anus,[5,6,67] late diagnosis or complicated Hirschsprung disease,[68] complex pelvic malformations,[92] colonic atresia[93]). Colostomies are also used in patients with severe colonic, anorectal or perineal trauma,[32,94,95] perineal burns,[96] and complications of malignant conditions.[58,97] Unlike in the adult population, in which colorectal cancer is the most common indication, colostomies are rarely permanent in children.

## UROSTOMIES

Exteriorized segments of ileum or colon have been used as conduits in the management of urinary tract pathologies, although these diversions are seldom used today. However, the mobilized appendix, interposed between the bladder and the abdominal wall surface, is used in children with

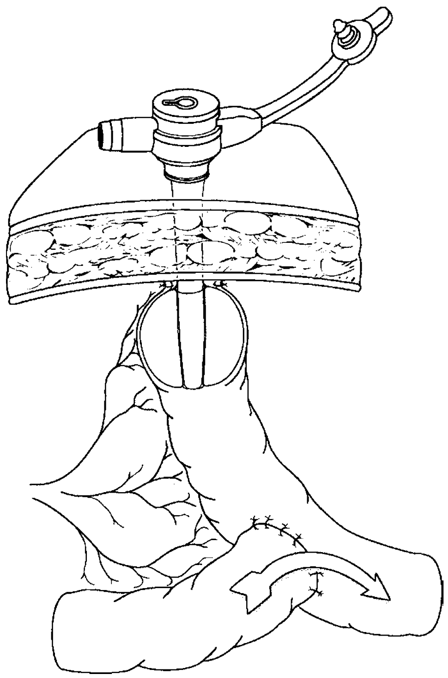

**FIGURE 98-2** Roux-en-Y feeding jejunostomy with a balloon-type skin-level access device.[108]

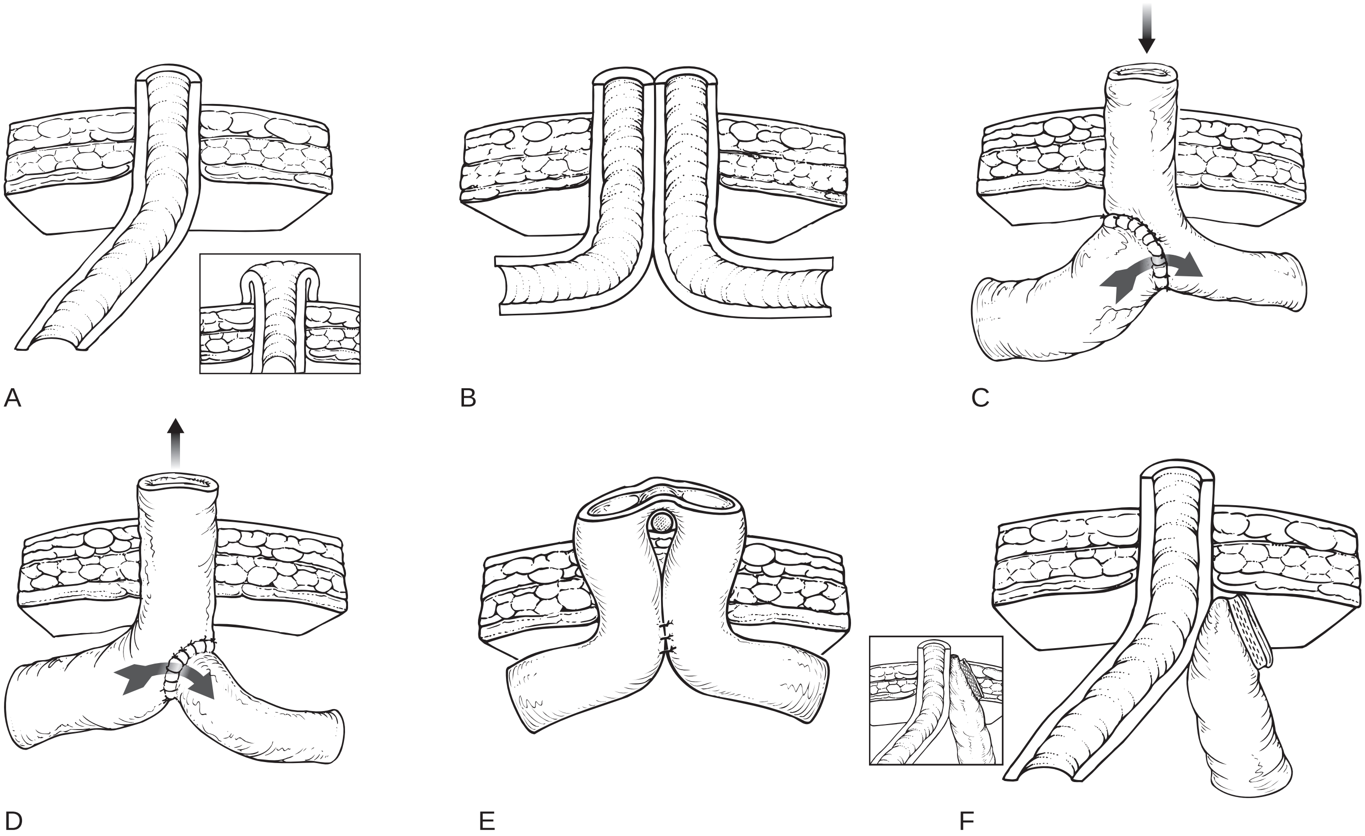

FIGURE 98-3 Examples of decompressing, diverting, or evacuating stomas. **A,** End stoma (*inset* shows typical maturation).[11] **B,** Double-barrel stoma.[10] **C,** End-to-side anastomosis with distal vent for irrigation.[13] **D,** Side-to-end anastomosis with proximal vent.[15] **E,** Loop stoma.[8] **F,** End stoma with closed subfascial distal of the end of the intestine (*inset* shows rodless end-loop stoma).

| Closure after placement of a catheter for subsequent access for irrigation or contrast studies |

various urinary tract dysfunctions to provide a catheterizable conduit to the urinary bladder.[98,99]

# Choice of Enterostoma

## FEEDING JEJUNOSTOMY

Various approaches for establishing direct long-term access to the jejunum are now available. "Open" placement through a small, left upper quadrant incision permits excellent identification of the stoma site in the proximal jejunum, as well as secure attachment of the bowel to the abdominal wall.[36,37,100,101] Direct percutaneous endoscopic jejunostomy (PEJ) is applicable to older patients but difficult in small children due to limitations imposed by the endoscopic equipment.[102] A number of image-guided jejunostomies have been described but have been within the purview of radiologists in a few pediatric centers.[37,103,104] Laparoscopic or laparoscopically assisted techniques are now used with increasing frequency in all age groups.[105–107] Bringing the loop directly to the abdominal wall and placing a skin-level access device is simple and effective. Peristomal leakage is always a concern. An alternative intended to decrease this problem is the more complex Roux-en-Y approach.[108,109] However, this method has a greater potential for serious complications such as volvulus and internal hernias with intestinal obstruction.[110,111]

The choice of access device depends on the type of stoma and the age of the child.[27,112] Because straight catheters can be difficult to immobilize or replace in conventional tunneled jejunostomies, a good alternative is a T-tube for infants (because it does not obstruct the narrow lumen) (see Fig. 98-1, *C*), and an original type button (Fig. 98-1, *D*) or other nonballoon skin-level device for older pediatric patients. Balloon-type devices are suitable for the Roux-en-Y loop (see Fig. 98-2). As with a gastrostomy, these devices are both replaceable as an office procedure.

## ILEOSTOMY

In intra-abdominal interventions requiring intestinal resection, such as neonatal necrotizing enterocolitis, many surgeons prefer to exteriorize a single-end stoma through a counterincision

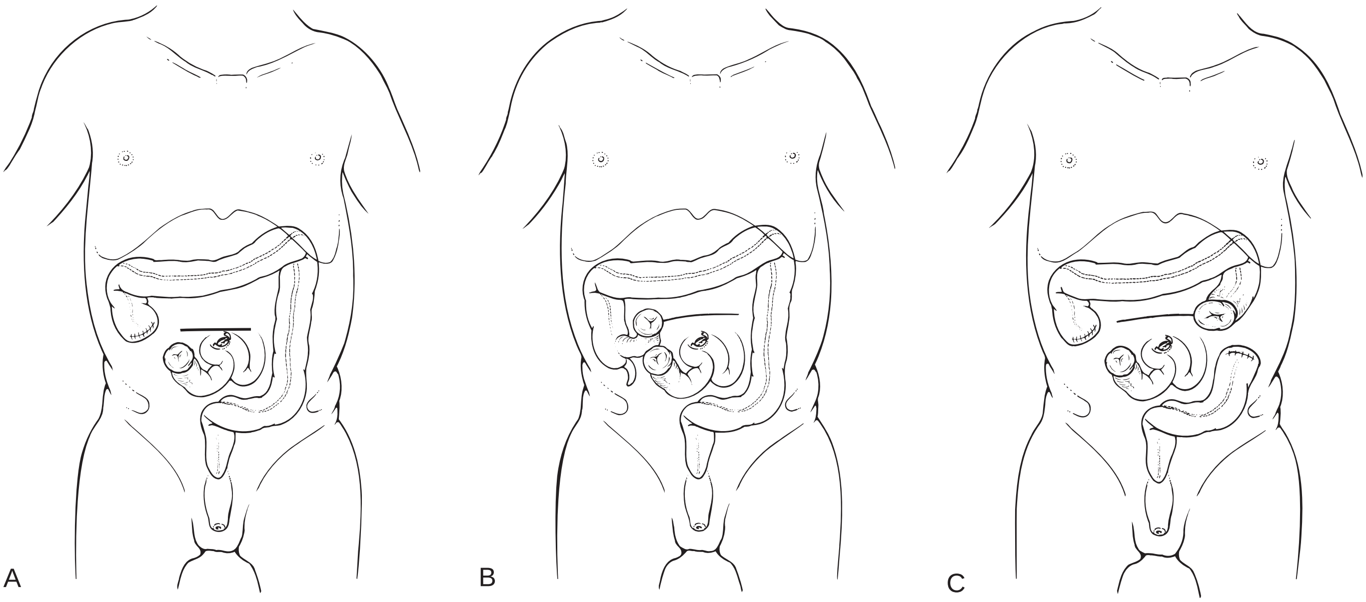

**FIGURE 98-4** Examples of options for the management of infants after intestinal resection. **A,** Exteriorization of proximal intestine through a counter-incision and closure of distal intestine beneath the abdominal wall. **B,** Same procedures as in **A** with exteriorization of proximal end of distal intestine through the wound edge. **C,** Arrangement after resection of two intestinal segments.

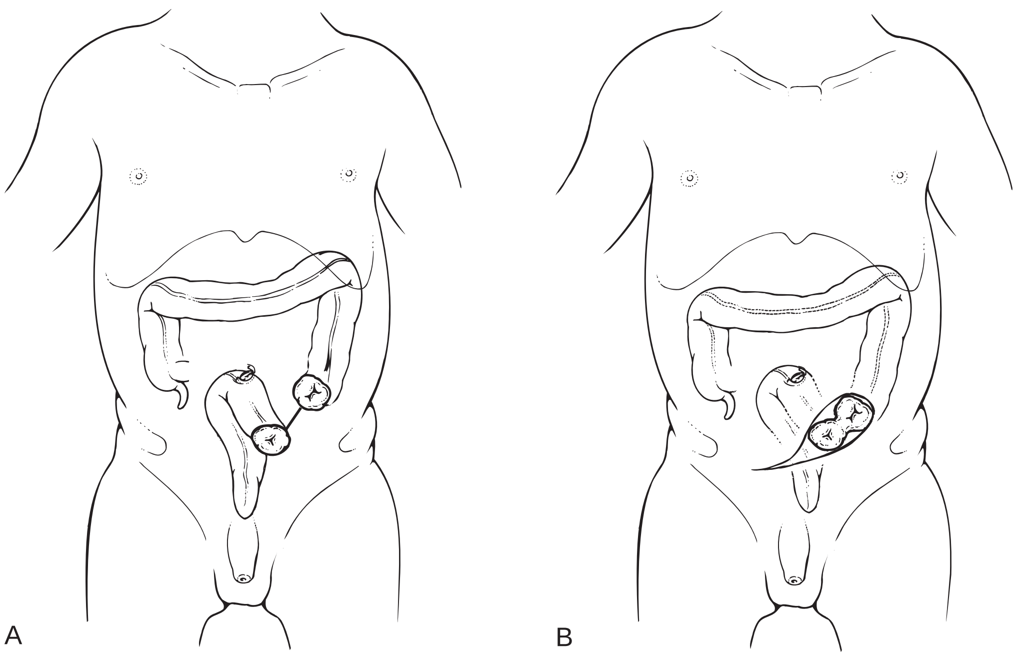

**FIGURE 98-5** Sigmoid colostomies. **A,** Separated stomas. The proximal intestine is at the upper end of the incision, and the mucus fistula is at the lower one. **B,** Loop colostomy. The intestine is exteriorized over a rod or skin bridge or with the help of sutures. The circumscribing comma-shaped incision is used for takedown and pull-through procedures.

(see Figs. 98-4, *A*, 98-6, and 98-7). A more expedient alternative is to bring the proximal intestine through the end of the incision (see Fig. 98-4, *B*). However, with this approach, wound complications are more common. In addition, if the stoma must remain for a prolonged period of time and the child gains weight, the fold created by the laparotomy incision may interfere with fitting of the stoma appliance (see Fig. 98-7).

With a healthy distal intestine and anticipated downstream patency, the distal limb may be closed and placed intra-abdominally adjacent to the proximal stoma. Otherwise, exteriorization as a mucus fistula is prudent (see Fig. 98-4, *B*). The use of an exteriorized loop stoma rather than an end stoma is an alternative in which the intact mesentery provides maximal perfusion.[79] A double-barreled stoma is a time-honored option.[77,78] To save as much intestine as possible, the placement of multiple stomas may be necessary (see Fig. 98-4, *C*). Although some ileostomy types were developed specifically for newborns with meconium ileus, they are no longer used. However, T-tube ileostomies have been useful for the instillation of liquefying solutions.[82]

In children with ulcerative colitis or familial polyposis, the enterostomal principles are similar to those established for adult patients. Choices for a temporary protective diverting

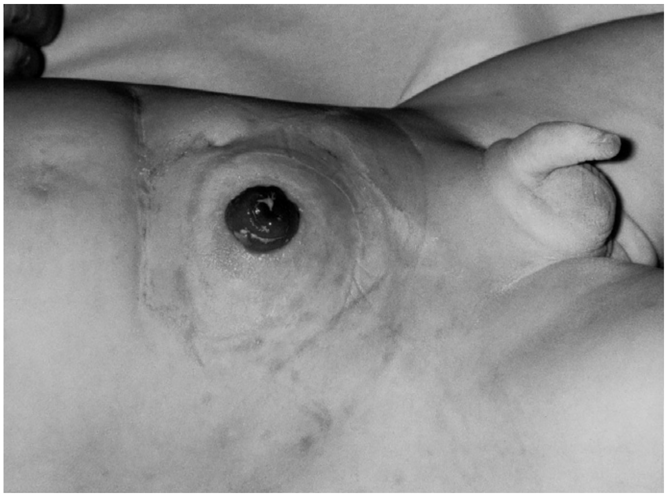

**FIGURE 98-6** One-year-old boy with severe necrotizing enterocolitis with loss of distal ileum and colon down to the peritoneal reflection before reanastomosis. Liquid stools precluded earlier reestablishment of intestinal continuity. Notice the appliance mark and the appropriate distance from the incision, the umbilicus, the inguinoabdominal fold, and the right anterior superior iliac spine.

**FIGURE 98-7** Same child as in Figure 98-6 in a sitting position. Notice the deep crease produced by the transverse supraumbilical incision. A stoma brought out through such an incision would have precluded proper use of the pouch, and a revision would have become necessary.

ileostomy include a simple loop, an end (distally closed) loop, and an end stoma, with the closed distal end under the fascia (see Fig. 98-3, *F*).

### APPENDICOSTOMY, TUBE CECOSTOMY, OR TUBE SIGMOIDOSTOMY

The choice of antegrade colonic enema (ACE) depends on the type of colonic pathology being managed. With normal peristalsis, either the right[41] or left[40,113] colon may be chosen for access. However, if dysmotility is a concern, access to the right colon is indicated. If the appendix is present, it is exteriorized with or without interposition of a "valve" by either an "open,"[88] or laparoscopic approach.[43,90] If the appendix is no longer available, the wall of the cecum may be fashioned into a conduit that is then brought to the skin level.[114] Exteriorizing the appendix at the umbilicus has cosmetic advantages. Either the appendix or the conduit so constructed is then catheterized to instill the enema fluid. A simpler technique, especially if there is no appendix, is the placement of skin-level device in the cecum by an open[115] or percutaneous approach.[87] For patients with normal colonic motility, access to the left colon by means of a sigmoid irrigation tube can be advantageous.[40]

### COLOSTOMY

Most colostomies fall into three categories: right transverse, left transverse, and sigmoid. The significant physiologic and anatomic differences among these three must be taken into consideration when choosing the site for the stoma. For infants with high imperforate anus, the high (proximal) sigmoid is the preferred site for exteriorization (see Fig. 98-5).[62,116] The main advantages are firmer stools with less tendency for skin excoriation, less tendency for prolapse, less surface for urine absorption, and less contamination of the urinary tract in male children with rectovesical fistula. Sigmoid stomas assist evacuation of meconium from the often dilated distal portion of the bowel during the initial procedure. The precise site is easily identified using the pelvic peritoneal reflection as a guide. A further advantage is that there are no scars in the epigastrium. However, if the low or mid sigmoid is inadvertently exteriorized, there may be interference with the blood supply, as well as insufficient bowel length for the future pull-through.[67,116] If the stoma is placed in the transverse colon, there is always adequate bowel length for pull-through, and the intestine is easy to mobilize and has a smaller diameter and no meconium. The disadvantages of transverse colon colostomy, however, are sizeable: The stools are looser, skin maceration and dehydration are more common, there is a greater prolapse rate, and there is an increased possibility of urinary tract problems. In addition, adequate evacuation of meconium is nearly impossible. Although high sigmoid loop colostomy is still used (Fig. 98-8), contemporary preference is for separation of the stomas, particularly in boys (Fig. 98-9).[67]

In children with Hirschsprung disease requiring a preliminary colostomy, the best site is the dilated segment that contains normal ganglion cells found proximal to the transition zone. A loop colostomy is usually chosen, although the tendency for prolapse is increased.[68] Because most transition zones are in the sigmoid colon, this lower left quadrant stoma is taken down at the time of the definitive corrective operation (see Fig. 98-5, *B*). If separation of the stomas is chosen, the distal intestine should not be oversewn in patients with Hirschsprung disease, particularly if the aganglionic segment is long, because mucus cannot be appropriately evacuated or washed out. Although similar data are not available in children, properly constructed loop colostomies are fully diverting in adults.[117]

## Select Technical Aspects

Feeding jejunostomies are generally placed in the left upper abdomen, slightly above the umbilicus, not so cephalic as to interfere with a possible gastrostomy and/or fundoplication.

FIGURE 98-8 Five-month-old child with high imperforate anus. The proximal sigmoid loop colostomy is equidistant from the umbilicus, the anterior superior iliac spine, and the inguinal fold. The original incision is only slightly longer than the stoma. Notice the raised "spur" between the two lumina, essential for proper diversion of stool.

FIGURE 98-9 Neonate with high imperforate anus. A divided proximal sigmoid colostomy was placed. The separation of the bowel ends minimizes the incidence of stoma-related problems.[67] The proximal bowel is slightly everted, and the mucus fistula is flush with the skin. (Courtesy Dr. Mark Levitt.)

In the "open" technique, the proximal jejunum is approached through a small, upper left quadrant incision. The ligament of Treitz is identified, and the catheter or skin-level device is inserted in the antimesenteric portion of the intestine, 10 to 20 cm distal to the duodeno-jejunal junction. A purse-string suture of fine multifilament synthetic absorbable material is placed around the enterotomy and tied. The catheter or skin-level device is then brought out through a counterincision. A second purse-string suture, made of monofilament synthetic absorbable suture is applied, with the sutures alternating between the intestine and the exit site of the catheter in the abdominal wall. When tied, this second suture approximates the intestinal serosa to the parietal peritoneum in a watertight manner.[100]

If a PEJ is chosen, the retaining intraluminal bumper must be size appropriate. Laparoscopic control can be used to increase the safety of PEJ, particularly in patients with abnormal epigastric anatomy. With laparoscopically assisted jejunostomies, particularly the Roux-en-Y type, proper loop orientation is essential. To minimize leakage (the most common problem with jejunostomies), appropriately sized skin-level devices must be selected. Devices that are too short or excessive tension on immobilizing crossbars must be avoided to minimize bowel wall or skin ischemia.

Decompressing ileostomies are usually placed in the right lower quadrant (see Figs. 98-4 and 98-6). The umbilicus is a possible site for a stoma[118] and is an excellent choice for the distended proximal intestine in newborns who have gastroschisis with atresia (Fig. 98-10).

Figure 98-11, *A* illustrates both appropriate and undesirable stoma exit sites in neonates, infants, and small children (e.g., those with necrotizing enterocolitis). Figure 98-12, *B* demonstrates ideal exit sites in older children or adolescents (e.g., those with ulcerative colitis or familial polyposis). Laparotomy incisions in the lower quadrants should be avoided in patients who may eventually have long-standing or permanent stomas because such incisions can create an uneven surface that interferes with pouch adherence.

When an enterostoma is anticipated, it is important that the site of the stoma and possible alternatives are marked on the abdominal wall before any incision is made. This planning is desirable in both elective and emergency settings. For elective, long-standing stomas, the best location is determined and marked the day before the operation (Fig. 98-12, *A* and *B*). The exit site should be located over the convex midportion of the rectus muscle, away from the incision, umbilicus, bony prominences, and skin folds. Special attention must be paid in overweight children because of the deep creases of the abdominal wall. In older children, if a vertical midline laparotomy is planned, it is advisable to create the opening for the ileostomy before making the incision. This is done in order to achieve a

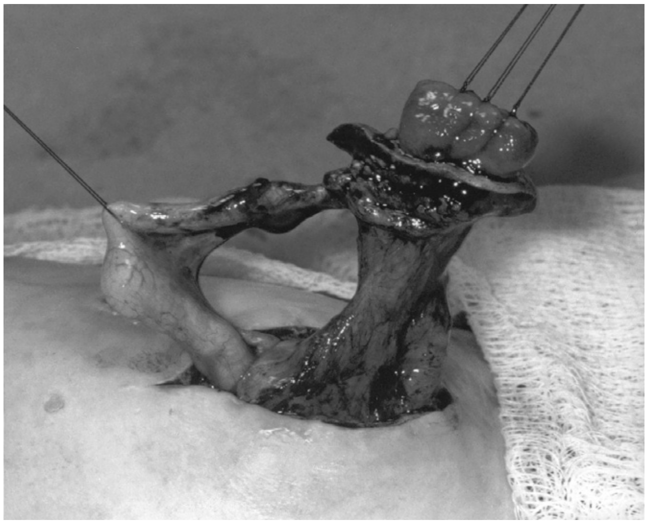

FIGURE 98-10 Four-month-old child with gastroschisis and small bowel atresia during reestablishment of bowel continuity. The dilated and edematous ileus was brought out as an end stoma through the umbilical site. The proximal closed end of the colon was attached to the side of the ileum underneath the abdominal wall. This maneuver allows prompt identification of the distal bowel, minimizing dissection and incision size.

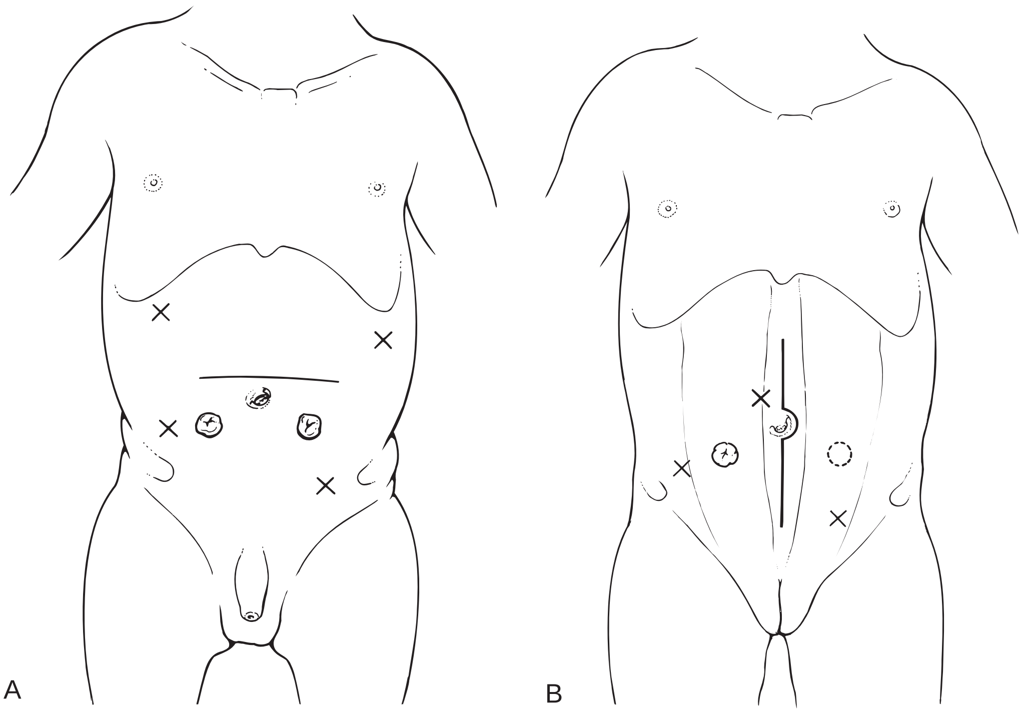

**FIGURE 98-11** Ideal sites for stomas. **A,** Infant. The end stoma can be brought out through a counterincision in the lower right or left quadrants. The sites marked with an "X" are unsuitable because they are too close to the rib cage, the anterior superior iliac spine, the flank, or the groin. **B,** Older child or adolescent. The best site for the stoma is in the mid rectus abdominis muscle in the right lower quadrant. The opposite side is an alternative. Areas marked with an "X" are unsuitable. The same sites are used with minimally invasive procedures.

straight course for the bowel and avoid distortion of the layers by traction on the edge of the incision. The entire opening should be just wide enough to allow for comfortable passage of the ileum without interfering with the blood supply. In laparoscopically placed stomas, adequate stoma exit size and bowel orientation are critical. With either approach, the bowel is secured intraperitoneally to avoid torsion and internal hernias and then secured with fine absorbable sutures to the rectus sheath. Depending on the size of the child, the matured ileostomy must protrude 2 cm or more to allow proper pouch fixation. This pouch is applied at the end of the procedure (Fig. 98-12, *C*). Stomas in neonates, particularly those established for necrotizing enterocolitis, should not be matured because this will interfere with the already tenuous blood supply. The exteriorized end of the stoma is simply anchored to the skin with four delicate sutures of a synthetic absorbable material. An antibacterial ointment is applied, and dressings are avoided. A pouch is applied with the onset of defecation. In infants, the mucosa grows rapidly over the exteriorized serosal surface. Deep, full-thickness sutures in the bowel should be avoided because they may cause a fistula from the lumen to the peristomal tissue, which will interfere with stoma pouch adherence.

The preferred colostomy site is the lower left quadrant. The guidelines for placement are similar to those for ileostomies. The most common site problem, particularly in newborns, is that the stoma is placed too caudally, close to the inguino-abdominal skin folds. When an infant flexes his or her hips, the resulting folds tend to lift the edges of the stoma appliance, leading to leakage. In children with imperforate anus, the meconium-filled sigmoid colon and the pelvic peritoneal reflection are identified once the abdominal cavity is opened. A suitable portion of the uppermost sigmoid colon is selected, and the bowel is exteriorized. When the dividing technique is used (see Fig. 98-5, *A*), the stomas are placed at each end of the incision and the intestine is secured with fine, synthetic, absorbable suture to all layers of the abdominal wall. There should be enough space between the two openings to permit a good fit for a pouch over the proximal stoma (or the distal stoma must be flush with the skin) (see Fig. 98-9). To avoid excessive narrowing of the stoma, an appropriately sized Hegar dilator or catheter is inserted into the intestinal lumen at the time of wound closure. End colostomies should only protrude slightly. With a loop stoma (see Figs. 98-5, *B* and 98-8), the incision is the length of that loop or only slightly longer. With the loop technique, a temporary catheter is placed through the mesentery of the selected segment, which is then lifted above the level of the skin. Triangulating sutures approximate the two limbs to each other and to the peritoneum on both sides to prevent internal hernias. The full circumference of the intestine is then attached to the peritoneum and fascia. Sutures lift the posterior bowel wall above the skin level. The intestine is opened longitudinally, and the edges everted. In all children with imperforate anus, the distal, meconium-filled segment of intestine is evacuated and flushed out at the time of colostomy placement. This is important to avoid formation of a fecaloma. In patients with Hirschsprung disease, the construction of the loop stoma must also be meticulous and may include tightening of the distended intestine to decrease the possibility of prolapse. This is particularly important in the distal segment. Rods or skin flaps placed under the loop are unnecessary if an appropriate "spur" between the two openings was created.

To facilitate subsequent takedown, when exteriorizing both ends of the small or large intestine, these should be kept as

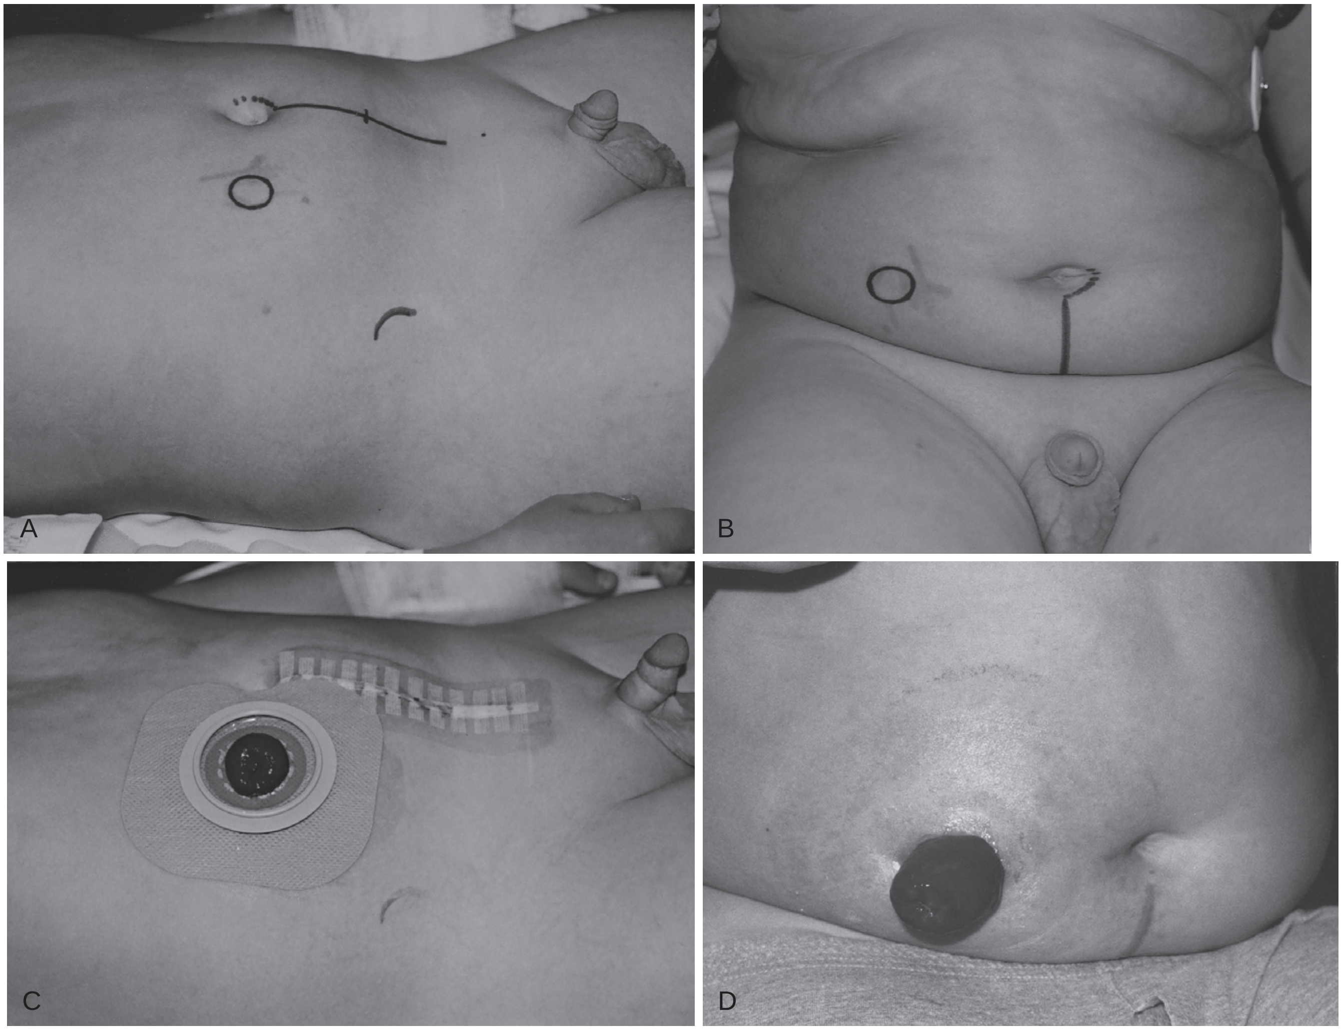

**FIGURE 98-12** Eight-year-old boy with intractable ulcerative colitis that failed to respond to aggressive medical management including corticosteroids, azathioprine, and infliximab. He underwent a total abdominal colectomy and ileostomy as a preliminary stage to an ileoanal anastomosis. **A,** The patient in a supine position. The stoma site had been determined several days before the procedure. The boy was asked to wear a two-piece pouch using the selected site as a guide. **B,** Bringing the already anesthetized patient into a sitting position confirmed the adequacy of the stoma site away from major abdominal folds. **C,** Skin barrier with flange (two-piece system) applied to the ileostoma at the completion of the colectomy. **D,** Six weeks later the stoma was well healed with mild residual edema. **E,** Same boy wearing a two-piece system with an opaque pouch. He emptied the pouch three to four times during the day and two to three times evening and nights. He enjoyed full physical activities including basketball. He did not use an ostomy belt and changed the skin barrier and pouch every 3 days. Bowel continuity has since been reestablished.

close as possible without interfering with the pouch. If the distal limb is placed underneath the abdominal wall, it is tagged with a nonabsorbable suture or a metallic clip (or both) and placed as close as possible to the exiting stoma to simplify identification at reanastomosis. Placing a metallic clip also helps with radiographic identification of the proximal end of the distal bowel and its patency when a barium enema is performed before reestablishment of bowel continuity in children with necrotizing enterocolitis.

Several of these techniques can be adapted for a minimally invasive approach.[43,107,119–123] In addition to smaller access sites, laparoscopy can be helpful in the precise identification of intestinal loops and targeted lysis of adhesions. However, the surgeon must exercise caution because the advantages of the laparoscopic approach can be negated by less than optimal handling of the bowel and exteriorization through openings of inadequate size.[119]

## Stoma Care

Proper care of an enterostoma begins with preoperative preparation whenever possible.[24,25,124] Parents, as well as older children, must be carefully taught and reassured before leaving the hospital and on subsequent follow-up visits. Ileostomies and proximal colon colostomies always require pouches. With the well-formed stools that result from sigmoid stomas, some parents of infants have used a skin barrier and diapers instead. A plant leaf has been recently suggested as an alternative.[125] A large selection of stoma appliances are commercially available including disposable and reusable pouches for all ages and sizes, even the smallest premature infants. Skin barriers, adhesives, powders, vented pouches, and odor control solutions are among the products that make the care of today's ostomate easier.[1,2,27,112,126]

Properly fitted appliances should remain in situ for several days; 3 days is a reasonable expectation. There are two basic types of pediatric appliances: the one-piece pouching system in which the adhesive skin barrier is already attached to the pouch and the two-piece system in which the adhesive skin barrier is separate from the pouch. In the latter, the pieces snap together with a flange (see Fig. 98-12, *C* and *E*). Because of the holding power of contemporary adhesive skin barriers, additional fixation with tape or belts is usually not necessary. The skin barrier is cut to the proper stoma size with the help of a template provided with the pouches. In addition to instructions provided by the surgeon, nurses, and the enterostomal therapist, parents are encouraged to contact one of the enterostomal societies such as the United Ostomy Association of America (an affiliate of the International Stoma Association) or the Wound Ostomy and Continence Nurses Society[23,127] and make use of the extensive printed and electronically available educational material. Although "continent stomas" using special intra-abdominal intestinal pouches,[83,128] magnetic caps,[129] valves,[130] inflatable plugs,[131] and other forms of luminal occlusion[132] have been attempted, there is limited experience with such operations or devices in children.

Candidiasis remains a common problem in the parastomal skin, and local antifungal medication should be used at the earliest sign of irritation. With skin excoriation, the area is exposed to air and a synthetic barrier is applied. A hair dryer can be useful. Mild stomal bleeding is usually self-limiting. Excision and/or application of silver nitrate may be necessary to control granulation tissue around the mucosa-skin interface in the early stages.

Remaining sutures are often the cause and should be removed. Routine dilatation of stomas is not recommended. Malfunctioning stomas often require early takedown or revision before more serious complications occur. Occasional irrigation of the distal intestine can be useful and help eliminate malodorous mucus plugs. Dietary and select pharmacologic manipulations are helpful in producing firmer stools. Children with high ileostomies must be carefully monitored to prevent electrolyte imbalance and insufficient nutrient absorption.[49,133,134]

## Reestablishing Intestinal Continuity

Timing of enterostoma closure varies widely depending on the underlying condition, health status of the child, and presence or absence of stoma-related complications.[78,135–139] Unnecessary delays in the reestablishment of bowel continuity tend to increase morbidity and should be avoided.[62,63,137] The more proximal the stoma, the earlier it should be closed to decrease metabolic complications.[62,133,134] Children who previously underwent resection because of ischemic intestine must have a preoperative contrast study of the distal segment to rule out strictures or complete luminal obstruction. Use of routine studies in other settings has been questioned.[140] Reestablishment of small bowel continuity generally does not require intestinal preparation. Takedown of a colostomy is preceded by antegrade intestinal irrigation, supplemented by conventional enemas. Although perioperative intravenous antibiotics are routinely administered, the use of intraluminal antibiotic solutions is controversial[141] and probably not indicated. When reestablishing continuity involves the left colon or sigmoid, the insertion of a soft catheter into the rectum assists the intraoperative identification of that loop, particularly if the anatomy has been altered by peritonitis or a previous operation. Good exposure with full mobilization of the intestinal ends is important. Laparoscopy can be helpful in select patients.[142] Although extraperitoneal closure has been used in children, it is not recommended for routine use.[143] For the intestinal anastomoses, a single-layer technique using fine interrupted sutures of synthetic absorbable suture material provides excellent results. Primary wound closure is generally safe and advantageous.[139,144,145] Early postoperative feeding after colostomy closure is encouraged.[146]

## Complications of Enterostomas

Problems related to construction, care, and closure of stomas in the small and large intestines are numerous and common. They can lead to significant morbidity and occasional mortality (Table 98-3). Analysis of pediatric series reveals complication rates that often reach and sometimes exceed 50%.[16–18,46–70,132–139]

In addition, stoma revision or early takedown is frequently necessary.[47,54,68,135] Complications of enterostomas used for feeding are often accentuated by the patient's underlying disease, particularly in malnourished, neurologically impaired children.[57,72,109] Stomas used for evacuation of the small intestine are associated with a higher morbidity than are

**TABLE 98-3**
**Common Complications of Enterostomas**

| Electrolyte imbalance |
| Acidosis (caused by urine absorption in the distal loop of intestine) |
| Fecal impaction (in the distal loop of intestine) |

colostomies because these stomas are compounded by fluid, electrolyte, and absorption losses.[39,133,134] Transverse colostomies are more prone to complications than are sigmoid stomas[47,53,62,67,147]; in several series, divided colostomies have been preferred over loop colostomies.[62,67]

Among the more common serious complications are prolapse (Fig. 98-13), stricture, and retraction.[51–57,63,66,67] The incidence of prolapse in children may exceed 20% and is more common if the distal loop is exteriorized.[51–57,62–69] Stomal prolapse may be categorized into minor and major forms. Minor prolapse is associated with a protuberant, edematous stoma that is still functional. It is usually amenable to nonsurgical techniques aimed at decreasing bowel edema, permitting manual reduction. The application of table sugar, ionized salt crystals, hyaluronidase, and hypertonic saline injections have been shown to effectively diminish bowel edema osmotically.[148–151] In major prolapse there is cyanotic, dusky, and edematous protruding bowel that may totally occlude the stomal orifice. This requires prompt attention, and general anesthesia is often necessary for intestinal reduction. Temporizing measures for control of prolapse include external devices,[152,153] modified purse-string suture techniques[154–156] or placement of U-shaped stitches from the lumen of the reduced intestine through the abdominal wall over an internal and external pledget or clothing button.[157,158] These pledgets hold the intestine against the abdominal wall and prevent the suture from cutting through. Stricture, if mild, may respond to dilatation. However, if evacuation is decreased and the proximal intestine begins to dilate, revision is advisable. This procedure is usually possible by incising all layers around the strictured stoma and bringing out healthy, at times dilated, bowel. The opening should not be excessive, however, because this might lead to prolapse. If the problem is more complex or a parastomal hernia is present, the pathologic process is addressed through a counterincision or laparoscopic repair.[159] Retraction of an end stoma results in poor fitting of the appliance and may lead to skin-level stricture and obstruction, whereas retraction of a loop stoma interferes with proper evacuation and leads to filling of the distal intestinal loop with stool. Stomal bleeding is a rare but serious complication in children on long-term parenteral nutrition with liver dysfunction leading to portal hypertension. The varices developing between the portal and systemic circulations at the level of the stoma are vulnerable and may result in significant drops in hemoglobin levels. Following the correction of a possible coagulopathy, most of these hemorrhages are amenable to direct pressure, suture ligation, or application of hemostatic substances.[160] Tranexamic acid, an antifibrinolytic amino acid, has been reported to stabilize formed clots and reduce rebleeding.[161] Nonparietal intestinal obstruction from adhesions or internal hernias can occur at any time,[111] even in the immediate postoperative period.[162]

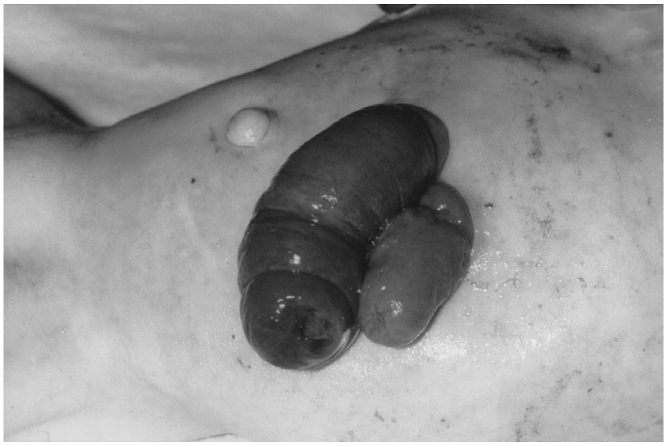

**FIGURE 98-13** Six-month-old child with Down syndrome, congenital heart, and Hirschsprung diseases. Proximal and distal colon prolapse have occurred through a left transverse colon loop colostomy. Notice the three openings at the end of the larger everted loop that correspond to the lumen of the cecum, the ileocecal valve opening, and the lumen of the appendix. The problem was managed by anchoring the cecum in the right lower quadrant and then securing the distal loop with a U-stitch and two rubber bolsters.[157] A definitive operation followed several months later.

Intestinal reanastomosis is also associated with a high rate of complications, most notably wound infection, dehiscence, fistula formation, and intestinal obstruction.[56,62,135,136] Among the various factors contributing to this morbidity are poor timing, inadequate bowel preparation, technical errors, and shortcuts such as improper choice of suture material and the excessive use of the electrocautery. Malnourished, debilitated, anemic patients and those on corticosteroids are at greatest risk for complications. These contributing factors should be corrected before reestablishment of intestinal continuity is contemplated.

Although the need, the indications, and various techniques for establishing stomas of the small and large intestine have shifted in the past couple of decades, the use of stomas remains a critical tool in the surgical care of children. Placement and takedown of any enterostoma should be carefully planned and considered a major procedure. Requirements include ideal operating conditions and, in a teaching setting, appropriate supervision. Pediatric stomas are quite different from adult stomas, and the importance of meticulous attention to detail cannot be overemphasized. Close follow-up is imperative to render these interventions as beneficial and complication free as possible.

CHAPTER 99

# Atresia, Stenosis, and Other Obstructions of the Colon

Marjorie J. Arca and Keith T. Oldham

## Atresia and Congenital Stenosis of the Colon

Although Binninger first described colonic atresia in 1673,[1] the first survivor was not reported until 1922, when Gaub[2] treated a child with atresia of the sigmoid colon with a proximal diverting colostomy. In 1947 Potts[3] performed a primary anastomosis of the transverse colon for atresia in a newborn who survived. Although colonic atresia is uncommon, colonic stenosis is exceedingly rare. Only 10 congenital colonic stenosis patients have been reported since 1966.[4–10] Most cases with congenital stenosis and atresia were managed with resection of the involved colonic segment and end-to-end anastomosis, but a staged approach using a decompressive colostomy in the proximal dilated segment was judged necessary in several patients. All the reported infants with congenital colonic stenosis have survived, while mortality in atresia patients is generally attributed to associated anomalies. It is clear that many such patients are no longer the subject of individual reports.

Colonic atresia is reported to occur from 1 in 1498 live births[1] to 1 in 40,000.[11] Episodic cases of isolated congenital colonic atresia are seen annually at most children's hospitals in the United States, corresponding to 1 in approximately 20,000 births.[5,12] Colon atresia is considered the rarest atresia of the gastrointestinal (GI) tract, comprising 1.8%[13] to 15% of intestinal atresias;[5,10,14] these estimates exclude related malformations of the rectum, which are traditionally considered within the spectrum of imperforate anus. There is no known gender or racial predilection of colonic atresia or stenosis. Although a similar abnormality is commonly inherited in an autosomal recessive pattern in Holstein cattle,[15] no familial association is known in humans. Hereditary multiple atresias of the intestines typically exclude the colon.

Colonic atresia is associated with several important anomalies of the musculoskeletal system (e.g., syndactyly, polydactyly, clubfoot, absent radius)[16]; eye[14]; heart[14]; GI tract[16]; and abdominal wall (e.g., gastroschisis, omphalocele, bladder or cloacal exstrophy).[17,18] Facial hemiaplasia, anophthalmia, and cloacal extrophy,[19] as well as facial asymmetry with agenesis of the corpus callosum, cerebellar hypoplasia, and enlargement of the fourth ventricle, are also reported.[20] Stickler syndrome, which is a chondrodystrophy with congenital alteration of type II collagen, has been reported in a patient with colon atresia.[21] In the largest relevant report, 22 of 36 infants with colonic atresia had no associated anomalies.[16] Of the remaining 14 infants in that report, 9 had midline abdominal wall defects and 5 had jejunal atresia. Davenport reported on 118 infants with colonic atresia. Twenty-eight percent of the lesions occurred in the ascending colon, 3% in the hepatic flexure, 23% in the transverse colon, 25% in the splenic flexure, and 20% in the descending and sigmoid colon.[22] A recent report from China reported on three babies with upper rectal atresia.[23]

Approximately 15% to 20% of infants with colonic atresia have proximal small intestinal atresia[14,16]; therefore neonates with intestinal atresia should routinely have distal patency including the colon evaluated in the operating room or with preoperative contrast enema. A combination of imperforate anus and colon atresia have been reported in six patients in the English literature.[24–29]

Hirschsprung disease is recognized in at least 2% of patients with colonic atresia.[30–34] Some authors have hypothesized that when a vascular insult occurs before retroperitoneal fixation of the colon at 11 weeks' gestation, caudal migration of the myenteric neurons is interrupted.[31] Therefore it is imperative to rule out Hirschsprung disease, typically with suction rectal biopsy, before reestablishing intestinal continuity in every patient with colonic atresia.

## Embryology

The classic etiology considered responsible for intestinal atresia is in utero vascular insufficiency after organogenesis.[35–37] Possible causes of vascular insult include volvulus, intussusception, embolic or thrombotic events, and incarceration or strangulation secondary to hernias or abdominal wall defects. Maternal use of cocaine, amphetamines, nicotine, and

decongestants has been implicated in intestinal atresia. Focal resorption of the compromised gut apparently occurs after ischemic necrosis. The spectrum of observed abnormalities is similar to that of small intestinal atresia, in which experimental work by Louw[38] and Barnard and Louw[39] confirmed the pathogenic role of in utero vascular occlusion. The classification system of Bland-Sutton[40] and Louw[38] for small intestinal atresia is also applied to the colon. Briefly, type I lesions are intraluminal obstructive webs; type II lesions are blind proximal and distal segments connected by a fibrous cord; and type III lesions are completely separated segments of intestine, with an intervening V-shaped mesenteric defect. Type III abnormalities are the most common.[14,17] Complex mesenteric defects and multiple atresias have been described. This classification system has limited clinical value because surgical principles and outcome are not dictated by the anatomic categorization of the lesion.

In the past decade, a possible genetic mechanism for intestinal atresia including duodenal, small bowel, cecal, and colonic has been elucidated. Fibroblast growth factor 10 (Fgf10), a protein expressed in the colon and mesenteric vasculature sites, has been widely implicated in cell survival and cell growth. Invalidation of the Fgf10 or its receptor, RFgfr2b, resulted in colon atresia in mice with intact mesenteric vasculature.[41] This finding suggests that intestinal atresia may be caused by more than simple vascular insufficiency.

Congenital colonic stenosis is much less common than colonic atresia. Seven of the eight reported cases of congenital colonic stenosis demonstrated a segmental stricture of the colon, with lengths ranging from 3 to 16.5 cm.[4–6,9,10] The cause of these stenoses has also been attributed to interruption of the blood supply of the developing colon. A partially obstructing intraluminal membrane has been described as the cause of colonic stenosis as well.[11,42]

## Clinical Presentation

Prenatal ultrasonography typically shows an enlarged loop of intestine or colon, leading to a presumptive diagnosis of distal intestinal atresia.[11,43] Polyhydramnios is usually not seen because the relatively distal point of obstruction allows amniotic fluid to be absorbed in the proximal small intestine.

Clinically, an infant with colonic atresia or stenosis usually develops a distended abdomen within 24 to 48 hours after birth. Because the obstruction is distal and usually complete, abdominal distention is predictably marked and progressive. Mechanical ventilatory support may be necessary due to massive intestinal dilatation and abdominal distention. Vomiting may be delayed in onset, with feculent vomiting as a late manifestation. Infants with colonic atresia typically pass little or no fecal matter. Rectal examination yields white mucus rather than bile-stained meconium. In neonates, coexisting cranial, musculoskeletal, or abdominal wall abnormalities may be apparent on inspection.

## Diagnosis

Abdominal radiographs of infants with colonic atresia show multiple distended intestinal loops with air-fluid levels. Although the small intestine and colon are not readily distinguishable in the neonatal period, the degree of distention immediately proximal to the obstruction is often more marked in the colon than in similarly obstructed small intestine (Fig. 99-1). In fact, the colonic obstruction may be so profound that it may be mistaken for a pneumoperitoneum. Pneumoperitoneum is a sign of proximal colon perforation, usually associated with abdominal tenderness. This is present in approximately 10% of

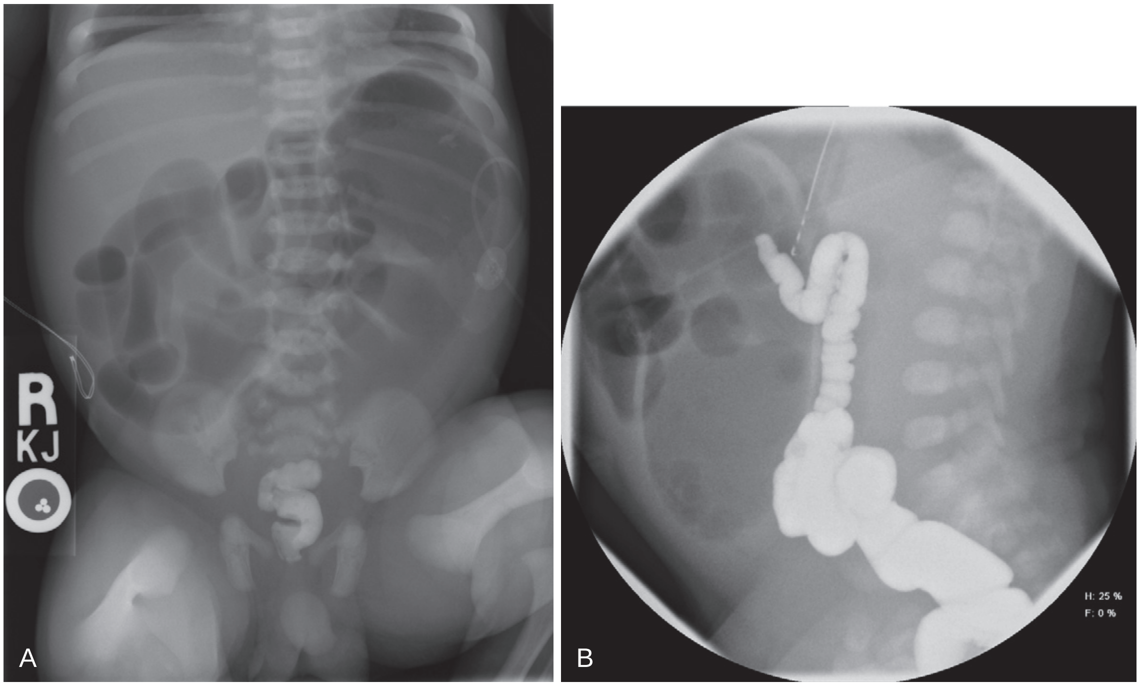

**FIGURE 99-1** Colonic atresia. **A,** Plain radiograph of a baby with significant intestinal dilation. Previously injected contrast that was injected per rectum remains in a diminutive rectal segment. **B,** Contrast enema in the same patient shows a microcolon. On exploration the atresia was at the level of hepatic flexure.

infants with this disorder at the time of diagnosis.[16] It appears that this scenario results when a competent ileocecal valve creates a segment of colon obstructed both proximally and distally, thereby increasing the risk for perforation.

Contrast enema using isotonic contrast agent establishes the diagnosis of colonic atresia or stenosis. Complete obstruction is characterized by a distal "microcolon," which is diminutive from disuse but is intrinsically normal in most circumstances. The contrast medium typically fills the lumen of the distal colon, terminating at the point of obstruction. Congenital stenosis is characterized by narrowing of the intestine and limited proximal filling with contrast medium; proximal intestinal dilatation is often seen.

A contrast enema is important in the evaluation of any neonate with suspected distal intestinal atresia because the surgeon must identify the likely cause of obstruction, as well as blockages that may be distal to the most proximal atresia before repair. Retrograde contrast may also differentiate between a fixed anatomic cause and other causes of distal obstruction such as meconium plug syndrome, Hirschsprung disease, or neonatal small left colon syndrome.[43] In patients with colonic atresia or stenosis, no other imaging is necessary to define the intestinal anatomy.

## TREATMENT

Any infant with suspected intestinal obstruction should have nasogastric tube decompression and resuscitation with intravenous fluids. Broad-spectrum antibiotics are generally administered before the procedure. Operative management should not be delayed because of the risks of perforation and segmental volvulus. The most common finding in colonic atresia is two blind ends of colon with no intervening mesentery (type III). In the past, emphasis was placed on the relevance of the site of atresia in surgical decision making.[14] In contemporary practice, primary anastomosis is preferred unless there is medical instability, vascular compromise, significant mismatch between the two ends, fecal soilage, or physiologically important comorbidities.

Laparotomy is usually undertaken through a transverse, supraumbilical position, taking into account the position of a possible stoma. The obstructing lesion is resected, along with compromised or excessively dilated proximal intestine in order to facilitate functional recovery. Preservation of intestinal length is, of course, an important principle for any intestinal atresia, but this can be reasonably moderated for colonic atresia, in an effort to minimize size mismatch for the anastomosis and facilitate onset of intestinal function. Patency of the distal segment should be demonstrated unequivocally either preoperatively or intraoperatively, as noted previously. Intestinal continuity is most commonly reestablished with a single-layer, end-oblique anastomosis.

Because of the association with Hirschsprung disease, a suction rectal biopsy to evaluate for ganglion cells should be performed in the operating room if primary anastomosis is planned. Similarly, if a colostomy is deemed appropriate, the myenteric plexus at the colostomy site should be examined at operation and a rectal suction biopsy done before reanastomosis.

Coloplasty is usually not recommended, given the excellent outcome of resection and anastomosis. Complex colonic atresias and those associated with abdominal wall defects may require other approaches such as proximal stoma formation and staged repair of the colon.

## RESULTS

Complications of colonic atresia and stenosis repair are generally the same as for other types of colonic surgery. These include anastomotic stricture, leak, proximal segment dysfunction, adhesive small intestinal obstruction, wound infection, and stoma-related problems.[14,16,44] In a report by Powell and Raffensperger,[14] 15 complications occurred in 19 patients treated between 1946 and 1978, with a mortality rate of 10.5% associated with colonic atresia. DellaVecchia and colleagues[45] reported 21 patients with colonic atresia and stenosis presenting from 1972 to 1997; 12 of these patients had complications including wound infection (1), stoma prolapse (1), prolonged ileus (2), and late adhesive bowel obstruction (8). In this more contemporary series, there was no operative mortality and the long-term survival rate was 100%.

# Acquired Colonic Stenosis

Various inflammatory, infectious, traumatic, and neoplastic processes may lead to acquired colonic stenosis in infants and children.[46] Of these, neonatal necrotizing enterocolitis (NEC) is the most common. About 11% to 35% of infants with this disorder develop intestinal strictures, with about 70% involving the colon.[47–49a] Submucosal fibrosis and varying maturation of intestinal scar are seen on resected stenotic specimens.[50] Butter and colleagues[51] performed a retrospective study of NEC patients with Bell's stage II or III disease and found an apparent increase in the overall stricture rate requiring operative intervention, from 46% in 1990-1994 to 69% between 1995 and 1999. Subgroup analysis showed the increase in stricture was seen in the medically treated infants, with stricture formation increasing from 15% to 48%. Interestingly, the surgically treated NEC patients had a stable stenosis rate between the two time points, from 36% to 33%. The sigmoid colon is the most common site of NEC-associated stenosis, but the entire intraperitoneal colon and small intestine are at risk. Several lesions may be present and are usually partially obstructing (Fig. 99-2). Failure to advance oral feeding, bilious vomiting, and abdominal distention are typical. The diagnosis is established by contrast enema radiography. Treatment generally consists of segmental resection and primary reconstruction. Resection with proximal diversion and staged reconstruction is an alternative in high-risk patients. Successful balloon catheter dilatation of focal colonic strictures has been reported, but the experience is quite limited and rarely used in contemporary practice.[52,53]

Other infectious and inflammatory disease states have been associated with colonic strictures. They have been reported as sequelae of hemolytic uremic syndrome[54] and methicillin-resistant *Staphylococcus aureus* enterocolitis.[55] In children with human immunodeficiency virus, angioinvasive *Candida* species have been reported to cause acute colonic obstruction and death.[56] A recent report of colon stenosis details a sealed perforation, apparently secondary to Mycobacterial infection, in a 10-year-old boy, managed with segmental colon resection and tuberculostatic medications.[87] Chronic nonsteroidal

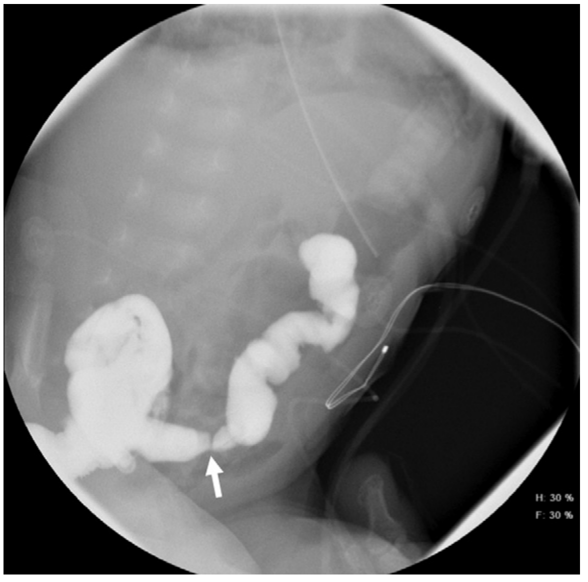

**FIGURE 99-2** Contrast enema radiograph in a 3-month-old infant with a history of necrotizing enterocolitis, treated without surgical intervention. He developed feeding intolerance, vomiting, and abdominal distention. A stricture is seen in the descending colon (*arrow*) and complete obstruction at the splenic flexure. Segmental resection and primary anastomosis were curative.

antiinflammatory drug use has been implicated in colonic stenosis in adults,[57] but thus far, there are no reports of this problem in the pediatric population.

Neoplasia may cause colonic obstruction by development of intraluminal lesions (polyps, neurofibromas,[58,59] adenocarcinoma[1,60,61,91–93]); extrinsic compression (lymphoma, retroperitoneal sarcomas or teratomas); or intramural infiltration (tuberous sclerosis, neurofibromatosis).[62] None of these is common. In all cases the underlying disease should be controlled, if possible. In general, focal benign lesions are resected, with primary reanastomosis of the colon. Congenital infantile fibrosarcoma of the colon has been reported in newborns, with perforation as the presenting sign.[64,90] Malignant and complex benign lesions may require fecal diversion, staged procedures, or more complex reconstruction of the colon.

Adenocarcinoma of the colon occurs rarely in young patients. A significant percentage of patients have predisposing factors such as ulcerative colitis and familial adenomatous polyposis.[65] Obstructive pain is the presenting complaint in 97% of patients younger than 21 years with adenocarcinoma.[66] Overall survival in children is approximately 25%; in adults, survival approaches 50%. Delay in diagnosis,[67,68] advanced disease stage at presentation,[69] and unfavorable histopathologic characteristics[66] all contribute to the observed lower survival rate in children. LaQuaglia and colleagues[35] reviewed 29 pediatric patients with adenocarcinoma and concluded that children are more likely to have poor-prognosis lesions such as "signet ring" or undifferentiated lesions (69%), compared with the moderately differentiated or carcinoma in situ (31%) found in adults. Histopathologic characteristics and lymph node involvement were the most important predictors of childhood mortality in patients who had resection. Patients with high-grade lesions or involved regional nodes should be considered for adjuvant therapy in addition to resection.[35]

# Functional Colonic Obstruction

Various disease processes are associated with functional colonic obstruction. These forms of colonic obstruction are discussed in detail in Chapters 101 and 102 but are noted here as part of the differential diagnosis of colonic obstruction in infants and children.

Intestinal neuronal dysplasia is a disorder of the myenteric nervous system that has a clinical presentation similar to that of Hirschsprung disease.[70] While controversy over nomenclature and treatment continues, type A intestinal neuronal dysplasia is characterized by decreased sympathetic innervation of the intestine, with moderately increased parasympathetic nerve fibers. Type B IND B has histopathologic involvement of the submucosal ganglia, where there is an increase of ganglionic (nerve) cells in the ganglion with more than eight nerve cells per ganglion. Nerve cells are smaller than normal and are grouped into spherical giant ganglia. A minimum 20% of giant ganglia in 30 serial sections must be found to make a diagnosis of type B IND.[71] Intestinal dysmotility is manifested by various degrees of abdominal distention or constipation.

Ogilvie syndrome is an acute distention of the colon, often occurring in nonambulatory and medically complex patients. There is absence of an identifiable mechanical cause. It is usually seen in adults but may also occur in children and adolescents. The cecum and the right colon are frequently involved. Risk factors for developing Ogilvie syndrome include electrolyte abnormalities and the use of certain medications, particularly narcotics, that impair intestinal motility. Distention of the cecum impedes the natural propulsive activity of the colon. Cecal distention may cause ischemic necrosis. Nasogastric suction, discontinuation of relevant medications, and colonoscopic decompression are the mainstays of therapy. Recently, the use of neostigmine (0.36 to 0.45 mg/kg), an acetylcholinesterase inhibitor, has been reported in the pediatric literature.[72,89] Oral erythromycin may also have efficacy.[73]

Chronic idiopathic intestinal pseudo-obstruction occurs in children and adults.[74,75] Abnormalities of the intestinal smooth muscle (myopathy), myenteric plexus (neuropathy), or a combination of both may occur.

In neonates, a visceral myopathy known as the *megacystis-microcolon-intestinal hypoperistalsis syndrome* is characterized by an anatomically patent intestinal tract with normal ganglion cells but clinical evidence of obstruction secondary to ineffective peristalsis. This syndrome is often fatal because definitive medical or surgical therapy is not available.[44,46,76,77,93]

The meconium plug syndrome and the small left colon syndrome appear to be specific but related entities in the spectrum of functional neonatal colonic obstruction. For clarity, they are considered separately as follows.

## MECONIUM PLUG SYNDROME

Meconium plug syndrome is a relatively common cause of functional colonic obstruction in neonates (see also Chapter 101).[78,88] Affected infants may be premature but are generally normal otherwise. It has been suggested that the syndrome results from an immature myenteric nervous system causing ineffective peristalsis[79] and excessive water absorption, thereby producing desiccated meconium plugs that obstruct the colon. The pathogenesis is unproved but is thought to be

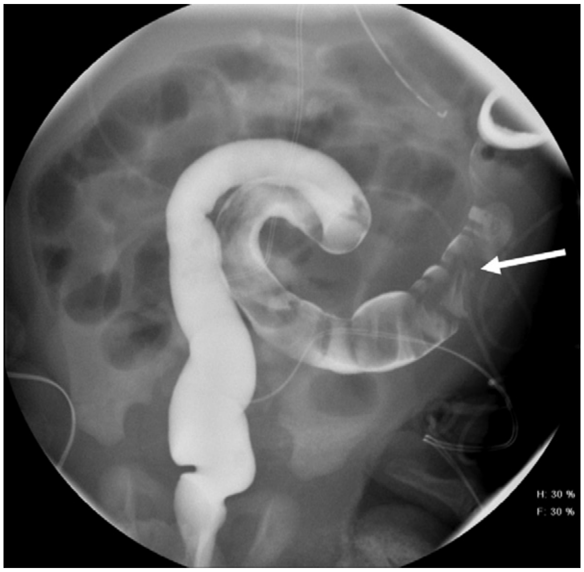

FIGURE 99-3 Radiograph of a term infant with the meconium plug syndrome. Contrast enema radiograph demonstrates many intraluminal filling defects (meconium plugs) throughout the colon (*arrow*).

related to temporary dysmotility. The clinical presentation is the same as that for distal intestinal obstruction. A water-soluble contrast enema is usually both diagnostic and therapeutic, but repeated enemas may be necessary for resolution (Fig. 99-3). Surgical management is rarely indicated, but rectal examination may be curative. Classically, two associated abnormalities need to be ruled out in a patient with meconium plugs—Hirschsprung disease and cystic fibrosis. In a retrospective survey encompassing 13 years, only 13% of patients with colonic meconium plugs were found to have Hirschsprung disease.[80] In the same analysis, no patient had cystic fibrosis, in contradistinction to other reports that showed up to 40% association between cystic fibrosis and meconium plug syndrome. The authors concluded that patients with isolated colonic plugs are less likely to have cystic fibrosis.[36] Suction rectal biopsy may be performed to identify Hirschsprung disease, although reserving this procedure for children who continue to have difficulties after evacuation of the plug is a reasonable approach. Sweat testing for cystic fibrosis may be reserved for infants with distal small bowel meconium plugging. Neonatal genotypic screening for the most common mutations for cystic fibrosis has become routine in most of the United States.

## SMALL LEFT COLON SYNDROME

Small left colon syndrome refers to a dysfunctional, diminutive left colon that causes transient obstructive symptoms.[69,81] Approximately 40% to 50% of infants with this disorder have diabetic mothers, almost all of whom are insulin dependent. In a retrospective study of infants born of mothers with either gestational or pregestational diabetes, Ellis noted a 4.7% incidence of small left colon syndrome.[82] Davis and Campbell[81] reported that 50% of asymptomatic infants of diabetic mothers also have radiographic evidence of a small left colon. The obstruction is typically partial and involves the descending colon distal to the splenic flexure (Fig. 99-4). The degree

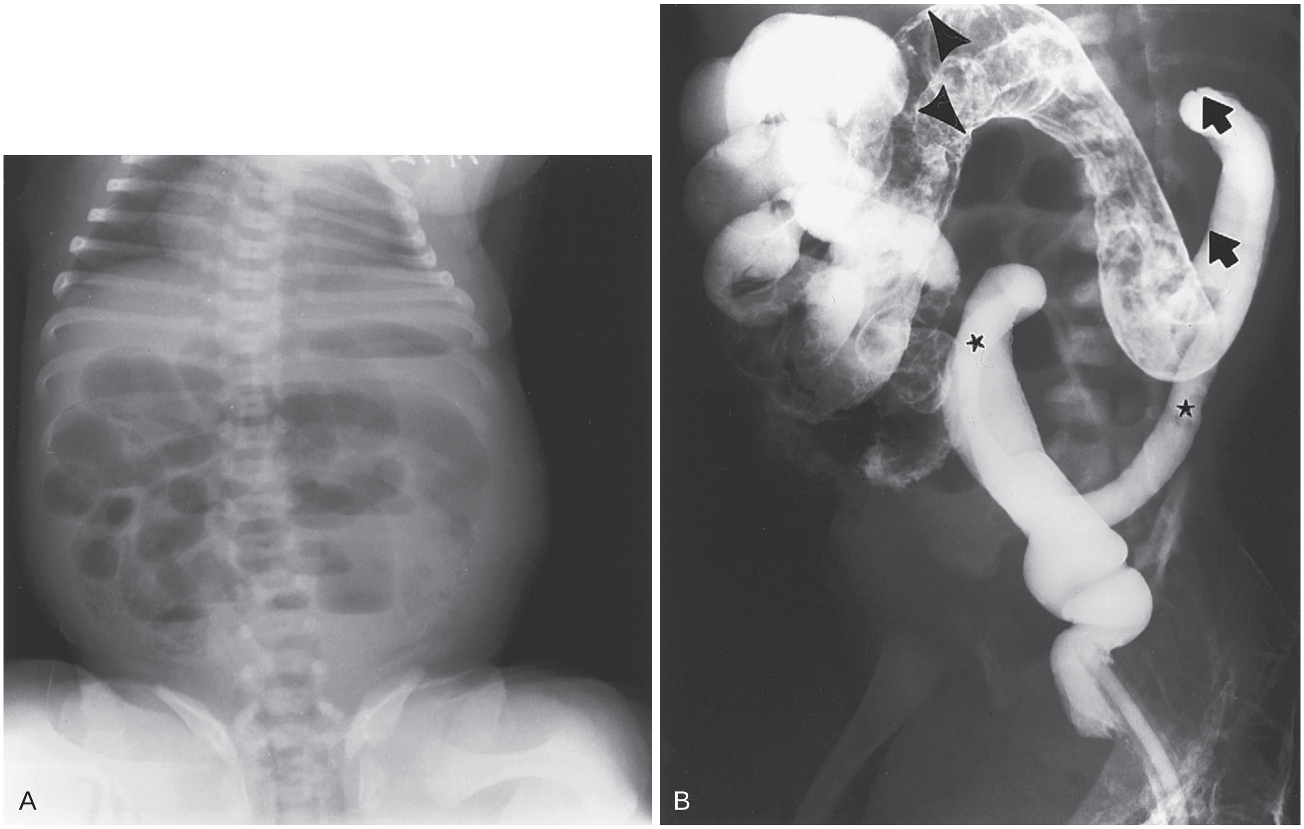

FIGURE 99-4 **A,** Plain radiograph of an infant born to a diabetic mother illustrating a distal intestinal obstruction. **B,** Barium enema radiograph shows typical findings of the small left colon syndrome. Note the distal microcolon (*asterisks*), the splenic flexure transition (*arrows*), and the dilated transverse colon proximal to the point of obstruction (*arrowheads*). (Courtesy D. Frush, MD)

FIGURE 99-5 Contrast enema radiograph illustrates inspissated stool in the transverse colon (*arrow*). The patient was an adolescent with cystic fibrosis who had recurrent obstructive episodes that were consistent with meconium ileus.

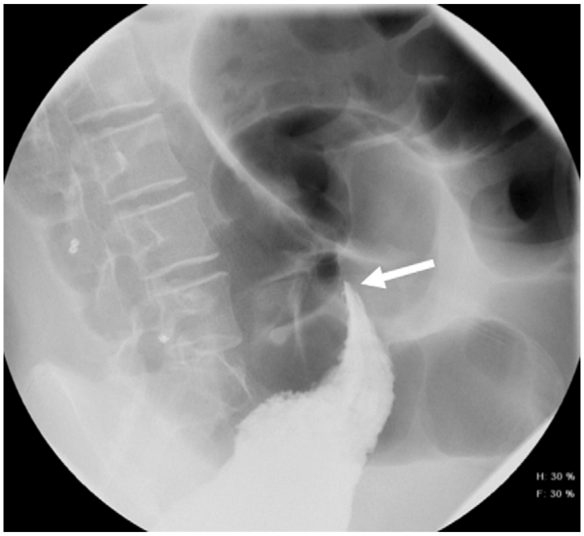

FIGURE 99-6 Contrast enema in a child with sigmoid volvulus. The *arrow* depicts the point of obstruction.

of obstruction varies. Proximal perforation, especially of the cecum, has been described.[83] The pathogenesis is thought to be related to hypoglycemia-induced release of glucagon in the infant. For reasons that are unclear, the neonatal left colon seems to be particularly sensitive to the smooth muscle constrictive effects of glucagon and other agents.[69] The problem is typically transient and resolves 24 to 48 hours after birth, corresponding to normalization of the infant's endogenous insulin output. A contrast enema is diagnostic and may be therapeutic by hastening resolution of the functional obstruction. The radiographic appearance of small left colon syndrome is quite similar to that of Hirschsprung disease because of the splenic flexure transition zone, so suction rectal biopsy is routinely performed to eliminate this possibility. It is prudent to also rule out cystic fibrosis.

## Meconium Ileus

Meconium ileus is the intestinal obstructive entity associated with cystic fibrosis and is discussed in detail in Chapter 83. Exocrine pancreatic insufficiency and water-deficient intestinal secretions are features of cystic fibrosis that combine to create thick, viscid stools that can impact and obstruct the small intestine or colon. This is classically seen in newborns but may also be a problem in adolescents with cystic fibrosis, whose compliance with exocrine enzyme replacement therapy may be erratic. The diagnosis is often revealed by the history and plain radiography but can be confirmed by contrast enema (Fig. 99-5). The preferred treatment is colonic irrigation in an antegrade or retrograde direction and the resumption of pancreatic enzyme replacement. Dilute (5% to 10%) N-acetylcysteine may be used occasionally. Chronic problems may require gastrostomy or cecal access for formal, periodic irrigation of the intestine.

## Miscellaneous Causes of Obstruction

Several rare causes of colonic obstruction merit brief mention. Among these are cecal or sigmoid volvulus, a wide variety of rare neoplastic lesions, anomalous congenital peritoneal bands,[63] hindgut duplication,[84] and congenital segmental dilatation (ectasia) of the colon.[27] Segmental dilatation of the colon is an idiopathic problem of infants and children and presents as partial colonic obstruction. It is a focal, functional defect in which the involved segment of colon lacks peristalsis and has no taeniae coli. Because both the proximal and distal colon are functionally and anatomically normal, surgical resection is curative.[85]

Segmental volvulus of the colon involves either the sigmoid colon or the cecum (Fig. 99-6). The typical patient is a child or adolescent with a long-standing history of constipation or pseudo-obstruction. The clinical presentation is abdominal distention, nausea, and vomiting. It may be difficult to distinguish from exacerbation of pseudo-obstruction in certain patients. Cecal volvulus has been reported in two children with Cornelia de Lange syndrome.[86]

The diagnosis is established with a contrast enema. Operative intervention, usually to resect the involved segment, is typically required. Endoscopic decompression can be useful to decompress the involved colon and convert this to a more elective operation, but this can be prohibitively difficult.

In the mid-1990s, long-segment colonic fibrosis was described in patients with cystic fibrosis. Colonic injury was determined to be caused by the ingestion of high doses of pancreatic enzymes (>19,000 units/kg/day).[85]

Resection of involved bowel was required in many of these patients. Alteration of the dosage of pancreatic enzymes has decreased the occurrence of this complication in recent years.

## Summary

The causes of colonic obstruction in infants and children are diverse. Generally, anatomic obstruction is easily addressed by surgical resection with primary anastomosis. Functional obstructions have a varied pathogenesis, and a nonsurgical approach is generally preferred. The clinical outcome of anatomic colonic obstruction is excellent in contemporary pediatric surgical practice; the exceptions are children with concurrent illness or peritonitis with sepsis at presentation.

# CHAPTER 100

# Appendicitis

James C. Y. Dunn

In 1886 Fitz[1] coined the term *appendicitis*. Morton is credited with performing the first deliberate appendectomy for a perforated appendix in the United States in 1887.[2,3] In 1889 McBurney[4] reported his treatment of appendicitis with appendectomy before rupture and described "the seat of greatest pain . . . has been very exactly between an inch and a half and two inches from the anterior spinous process of the ilium on a straight line drawn from the process to the umbilicus." From then on, this location was known as the McBurney point. Modern surgical care and antibiotic therapy have turned this once frequently fatal disease rarely so today. Appendicitis remains the most common acute surgical condition of the abdomen[5]; many aspects of the treatment of appendicitis remain controversial.

## Embryology and Anatomy

During embryogenesis, the appendix first becomes visible during the eighth week of gestation as a continuation of the inferior tip of the cecum.[6,7] The appendix rotates to its final position on the posteromedial aspect of the cecum, about 2 cm below the ileocecal valve, during late childhood. The variability in this rotation leads to multiple possible final positions of the appendix. The appendix is intraperitoneal in 95% of cases, but the exact location varies widely.[8] In 30% of cases the tip of the appendix is in the pelvis, in 65% it is behind the cecum, and in 5% it is truly extraperitoneal in the retrocolic or retrocecal position. In cases of malrotation or situs inversus, the malpositioned appendix may give rise to signs of inflammation in unusual locations.

The appendix averages 8 cm in length but can vary from 0.3 to 33 cm. The diameter of the appendix ranges from 5 to 10 mm. Its blood supply is the appendiceal branch of the ileocolic artery, which passes behind the terminal ileum. The base of the appendix arises at the junction of the three taeniae coli, a useful landmark in locating an elusive appendix. Its colonic epithelium and circular and longitudinal muscle layers are contiguous with the cecal layers. A few submucosal lymph follicles are present at birth. These increase to approximately 200 by age 12 and reduce abruptly after the age of 30.

Suppression of cecal development results in appendicular hypoplasia or agenesis. Appendiceal duplication has a reported incidence of 4 in 100,000.[9,10] The duplicated appendix may be partial (bifid appendix) or full, and it may have separate or common orifices in the cecum, which may also be duplicated.

The function of the appendix is unknown. Primates have an appendix, but most mammals do not. Curiously, rabbits do have an appendix and it is believed to be an important site for the immunologic development of B cells.[11]

## Spectrum of Disease

The geographic variation in the incidence of appendicitis is widespread. Appendicitis occurs less frequently in less industrialized countries.[12] Over the past few decades, the worldwide incidence has steadily decreased.[12–15] In the United States over 70,000 children are diagnosed with appendicitis annually, or approximately 1 per 1000 children per year. The lifetime risk for appendicitis is 9% for men and 7% for women.[16] About one third of patients with appendicitis are younger than 18 years of age. Appendicitis occurs more commonly in whites and during the summer months. The peak incidence occurs between ages 11 and 12. Although the disorder is uncommon in infants, perforated appendicitis can occur even in premature infants. Perforation may also be the end result of another disease process, as is seen in neonates with Hirschsprung disease.[17] Although the diagnosis and treatment have improved, appendicitis continues to cause significant morbidity and still remains, although rarely, a cause of death.[18,19]

Many terms have been used to describe the varying stages of appendicitis including acute appendicitis, suppurative appendicitis, gangrenous appendicitis, and perforated appendicitis. These distinctions are imprecise, with considerable variability among surgeons and among surgeons and pathologists. Clinically the only relevant distinction is between simple and complicated appendicitis. In general, acute and suppurative appendicitis tend to have a simple clinical course, whereas gangrenous and perforated appendicitis tend to have a complicated course.

Whether chronic and recurrent cases of appendicitis exist has been debated for decades. Literature contends that they do exist and should be considered in the differential diagnosis of recurrent lower abdominal pain.[20,21] Inflammation of the appendix does not inevitably lead to perforation because spontaneous resolution does occur.[22,23] Antibiotics may also assist the resolution of the inflammation. Recognition of this may contribute to the decreasing number of appendectomies.[14,15]

## Presentation

Traditional teaching is that appendicitis evolves as a continuum from simple inflammation to perforation, typically occurring after 24 to 36 hours of symptoms, and subsequent abscess formation occurring over a period of 2 to 3 days.[24,25] Nevertheless, the variability of the clinical presentation of appendicitis leads to laparotomies that do not reveal an inflamed appendix. Clinical experience and advances in imaging methods have improved the diagnostic accuracy but are not foolproof. The clinical presentation of appendicitis can be understood in terms of its pathophysiology.

Appendicitis results from luminal obstruction followed by infection. This process was first described by van Zwalenberg[26] in 1905 and experimentally confirmed by Wangensteen[27] in 1939. Wangensteen showed that the human appendix continues to secrete mucus even when intraluminal pressures exceed 93 mm Hg. Although it is clear that luminal obstruction causes appendicitis, the cause of the obstruction is not always clear. Inspissated and sometimes calcified fecal matter, known as a fecalith, often plays a role.[28] Fecaliths can be surgically found in approximately 20% of children with acute appendicitis and are reported in 30% to 40% of children with perforated appendicitis.[29,30] The presence of fecaliths can often be documented radiographically. Hyperplasia of appendiceal lymphoid follicles frequently causes luminal obstruction, and the incidence of appendicitis closely parallels the amount of lymphoid tissue present.[31] Causes of local or generalized reaction of lymphatic tissue such as *Yersinia, Salmonella,* and *Shigella*[32–35] can lead to luminal obstruction of the appendix, as can parasitic infestations by *Entamoeba, Strongyloides, Enterobius vermicularis, Schistosoma,* or *Ascaris* species.[36–38] Enteric and systemic viral infections such as measles, chicken pox, and cytomegalovirus may also cause appendicitis.[39,40] Patients with cystic fibrosis have an increased incidence of appendicitis, which presumably results from alterations in the mucous-secreting glands.[41,42] Carcinoid tumors can obstruct the appendix, especially when they are located in the proximal third. Foreign bodies such as pins, vegetable seeds, and cherry stones have been implicated as causes of appendicitis for more than 200 years. Trauma has also been reported as a cause,[43] as has psychologic stress[44] and heredity.[45]

Initially the patient may describe mild gastrointestinal symptoms before the onset of pain (e.g., decreased appetite, indigestion, or subtle changes in bowel habits). Anorexia is a helpful sign, particularly in children, because a hungry child rarely has appendicitis. Any severe gastrointestinal symptoms before the onset of pain, however, should suggest an alternative diagnosis. Distention of the appendix results in activation of its visceral pain fibers. Typical early visceral pain is nonspecific in the periumbilical region. This initial pain is poorly localized as a deep, dull pain in the T-10 dermatome. The continued distention of the appendiceal wall elicits nausea and vomiting, which typically follow the onset of pain within a few hours. Nausea is common, but vomiting is typically not severe. The appearance of these symptoms before the onset of pain casts doubt on the diagnosis.

The obstructed appendix is a perfect breeding ground for trapped bacteria. As intraluminal pressure increases, lymphatic drainage is inhibited, leading to further edema and swelling. Finally, the increase in pressure causes venous obstruction, which leads to tissue ischemia, infarction, and gangrene. Bacterial invasion of the wall of the appendix then occurs. Fever, tachycardia, and leukocytosis develop as a consequence of mediators released by ischemic tissues, white blood cells, and bacteria. When the inflammatory exudate from the appendiceal wall contacts the parietal peritoneum, somatic pain fibers are triggered and the pain localizes near the appendiceal site, most typically at the McBurney point. Pain occasionally occurs only in the right lower quadrant without the early visceral component. With a retrocecal or pelvic appendix, this somatic pain is often delayed in onset because the inflammatory exudate does not contact the parietal peritoneum until rupture occurs and infection spreads. Pain of a retrocecal appendix may be in the flank or back. A pelvic appendix resting near the ureter or testicular vessels can cause urinary frequency, testicular pain, or both. Inflammation of the ureter or bladder by an inflamed appendix can also lead to pain on micturition or the deceptive pain of a distended bladder secondary to urinary retention.

Further breakdown of the appendiceal wall leads to perforation with spillage of infected intraluminal contents with localized abscess formation or generalized peritonitis. This process depends on the rapidity of progression to perforation and on the patient's ability to mount a response and contain the spilled contents of the appendix. Signs of perforated appendicitis include a temperature higher than 38.6°C, leukocyte count greater than 14,000,[46] and the presence of more generalized peritoneal signs. Other reported risk factors include the male sex, extremes of age, and such anatomic factors as a retrocecal position of the appendix.[25,47] However, perforated and nonperforated appendicitis may be entirely separate entities.[13] Spontaneous resolution of appendicitis does occur. Patients may be asymptomatic before perforation, and symptoms may be present for longer than 48 hours without perforation. In general, however, the longer duration of symptoms is associated with a greater risk for perforation. Constipation is unusual, but the sensation of rectal fullness or tenesmus is common. Diarrhea occurs more frequently in children than in adults and can result in a misdiagnosis of gastroenteritis. Diarrhea is typically of short duration and often results from irritation of the terminal ileum or cecum; however, it may indicate a pelvic abscess.

Younger children typically present with complicated appendicitis due to their inability to give an accurate history and physicians' low index of suspicion that leads to misdiagnosis.[48–50] The most frequent presenting symptom in preschool children is vomiting, followed by fever and abdominal pain.[51] Perforation is almost always the finding at laparotomy, and these children may have associated small bowel obstruction secondary to extensive inflammation in the terminal ileum and cecum.

## Diagnosis

### PHYSICAL EXAMINATION

As with most disease processes, much can be learned before the patient is touched. Children with appendicitis usually lie in bed with minimal movement. A squirming, screaming child rarely has appendicitis. An exception to this is the child with retrocecal appendicitis and subsequent irritation of the

ureter presenting with pain similar to renal colic. Older children may limp or flex the trunk, whereas infants may flex the right leg over the abdomen. A recall of localized pain elicited by bumps in the road on the ride to the hospital is helpful.

Before starting palpation of the abdomen, it is useful to ask the child to point with one finger to the location of the abdominal pain. With the knees bent to relax the abdominal muscles, gentle palpation of the abdomen should begin at a point away from the location of perceived pain. Palpating the abdomen in an area remote from the site of pain may elicit tenderness in the right lower quadrant (Rovsing sign of referred pain), indicating peritoneal irritation. Younger children may be more cooperative if their hand or the stethoscope is used for palpation. The stethoscope can have several roles in the evaluation of a patient who potentially has appendicitis, the least important of which is auscultation. Although patients often have diminished or absent bowel sounds, this is not uniform and auscultation of the abdomen is of little benefit. However, auscultation of the chest to examine for lower respiratory infection is useful because right lower lobe pneumonia can mimic appendicitis. Cutaneous hyperesthesia, a sensation derived from the T10 to L1 nerve roots, is often an early although inconsistent sign of appendicitis. Lightly touching the patient with the stethoscope creates this uncomfortable sensation.

Localized tenderness is essential for diagnosis and is noted either on palpation or percussion. Tenderness can be mild and even masked by more generalized abdominal pain, especially during initial stages. The McBurney point is the most common location. Retrocecal appendicitis may be detected by tenderness midway between the twelfth rib and the posterior superior iliac spine. Pelvic appendicitis produces rectal tenderness. A child with malrotation will have localized tenderness that corresponds to the position of the exudative drainage from the inflamed appendix.

As the disease progresses to perforation, peritonitis ensues. The pattern of pain depends on the location of the appendix. Perforation may result in temporary relief of symptoms as the pain of the distended viscus is relieved. Initially, peritonitis is reflected as local muscular rigidity. This progresses from simple involuntary guarding to generalized rigidity of the abdomen. Other signs include rigidity of the psoas muscle (demonstrated by right hip extension or raising the straight leg against resistance) or of the obturator muscle (demonstrated by passive internal rotation of the right thigh), both of which indicate irritation of these muscles due to retrocecal appendicitis. Other tests of peritoneal inflammation such as rebound tenderness are seldom necessary for diagnosis and cause unnecessary discomfort.

The routine use of rectal examination in the diagnosis of appendicitis has recently been questioned.[52–54] Pain during this examination is nonspecific for appendicitis. If other signs point to appendicitis, the rectal examination is unnecessary. However, it may be a helpful diagnostic maneuver in questionable cases such as when a pelvic appendix or abscess is suspected or when uterine or adnexal pathologic conditions are being considered.

If appendicitis is allowed to progress, two results are possible: (1) diffuse peritonitis and shock will occur or (2) the infection will become isolated and an abscess will form. Diffuse peritonitis is more common in infants, probably because of the absence of omental fat. Older children and teenagers are more likely to have an organized abscess. The physical examination in cases of an organized abscess reveals a boggy, tender mass over the abscess.

A frequently unreported but critical aspect of the evaluation is serial examinations done by the same person. The safety and efficacy of serial observation was first reported by White in 1975[55] and has since been reinforced by other studies. Surana[56] reported a prospective study showing no increase in morbidity with appendectomy after active observation in a hospital compared with urgent appendectomy. When the diagnosis is unclear, serial abdominal examinations permit the physician to decrease the number of unnecessary laparotomies without increased risk to the patient.

## LABORATORY STUDIES

Much has been discussed concerning the laboratory findings of appendicitis. Total leukocyte and neutrophil counts have been extensively investigated.[57–59] The sensitivity of an elevated leukocyte count ranges from 52% to 96% and that of a left-shifted neutrophil count ranges from 39% to 96%. The latter is of better diagnostic value, but misinterpretation of the values is still common. Normal leukocyte count occurs in 5% of patients with appendicitis. Greater specificity and sensitivity have been reported using a neutrophil-lymphocyte ratio greater than 3.5.[60]

In the majority of children with suspected appendicitis, the combination of clinical history, physical findings, and laboratory studies should provide sufficient data for making the diagnosis. Nevertheless, misdiagnosis leading to negative appendectomy ranging from 10% to 30% has been reported.[61] An appendicitis score based on weighing eight clinical factors (localized right lower quadrant tenderness, leukocytosis, pain migration, left shift, fever, nausea-vomiting, anorexia, peritoneal irritation) was proposed to improve the diagnostic accuracy.[62,63] In prospective evaluations of children with acute abdominal pain, the sensitivity of the scoring system ranged from 76% to 100% and its specificity ranged from 79% to 87%.[64,61] In cases where the diagnosis is equivocal, serial observation is warranted and imaging studies may be useful.

## IMAGING STUDIES

Imaging studies have variable success in improving diagnostic accuracy. Plain radiography can be helpful. Fecaliths are present in 10% to 20% of patients and may be an indication for surgery when symptoms are present. An abnormal gas pattern in the right lower quadrant, lumbar scoliosis away from the right lower quadrant, and obliteration of the psoas shadow or fat stripe on the right are also helpful. A chest radiograph to rule out pneumonia may be indicated.

A barium enema contrast radiograph may show absent or incomplete filling of the appendix, irregularities of the appendiceal lumen, and an extrinsic mass effect on the cecum or terminal ileum. The sensitivity and specificity of this technique are low,[65] and it is best used in the diagnosis of nonspecific abdominal pain.

In skilled hands, ultrasonography has proven to be an effective diagnostic aid. A prospective study showed that ultrasonography was more accurate than the surgeon's initial clinical impression.[66] Most studies demonstrate a sensitivity greater than 85% and a specificity greater than 90%.[67]

Demonstration of a noncompressible appendix that is 7 mm or larger in anteroposterior diameter is the primary criterion for the diagnosis. The presence of an appendicolith is helpful. Such techniques as graded compression, self-localization,[68] and transvaginal or transrectal ultrasound approaches[69] have also improved results.

Computed tomography (CT) has become more widely used in the diagnosis of appendicitis.[70–73] The findings of an enlarged appendix (>6 mm), appendiceal wall thickening (>1 mm), periappendiceal fat stranding, and appendiceal wall enhancement are useful diagnostic criteria.[74,75] The sensitivity of CT scans is over 90%, and its specificity is over 80%.[76] Comparisons of ultrasonography and CT have shown that the latter is more sensitive, whereas the former is more specific.[67,70,77] These two imaging modalities, however, should be employed only if the diagnosis is uncertain. In a protocol that evaluated children with equivocal clinical findings for appendicitis, the combination of pelvic ultrasound followed by limited CT with rectal contrast, if necessary, yielded a sensitivity of 94% and a specificity of 94%.[78] The same protocol reduced the negative appendectomy rate from 12% to 6% at the same institution during the study period but performed imaging in almost 80% of children with suspected appendicitis. The perceived improved diagnostic accuracy led to a dramatic increase in the number of CT performed in the pediatric population,[79–81] even though there is no good evidence that supports the routine use of CT in the diagnosis of appendicitis.[82] In addition to the hospital resource utilization and the delay in surgical care, the potential cancer risk associated with ionizing radiation from CT should be considered.[79]

## DIFFERENTIAL DIAGNOSES

Acute appendicitis can mimic virtually any intra-abdominal process.[83] The differential diagnosis of appendicitis is listed in Table 100-1. Consideration of these other disease processes before surgery is as important as it is to examine for them carefully when the patient is under anesthesia and during surgery in the case of a normal appendix.

The clinical diagnosis of appendicitis is challenging because many symptoms of appendicitis are nonspecific and the presentations can be variable. Acute gastroenteritis is a common cause of abdominal pain in children. It is usually due to a viral illness and is self-limited. The symptoms include watery diarrhea, crampy abdominal pain, fever, nausea, and vomiting. Constipation is another common pediatric problem and may cause abdominal pain, nausea, and vomiting. Pain is usually persistent but not progressive. History and a plain radiograph will suggest the diagnosis. Urinary tract infection will also cause fever, nausea, and vomiting. A urinalysis should be obtained if urinary symptoms are present.

Despite advances in diagnostic imaging, operation done for appendicitis does not always reveal an inflamed appendix. Formerly accepted rates of laparotomy that did not reveal appendicitis range from 15% to 40%.[25] These rates are not supported by the recent literature that report negative appendectomy rates to be less than 10%.[84–87] When a normal appendix is encountered, most surgeons recommend that it be removed to allow for pathologic examination and to avoid potential confusion if the patient experiences right lower quadrant pain in the future. An exploration of the right lower quadrant should be performed to look for other causes of the symptoms. The terminal ileum may demonstrate mesenteric adenitis, enlarged lymph nodes in the ileal mesentery that may be secondary to an upper respiratory infection. These patients may have abdominal pain, fever, and nausea, but their

tenderness is not as well localized as that in appendicitis. Lymphocytosis may be noted on the blood count differential. A search for a Meckel diverticulum should be done, but it rarely causes pain. Painless bleeding and obstruction are the more common presenting symptoms. If the patient has Crohn disease, the appendix should not be removed if it or the cecum is involved in the disease process because removal is associated with a high incidence of subsequent fistula formation.[88]

The diagnostic accuracy for appendicitis is lowest among young women because of the variety of gynecologic conditions that can cause low abdominal pain. Ectopic pregnancy should be considered in teenage girls with low abdominal pain. They may present with vaginal bleeding, amenorrhea, dizziness, nausea, and vomiting. Rupture of ovarian cysts and ovarian torsion may also present with low abdominal pain. Sexually active girls with pelvic inflammatory disease may present with low abdominal pain, vaginal discharge, and adnexal enlargement. Most will have cervical motion tenderness and will respond to antibiotics. Operative intervention may be indicated for those who do not respond or persistent abscess.

Carcinoid tumors are present in less than 1% of patients undergoing appendectomy.[89] Most appendiceal carcinoid tumors lack the serotonin-containing cells that are typical of midgut carcinoid tumors, so they are rarely symptomatic and typically present incidentally at appendectomy.[90] Most are benign, and simple appendectomy is curative.[91,92] Controversy surrounds the proper surgical management of potentially malignant carcinoid tumors. The consensus is that carcinoid tumors larger than 2 cm in diameter, those that have obviously metastasized, and those located at the base of the appendix require right hemicolectomy,[90,93] whereas those that are smaller than 1 cm in diameter and have not metastasized at the time of diagnosis are treated by appendectomy alone. Treatment of tumors that are 1 to 2 cm in diameter remains controversial. Moertel[91] believes that a conservative surgical procedure is all that is required regardless of tumor size or location as long as metastases are not present.

# Treatment

Although it is generally agreed that the treatment for appendicitis is appendectomy, the details of the management vary considerably.[94] For example, surgical techniques such as the laparoscopic approach, the use of drains, the necessity of peritoneal irrigation, the handling of the appendiceal stump, and the closure of the incision continue to be debated. The need for interval appendectomy after initial nonoperative management of an appendiceal phlegmon is unclear. The choice of antibiotics and the length of its use vary considerably from surgeon to surgeon.

## ANTIBIOTICS

The use of antibiotics for the treatment of appendicitis is clearly beneficial.[95] Intraoperative cultures have not been shown to alter the treatment outcome.[96,97] The best regimen and duration of antibiotics use is a subject of continued controversy. A 10-day course of intravenous ampicillin, gentamicin, and clindamycin or metronidazole is the gold standard for the treatment of complicated appendicitis,[98] and the effectiveness of other antibiotic combinations are usually measured against this empiric regimen. More recently, it has been shown that a single or double broad-spectrum antibiotic is equally effective for the treatment of complicated appendicitis.

There is a trend toward decreasing the duration of antibiotic therapy.[99] Only perioperative antibiotics are required for simple appendicitis. The recommended duration is from a single, preoperative dose to 24 hours of postoperative antibiotic therapy for simple appendicitis.[100,101] For complicated appendicitis, recent studies have suggested that as little as 48 hours of coverage is adequate.[69] Others suggest that treatment be continued as clinically indicated using the leukocyte count and presence of fever as guides.[102–104] There is also a trend to use oral antibiotics instead of intravenous antibiotics when gastrointestinal function returns. A prospective, randomized study demonstrates equivalency between a 10-day course of intravenous antibiotics and a 10-day course of combined intravenous and oral antibiotics for complicated appendicitis.[105]

## APPENDECTOMY

The most widely accepted treatment of appendicitis is appendectomy. Randomized trials that compared medical therapy with appendectomy in adults with appendicitis showed that medical therapy is associated with a 10% to 20% chance of recurrence but has lower rates of complications. There is a trend away from performing immediate operation.[106,107] There was no increased rate of complications noted between a group of patients diagnosed with acute appendicitis and operated upon within 6 hours of admission and those with delays between 6 and 18 hours of admission.[55,56] Nevertheless, the majority of pediatric surgeons will perform appendectomy within 8 hours.[94]

In the open technique, a transverse or oblique right lower quadrant incision is made through the McBurney point (Fig. 100-1). The muscles of the abdominal wall are usually split. After the abdomen is entered, the cecum and appendix are mobilized and the appendix is brought out through the incision. The mesoappendix is then divided, and the base of the appendix is ligated. A short base is left to avoid inflammation in the stump.[108] The stump is managed by simple ligation, ligation with inversion using a purse-string or Z-stitch suture, or inversion without ligature. Simple ligation can be done quickly and may reduce adhesions.[109] Inversion theoretically leads to better hemorrhage control, a doubly secure closure, and less chance of contamination; however, it can create artifacts on future contrast examinations and can cause intussusception.[110] For simple appendicitis, irrigating the wound is unnecessary. The wound is closed in layers, and no drains are placed. A normal diet can be given soon after appendectomy, and the patient can be discharged in 1 to 2 days. If a normal appendix is found, the peritoneal cavity should be inspected for inflammatory bowel disease, mesenteric adenitis, Meckel diverticulitis, or, in females, pathologic conditions of the ovary.

"Endoscopic" appendectomy was first described in 1983.[111] Laparoscopic appendectomy can be done by a laparoscopic-assisted technique in which the appendix is mobilized laparoscopically using one or two ports and is drawn through a small abdominal opening and removed by standard open technique.[112,113] Alternatively, the appendix can be removed entirely laparoscopically. Three trocars are usually

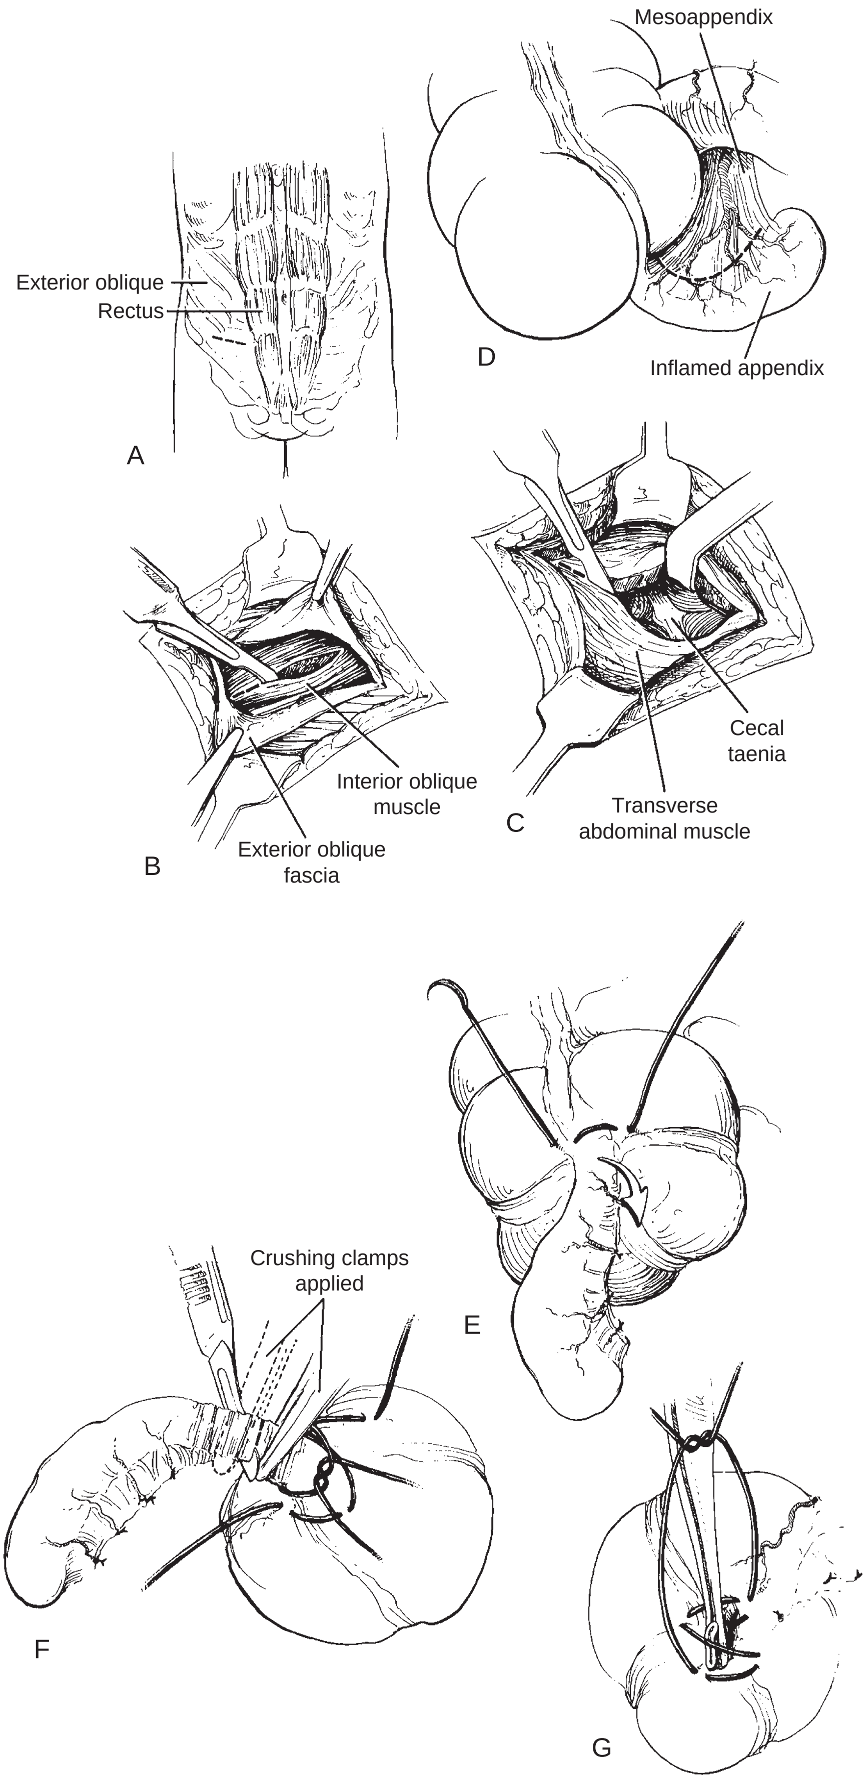

**FIGURE 100-1** **A,** A transverse incision is made in the right lower quadrant over the lateral musculature. **B,** The external oblique fascia is incised exposing the internal oblique fascia and muscle. **C,** The transverse abdominal muscle and peritoneum are opened, and the cecum is identified. **D,** An inflamed appendix is identified, and the mesoappendix is isolated, clamped, divided, and tied. **E,** A purse-string suture is placed in the cecal wall. **F,** The base of the appendix is crushed and tied, and the appendix is excised. **G,** The appendiceal stump is inverted into the cecal wall, and the purse-string suture is tied. employed: one at the umbilicus for the scope, one in the suprapubic area, and one in the left lower quadrant (Fig. 100-2), although a single-incision multiport approach may also be employed. The appendix is found by following the cecum, and the mesoappendix is grasped near the tip to lift the appendix toward the abdominal wall. A window is made in the mesoappendix near the base to allow its division by applying electrocautery, clips, staples, or the harmonic scalpel. Many variations of ligating and removing the appendix have been described.[85,114] The simplest technique applies an endoscopic stapler to the base of the appendix, and the appendix is delivered through the umbilical trocar site. There is now early experience with single port/incision techniques.

Despite prospective, randomized trials that compared open and laparoscopic appendectomy, the advantages and disadvantages of laparoscopic appendectomy continue to be debated.[115–124] Advantages claimed include shorter hospitalizations, decreased postoperative pain, decreased wound complications, increased ability to diagnose uncertain cases, surgical ease in an obese patient, and faster postoperative recovery.[84,85,125–129] Disadvantages are a higher cost because of equipment needs and longer time for surgery, increased training and experience required for surgeons and ancillary support staff, increased incidence of finding a normal appendix, and an increased incidence of intra-abdominal infection.[84,130–133] Although the conclusions regarding the

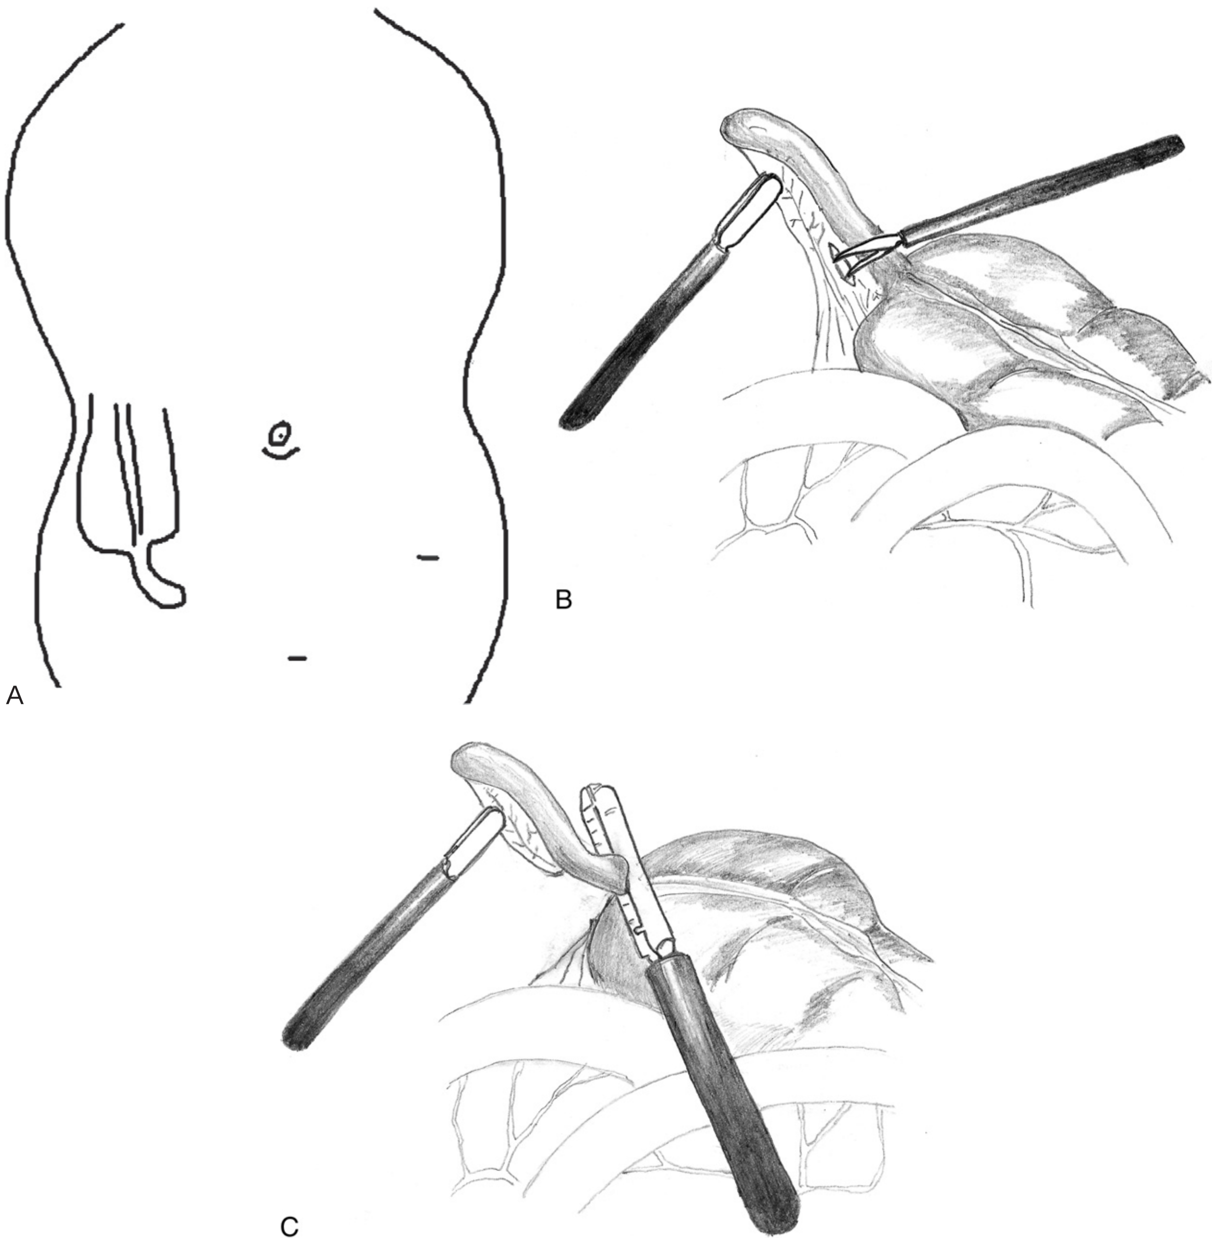

FIGURE 100-2 **A,** Three ports are placed for laparoscopic appendectomy. The umbilical port is 12 mm in size to accommodate the endoscopic stapler. The other two ports are 3 or 5 mm in size for dissecting instruments. **B,** The appendix is lifted upwards by a grasper placed on the mesoappendix, and a window is made at the base of the mesoappendix by a dissector. The mesoappendix is divided by electrocautery or harmonic scalpel. **C,** The scope is switched to the left lower quadrant port to allow the endoscopic stapler to come through the umbilical port to divide the appendix.

advantages of this technique over the open technique vary widely, laparoscopic appendectomy is a safe and effective means of performing an appendectomy and its utilization has increased dramatically over the past decade.

Treatment of patients with complicated appendicitis is more controversial. Due to social, cultural, economic, and medical influences on the diagnosis and treatment of this disease process, perforation rates vary from 16% to 57% in different institutions. There is no consensus on the optimal treatment of patients with complicated appendicitis. Opinions range from nonoperative treatment to aggressive surgical resection with antibiotic irrigation, drainage of the peritoneal cavity, and delayed wound closure.[134–138] Weiner[139] reported no significant differences in the number of hospital days, cost of treatment, or overall complication rates using initial nonoperative treatment of complicated appendicitis followed by interval appendectomy in 8 weeks. In another study that examined initial nonoperative therapy for complicated appendicitis confirmed by imaging, 22% of the patients were converted to appendectomy because of small bowel obstruction.[140] Operative treatment remains the standard approach because of the difficulty in determining whether perforation has occurred before exploration.

The operative procedure for complicated appendicitis is appendectomy. Controversy continues regarding the details of the procedure: whether to drain the peritoneal cavity, whether to close the wound or leave it open with delayed closure, whether to irrigate the peritoneal cavity and, if so, whether to use antibiotic solutions. Drains have been described as both increasing infectious complications and preventing them.[29,30,46,141–143] Most studies do not support the use of drains, with the possible exception of retrocecal abscesses that cannot be properly debrided. Delayed wound closure is not supported by the literature[46,85–87,98] and does not seem to be warranted because the wound infection rate associated with appendectomy is less than 3%. Irrigation remains controversial. Putnam, Gagliano, and Emmons[87] suggest that irrigation prolongs ileus and may cause small intestinal obstruction and report excellent results without irrigation. Other recent studies support saline irrigation of the peritoneal cavity with or without antibiotics.[29,46,85,86,98]

Management of patients with a palpable abdominal mass is another controversial topic. It occurs in a small but significant fraction of patients with complicated appendicitis, especially in young children after perforation. Some advocate immediate appendectomy,[144] whereas others perform the procedure only if a mass is confirmed with the patient under anesthesia. If an operation is done, care should be taken to avoid damage to adjacent structures subject to inflammatory processes such as the small intestine, the fallopian tubes and ovaries, and the ureter. Surana[145] and Nitecki[146] recommend treatment with intravenous antibiotics until the leukocyte count is normal and the patient remains afebrile for 24 hours. If the patient's condition worsens or the mass enlarges on serial ultrasonography, the mass is drained percutaneously, followed by interval appendectomy. Interval appendectomy prevents repeated episodes of appendicitis and affords the surgeon the opportunity to evaluate the patient for other conditions that can masquerade as an appendiceal mass. Whether an interval appendectomy is necessary is also debated.[146–152] Nitecki[116] has suggested that interval appendectomy is unnecessary because only 14% of patients have recurrent symptoms, and recurrence within 2 years after initial diagnosis is uncommon. The current standard of treatment is conservative management with interval appendectomy after 8 to 12 weeks.

# Complications

The incidence of complications increases with the degree of severity of the appendicitis. The complications include wound infection, intra-abdominal abscess formation, postoperative intestinal obstruction, prolonged ileus, and rarely enterocutaneous fistula. Wound infection is the most common complication, but the rate has fallen from 50% to less than 5%, even in complicated appendicitis.[29,30,47,85–87] Intra-abdominal abscess formation is also more common in complicated appendicitis but is still less than 2%. The abscess can be drained percutaneously under CT guidance or transrectally in the operating room, although others have advocated more conservative management.[153–155] Postoperative intestinal obstruction occurs in 1% of patients with complicated appendicitis, which often requires operative adhesiolysis.[156] Enterocutaneous fistula is a rare complication and will usually respond to nonoperative management. Suppurative pylephlebitis is a particularly serious, although rare, complication.[157] Sepsis and multisystem organ failure can occur in young children who had prolonged illness before diagnosis. Major complications including postoperative intestinal obstruction and intra-abdominal abscess formation have also fallen to an incidence of less than 5%.

An unresolved issue is the effect of complicated appendicitis on fertility in females; available studies contradict each other. Puri, McGuinness, and Guiney[158] report that complicated appendicitis before puberty plays little if any role in the cause of tubal infertility, whereas Mueller[159] reports that the condition is associated with a fourfold risk for tubal infertility. The consequences of complicated appendicitis may be mitigated through both public and medical education that ensures prompt, early treatment before perforation.

# Outcomes

The mortality rate for complicated appendicitis has dropped to nearly zero. Antibiotics have markedly decreased the incidence of infectious complications. Although the length of hospitalization and the morbidity of patients with complicated appendicitis still far exceed those with simple appendicitis, the overall morbidity in children with complicated appendicitis is less than 10%.

The widely varied postoperative management of appendicitis is beginning to be addressed by implementing evidence-based clinical pathways.[160,161] Prompted primarily by economic pressures, there is increasing scrutiny of patient treatment and outcome.[162–164] Early outcome research has shown that hospitals that perform fewer than one appendectomy per week are associated with higher likelihood of misdiagnosis.[165] There are also reports that suggest better outcome in younger children with appendicitis when they are cared for by pediatric surgeons.[166,167] The combination of surgical evaluation, prompt operation when the diagnosis is clear, a period of observation if the diagnosis is equivocal followed by imaging if necessary, and care provided by

experienced clinicians and institutions will lead to the best outcome for children with appendicitis.

# CHAPTER 101

# Hirschsprung Disease

Jacob C. Langer

Hirschsprung disease is a developmental disorder of the intrinsic component of the enteric nervous system that is characterized by the absence of ganglion cells in the myenteric and submucosal plexuses of the distal intestine. Because these cells are responsible for normal peristalsis, patients with Hirschsprung disease present with functional intestinal obstruction at the level of aganglionosis. In most cases the aganglionosis involves the rectum or rectosigmoid, but it can extend for varying lengths, and in 5% to 10% of cases can involve the entire colon or even a significant amount of the small intestine. The incidence of Hirschsprung disease is approximately 1 in 5000 live-born infants.

## History

The condition of "congenital megacolon" has been recognized for centuries. The first description of this condition was in the seventeenth century by Frederick Ruysch, who described a 5-year-old child dying from an intestinal obstruction, followed by another account of a child with congenital megacolon by Battini in 1800.[1] It was not until 1887 that Harald Hirschsprung, a pathologist at Queen Louise Children's Hospital in Copenhagen, described two cases of the condition that ultimately bore his name.[2] Until the beginning of the twentieth century, most children with congenital megacolon died, presumably from malnutrition and enterocolitis. Because the underlying pathologic abnormality was not recognized, surgeons who operated on these children usually resected the dilated proximal bowel with or without primary anastomosis, with mixed results.[3]

The absence of ganglion cells in the distal colon of a child with Hirschsprung disease was first noted by Tittel in 1901. Over the following decades numerous papers were published to document abnormalities of innervation within the colon and recognize the absence of ganglion cells that is now pathognomonic of Hirschsprung disease. The first surgical recognition of aganglionosis as the cause of congenital megacolon was by Ehrenpreis in 1946. In a landmark paper, Whitehouse and Kernohan summarized the literature and presented a series of cases of their own, which documented that the aganglionosis within the distal colon or rectum was the cause of the functional obstruction.[4]

In 1949 Swenson published a paper in the *New England Journal of Medicine* recommending rectosigmoidectomy with preservation of the sphincters as the optimal treatment of this disease.[5] This operation was originally performed without a decompressing colostomy.[6] However, technical difficulties in small infants and the debilitated and malnourished state in which most children presented caused most surgeons to adopt a multistaged approach with colostomy as the initial step,[6] an approach that became the standard of care for decades. In recent years, improvements in surgical technique and earlier suspicion and diagnosis of the disease have resulted in an evolution toward one-stage and minimal access procedures. These advances have resulted in significantly improved morbidity and mortality in infants with Hirschsprung disease.

## Etiology and Genetics

Ganglion cells are derived from the neural crest. By 13 weeks postconception, the neural crest cells have undergone a process of migration through the gastrointestinal tract from proximal to distal, after which they differentiate into mature ganglion cells.[7] In infants with Hirschsprung disease this process is disturbed, so the ganglion cells are absent in the distal bowel. There are two theories as to why this occurs. The most prevalent is that the neural crest cells never reach the distal intestine because they either mature or differentiate into ganglion cells earlier than they should. Data supporting this theory come from spontaneously occurring animal models of aganglionosis[8] and from studies of normal neural crest cell migration done in chick embryos and human fetuses.[9,10] The second theory is that the ganglion cells do reach their destination but fail to survive or proliferate. Data in support of this theory include animal studies suggesting that there are at least two sources of neural crest cells (vagal and sacral), with migration both proximally and distally. In addition, a number of studies have suggested that the smooth muscle and extracellular matrix in the aganglionic bowel provides an inhospitable microenvironment for neuronal growth.[11,12] It is likely that Hirschsprung disease is actually a heterogeneous condition with multiple genetic causes and etiologic mechanisms, so each of these theories may be true in individual cases.

The heterogeneous nature of Hirschsprung disease is supported by increasing evidence that mutations in a variety of genes may be responsible.[13–15] The most commonly identified gene is the *RET* proto-oncogene, which was first identified in studies of Mennonite populations. *RET* encodes a tyrosine kinase receptor, and many mutations of this gene and related genes such as neurturin and glial cell line–derived neurotrophic factor (GDNF) have been identified in association with Hirschsprung disease. It remains unclear how these mutations result in aganglionosis, but there is some evidence that early neuronal cell death may be a prominent mechanism.[16,17] RET abnormalities are more commonly found in familial and long-segment disease. Mutations in the endothelin family of genes, particularly endothelin-3 and the endothelin-B receptor, are also commonly associated with Hirschsprung disease, although many of these children also have other abnormalities of neural crest–derived tissues, the most common of which is Shah-Wardenberg syndrome. There is evidence from animal models that mutations in the endothelin and SOX-10 genes may produce early maturation or differentiation of neural crest cells, which decreases the number of available progenitor cells and prevents the neural crest cells from migrating any further.[18,19] Other genes that have been associated with Hirschsprung disease include *S1P1* (now known as *ZFHX1B*), and *Phox2B*.

Hirschsprung disease is also associated with a number of syndromes for which the precise genetic basis of the aganglionosis has not yet been elucidated. These include Trisomy-21, congenital central hypoventilation syndrome, Goldberg-Shprintzen syndrome, Smith-Lemli-Opitz syndrome, neurofibromatosis, neuroblastoma, and a variety of other congenital anomalies.

# Diagnosis

## CLINICAL PRESENTATION

### Neonatal Obstruction

Approximately 50% to 90% of children with Hirschsprung disease present during the neonatal period with abdominal distension, bilious vomiting, and feeding intolerance suggestive of distal intestinal obstruction. Delayed passage of meconium beyond the first 24 hours is characteristic but is only present in approximately 90% of children with Hirschsprung disease. In some patients cecal or appendiceal perforation may be the initial event.[20] Plain radiographs usually show dilated bowel loops throughout the abdomen. The differential diagnosis includes intestinal atresia, meconium ileus, meconium plug syndrome, or a number of other less common conditions.

### Chronic Constipation

Some patients present later in childhood, or even during adulthood, with chronic constipation. This is most common among breast-fed infants, who typically develop constipation around the time of weaning. Although most children who present after the neonatal period have short-segment disease, this history may also be found in those with longer segment or even total colonic involvement, particularly if the child has been exclusively breast-fed. Because constipation is frequently seen in childhood, it may be difficult to differentiate Hirschsprung disease from more common causes of constipation. Clinical features that point to this diagnosis include failure to pass meconium in the first 48 hours of life, failure to thrive, gross abdominal distention, and dependence on enemas without significant encopresis.[21]

### Enterocolitis

Approximately 10% of children with Hirschsprung disease present with fever, abdominal distention, and diarrhea due to Hirschsprung-associated enterocolitis (HAEC), which may be chronic, or may be severe and life-threatening. Because Hirschsprung disease is generally thought of as causing constipation, presentation with diarrhea may be confusing and the diagnosis may not be considered. A careful history including the failure to pass meconium and the presence of intermittent obstructive episodes should lead to investigation for Hirschsprung disease.

The etiology of HAEC is controversial. The most common theory is that stasis caused by functional obstruction due to the aganglionic bowel permits bacterial overgrowth with secondary infection. Infectious agents such as *Clostridium difficile* or *Rotavirus* have been postulated as being causative, but there are few data to support a specific pathogen.[22] There is some evidence implicating alterations in intestinal mucin production and alterations in the mucosal production of immunoglobulins in children with Hirschsprung-associated enterocolitis, which presumably results in loss of intestinal barrier function and allows bacterial invasion.[23,24]

### Associated Conditions

Hirschsprung disease is associated with a variety of other congenital abnormalities, the presence of which should increase the clinician's level of suspicion (Table 101-1). These include malrotation, genitourinary abnormalities, congenital heart disease, limb abnormalities, cleft lip and palate, hearing loss, mental retardation, and dysmorphic features. In addition, Hirschsprung disease may be part of a large number of recognized syndromes such as trisomy 21, a variety of neurocristopathies, and congenital central hypoventilation syndrome.

## RADIOLOGIC EVALUATION

For the neonate with a clinical picture and plain radiographs suggesting distal neonatal bowel obstruction, the first step in the diagnostic pathway is a water-soluble contrast enema. The pathognomonic finding of Hirschsprung disease on contrast enema is a transition zone between the normal and aganglionic bowel (Fig. 101-1, *A*), although approximately 10% of neonates with Hirschsprung disease may not have a demonstrable radiologic transition zone.[25] It is important to use a water-soluble material because the enema may potentially be a definitive treatment for other conditions in the differential diagnosis such as meconium ileus and meconium plug syndrome. In older children an unprepped barium enema should be done rather than a water-soluble contrast study. The absence of a transition zone is less common in this age group but may still be present due to a short aganglionic segment. In both neonates and older children, the most important view is the lateral projection, in which a rectal transition zone will be most evident (Fig. 101-1, *B*). Other findings on the contrast enema that are suggestive of Hirschsprung disease include a reversed recto-sigmoid index (Fig. 101-1, *B*) and retention of contrast in the colon on a 24-hour postevacuation film.

## ANORECTAL MANOMETRY

The recto-anal inhibitory reflex (RAIR) is defined as reflex relaxation of the internal anal sphincter in response to rectal distension and is present in normal children but absent in children with Hirschsprung disease. The RAIR can be documented using anorectal manometry by inflating a balloon in the rectum while simultaneously measuring the internal sphincter pressure. Anorectal manometry is not widely available for neonates and is often operator dependent. In older children the test is technically easier, but false-positive results may occur due to masking of the relaxation response by contraction of the external sphincter, as well as artifacts created by movement or crying. Anorectal manometry is most useful in the evaluation of an older child with chronic constipation, where documentation of a normal RAIR effectively rules out Hirschsprung disease and avoids the need for a rectal biopsy.

## RECTAL BIOPSY

Definitive diagnosis of Hirschsprung disease is based on histologic evaluation of a rectal biopsy, which remains the gold standard diagnostic technique. The definitive finding that defines Hirschsprung disease is absence of ganglion cells in the submucosal and myenteric plexuses (Fig. 101-2, *A*). Most patients will also have evidence of hypertrophied nerve trunks (Fig. 101-2, *B*), although this finding is not always present, particularly in children with total colonic disease or a short aganglionic segment. Because there is normally a paucity of ganglion cells in the area 0.5 to 1 cm above the dentate line, the biopsy should be taken at least 1 to 1.5 cm above it. However, a biopsy too proximal may miss a short aganglionic segment. Most surgeons use a suction biopsy technique, which is associated with a low risk of perforation or bleeding. For children in whom the suction biopsy yields an inadequate specimen and in older children in whom the mucosa is too thick for a suction biopsy, punch biopsies or full-thickness biopsies provide more tissue and deeper levels.

In many centers the routine hematoxylin and eosin staining is supplemented by staining for acetylcholinesterase, which has a characteristic pattern in the submucosa and mucosa in children with Hirschsprung disease (Fig. 101-2, *C*). Other pathologists choose not to use acetylcholinesterase staining, believing that it is too subjective and does not add any information to the hematoxylin and eosin. A number of newer stains have recently been shown to have additional value for the diagnosis of Hirschsprung disease. The most accurate appears to be immunochemical identification of calcitonin, which is almost always absent in patients with Hirschsprung disease (Fig. 101-2, *D*).[26]

Occasionally a premature infant will develop distal intestinal obstruction, and the possibility of Hirschsprung disease will be raised on the basis of clinical and radiologic parameters. Early rectal biopsy in these children is not recommended for two reasons: (1) The pathologist may have difficulty recognizing ganglion cells due to their immaturity, and (2) it may be difficult to obtain enough tissue without increasing the risk of complications in a small premature infant. It is best in this situation to decompress the rectum using stimulations and/or irrigations and wait until the child is closer to term before

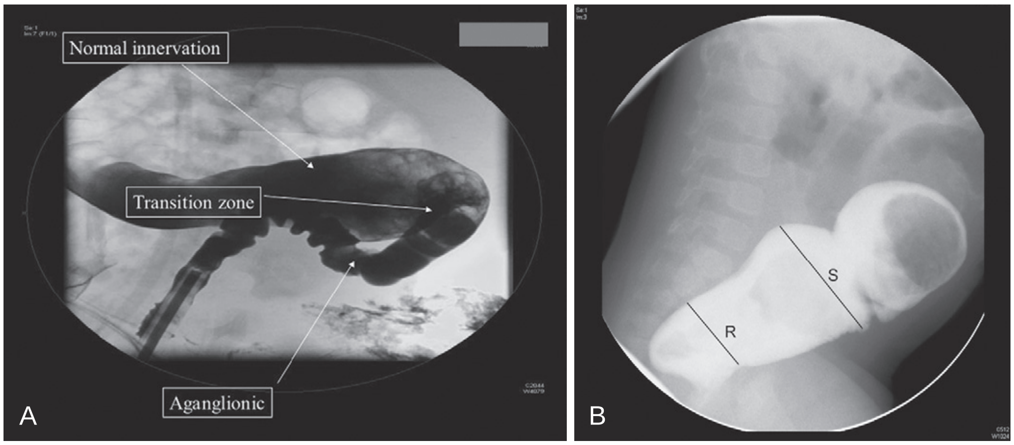

**FIGURE 101-1** **A,** Water-soluble contrast enema demonstrating a transition zone at the splenic flexure. **B,** The lateral view is the most important one to identify a low transition zone. In this case the recto-sigmoid index, consisting of the ratio of rectal diameter (*R*) to sigmoid diameter (*S*), is less than 1.0. D. Retention of contrast on a 24-hour postevacuation film.

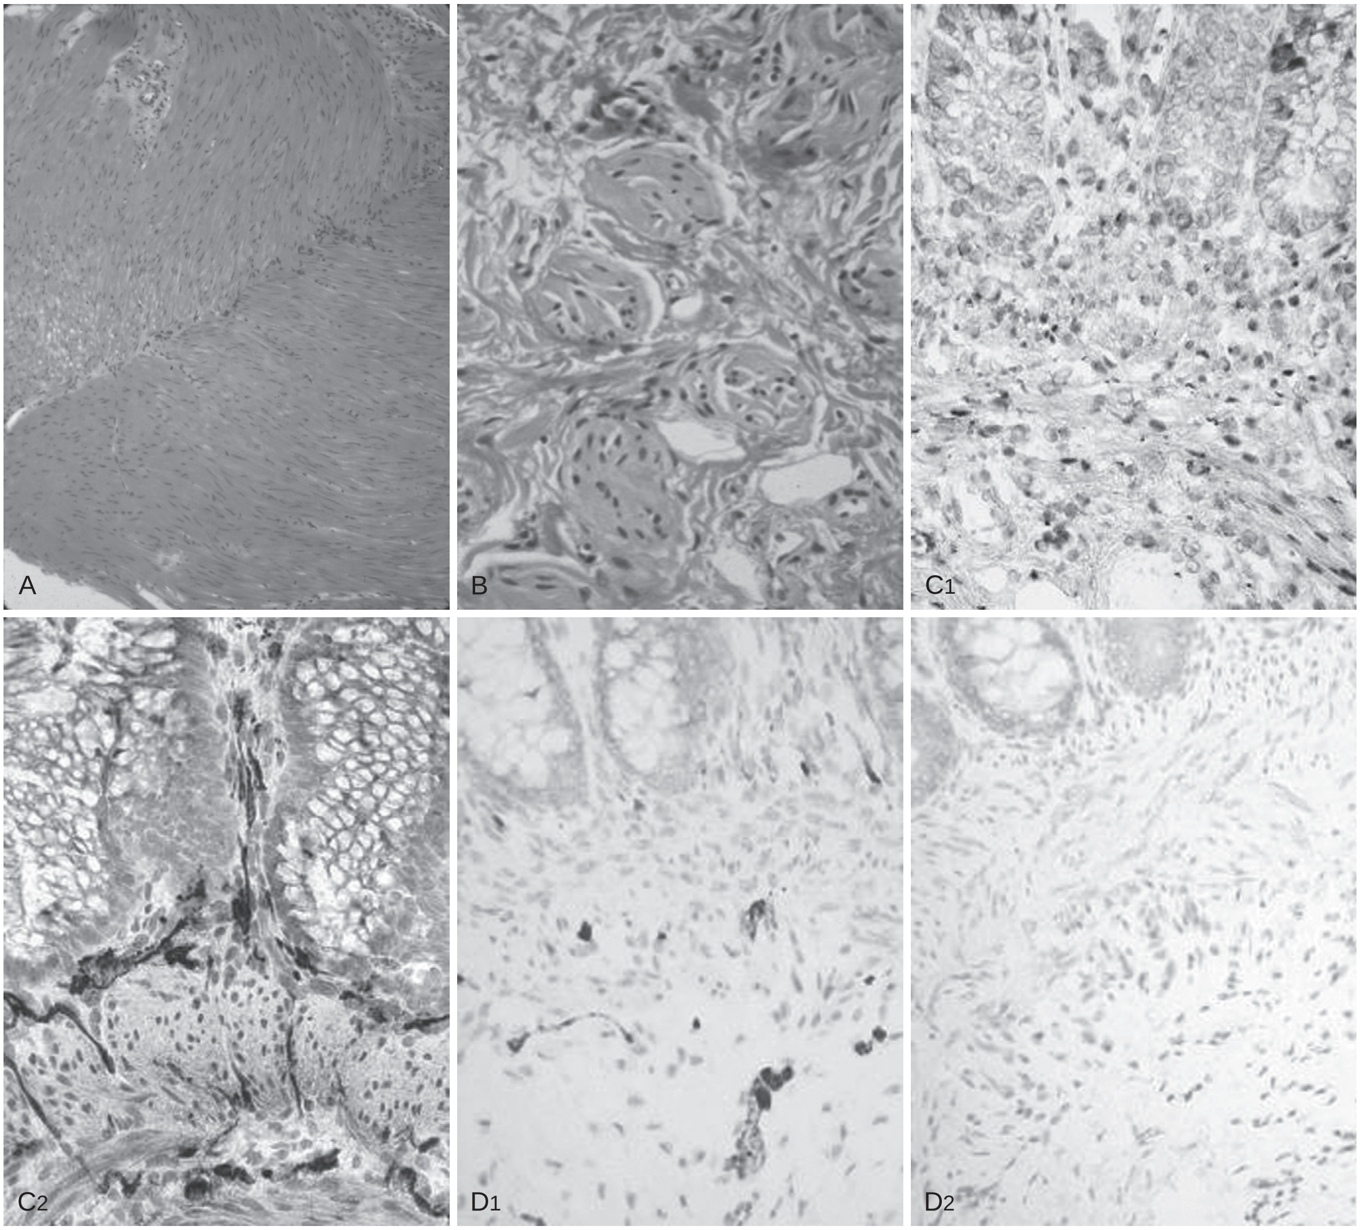

**FIGURE 101-2** Pathologic findings in children with Hirschsprung disease. **A,** Absence of ganglion cells in the myenteric plexus. **B,** Hypertrophied nerve trunks. **C,** Cholinesterase staining in normal colon and colon affected by Hirschsprung disease. **D,** Calretinin staining in normal colon and colon affected by Hirschsprung disease. (**D**, Courtesy Dr. Raj Kapur.)

doing the rectal biopsy. Although some surgeons believe that Hirschsprung disease is not seen in premature infants, this condition has been well-documented in a number of series.

## Preoperative Management

In most cases the treatment of Hirschsprung disease is surgical. However, there are a number of important preoperative interventions that must be considered before definitive surgical intervention. The first priority is resuscitation, particularly in neonates with intestinal obstruction or children presenting with enterocolitis. In both groups, intravenous fluids and broad-spectrum antibiotics against enteric organisms should be administered, and a nasogastric tube should be inserted. Children with associated abnormalities such as cardiac disease or congenital central hypoventilation syndrome must be investigated and managed before definitive surgical repair. Children with enterocolitis or those in whom immediate surgery cannot be done for other reasons should undergo decompression of the colon using digital rectal stimulation, irrigations, or occasionally an emergency stoma.

Once a child has been resuscitated and stabilized, operation can be done semielectively. While waiting, most children can be discharged home on breast milk or an elemental formula, in combination with rectal stimulations or irrigations. In the older child with an extremely dilated colon, operation should be delayed until the diameter of the colon has

decreased sufficiently to do a pull-through safely. This can sometimes be accomplished with weeks or months of irrigations, but some of these children may require a colostomy in order to adequately decompress the dilated colon (Fig. 101-3).

Some authors have advocated nonoperative long-term management of short-segment Hirschsprung disease using enemas and laxatives. Others have suggested that simple myectomy may be adequate.[27] However, these techniques do not provide a good quality of life for most children with Hirschsprung disease, and most pediatric surgeons recommend a pull-through procedure.

## Pull-through Procedure for Hirschsprung Disease

The goals of surgical management for Hirschsprung disease are to remove the aganglionic bowel and reconstruct the intestinal tract by bringing the normally innervated bowel down to the anus while preserving normal sphincter function. The most commonly performed operations are the Swenson, Duhamel, and Soave procedures (Fig. 101-4), although a number of other operations such as the Rebhein and State procedures have been described and are still done in some centers. Although many publications in the literature report results after each of these operations, few randomized or properly controlled prospective studies exist. Because of this lack of evidence, it is fair to say that all are acceptable alternatives and that the best operation for an individual patient is the one that the surgeon has been trained to do and does frequently.

### SWENSON PROCEDURE

Swenson provided the first description of a surgical approach to Hirschsprung disease in the late 1940s. Swenson's goal was removal of the entire aganglionic colon, with an end-to-end anastomosis above the anal sphincter. The operation was originally done through a laparotomy, with the anastomosis being performed from a perineal approach after eversion of the

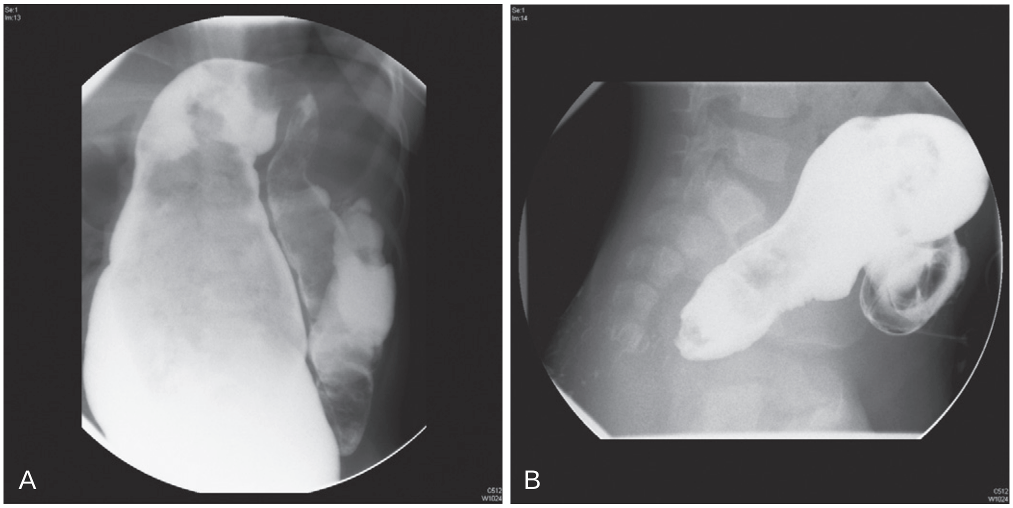

**FIGURE 101-3** Value of a decompressing colostomy to decrease the size of the dilated sigmoid colon before pull-through surgery. **A,** Before colostomy. **B,** Six months after colostomy.

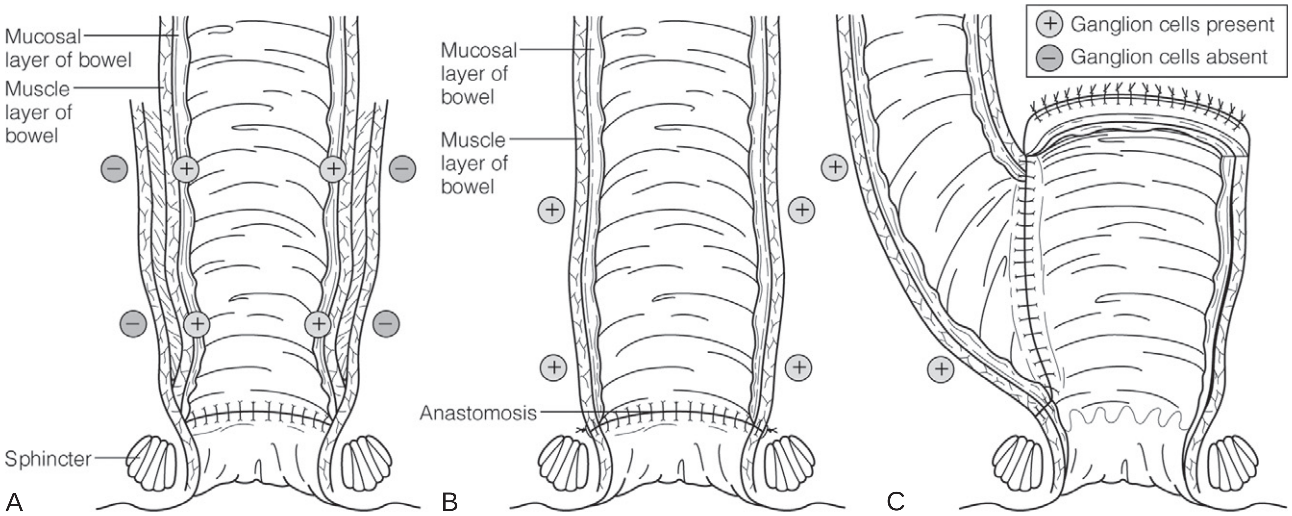

**FIGURE 101-4** The three most commonly performed operations for Hirschsprung disease. **A,** Soave. **B,** Swenson. **C,** Duhamel. + = ganglionic bowel, – = aganglionic bowel.

aganglionic rectum. Safe performance of the operation requires careful attention to dissection tightly on the rectal wall, in order to avoid injury to deep pelvic nerves, vessels, and other structures such as vagina, prostate, vas deferens, and seminal vesicles. Despite the theoretical risks inherent in the deep pelvic dissection, long-term outcome studies of the Swenson procedure report excellent functional results with respect to continence, urinary, and sexual function.[28]

### SOAVE PROCEDURE

The Soave procedure was designed to avoid the risks of injury to pelvic structures inherent in the Swenson procedure by doing a submucosal endorectal dissection and placing the pull-through bowel within a "cuff" consisting of aganglionic muscle. In the initial description of the operation, the pulled-through colon was left hanging out through the anus. This exteriorized bowel was excised, and the anastomosis done, at a second operation several weeks later. This was subsequently modified by Boley, who performed the procedure in a single stage.[29] Over the years there has been controversy regarding how long the cuff should be, as well as whether it should be split or a segment excised. Despite claims by some authors that the Soave procedure is more likely to result in long-term issues with constipation due to incomplete excision of the aganglionic rectum,[30] most late follow-up studies have reported similar outcomes to that seen with the Swenson procedure.[31]

### DUHAMEL PROCEDURE

The Duhamel procedure involves bringing the normal colon down through the bloodless plane between the rectum and the sacrum and joining the two walls to create a new lumen, which was aganglionic anteriorly and normally innervated posteriorly. In the initial description, two Kocher clamps were used to join the walls and were left in for a week. More recently, surgical staplers were used instead. The Duhamel procedure has several potential advantages over the Swenson or Soave procedures. It is believed to be easier and safer, with less pelvic dissection than the other two operations; it has a large anastomosis, which decreases the risk of anastomotic stricture; and the presence of a "reservoir" makes it appealing for children with longer aganglionic segments.

## Role of Colostomy

Swenson's initial operation was described as a one-stage procedure, but relatively high incidence of stricture, leak, and other adverse outcomes led him and others to recommend a routine preliminary colostomy, followed by a period of growth and a subsequent reconstructive operation.[32] This approach became surgical dogma, which was reinforced by the fact that many children with Hirschsprung disease presented late with malnutrition and dilated colon, so a colostomy was a lifesaving procedure. In the 1980s, however, a number of surgeons reported series of single-stage pull-through procedures even in small infants.[33,34] Over the next 10 to 15 years, one-stage operations became increasingly popular and many reports documented the safety of this approach, suggesting that a single-stage procedure avoids the known morbidity of stomas in infants and is also more cost-effective.[35–37] It is important to remember, however, that a stoma may still be indicated for children with severe enterocolitis, perforation, malnutrition, or massively dilated proximal bowel, as well as in situations where there is inadequate pathology support to reliably identify the transition zone on frozen section.

## Minimal Access Approaches

### LAPAROSCOPIC PULL-THROUGH

With the advent of laparoscopic surgery in the late 1980s, minimal access techniques became increasingly applied to pediatric surgical diseases. The first minimal approach to pull-through surgery for Hirschsprung disease was described by Georgeson in 1995,[38] who described a laparoscopic pull-through for Hirschsprung disease, involving laparoscopic biopsy to identify the transition zone, laparoscopic mobilization of the rectum below the peritoneal reflection, and a short mucosal dissection through a perineal approach (Fig. 101-5). The rectum is then prolapsed through the anus, and the anastomosis is done from below. This procedure has been associated with a shorter hospital time, and both early and mid-term results appear to be equivalent to those reported for the open procedures.[39] Laparoscopic approaches have been also described for the Duhamel and Swenson operations, with excellent short-term results reported.[40,41]

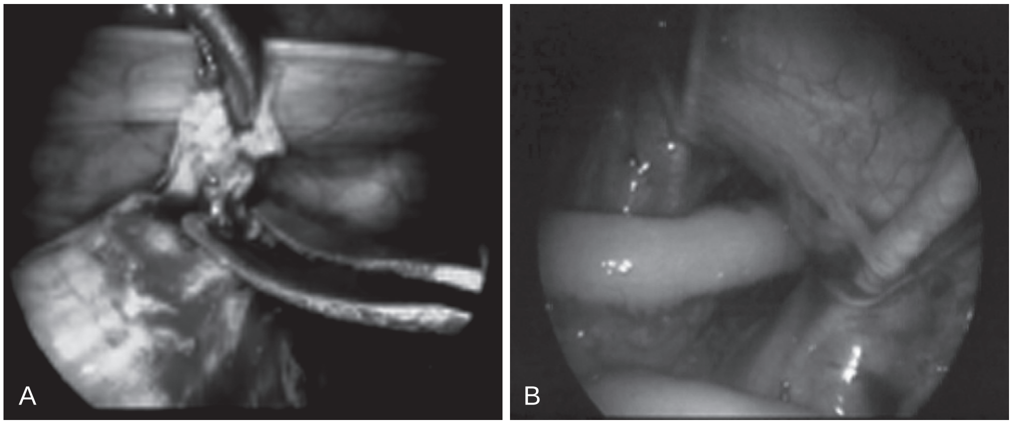

**FIGURE 101-5** Laparoscopic pull-through. **A,** Confirmation of the pathologic transition zone. **B,** Laparoscopic view of the completed pull-through from above. (Courtesy Dr. Steve Rothenberg.)

## TRANSANAL (PERINEAL) PULL-THROUGH

The transanal pull-through procedure uses the same mucosal dissection from below as the Georgeson operation, but without laparoscopic mobilization of the rectum. The mucosal incision is made 0.5 to 1 cm above the dentate line, depending on the size of the child, and the mucosa is stripped from the underlying muscle as in the Soave operation. The rectal muscle is then incised circumferentially, and the dissection is continued on the rectal wall, dividing the vessels as they enter the rectum. The entire rectum and part of the sigmoid colon can be delivered through the anus. When the transition zone is reached, the anastomosis is done from below (Fig. 101-6). In patients with a more proximal transition zone (usually above the proximal sigmoid colon), laparoscopy or a small umbilical incision can be used to mobilize the left colon and/or splenic flexure to achieve adequate length. A transanal approach can also be used if the patient has already had a colostomy, by using the stoma as the end of the pull-through bowel and performing the rectal excision using the transanal technique.

The transanal approach has a low complication rate, requires minimal analgesia, and is associated with early feeding and discharge.[42–45] Although there have not been any studies comparing the transanal and laparoscopic approaches, the transanal pull-through can be done by any pediatric surgeon, including those without laparoscopic skills, and by pediatric surgeons in parts of the world where access to appropriately miniaturized laparoscopic equipment is limited.

A number of ongoing controversies surround the transanal pull-through. The first is whether the pathologic transition zone should be defined before beginning the anal dissection. This was not done in the early descriptions of the operation and continues to be omitted by many surgeons. The main rationale for this practice is the known inaccuracy of the contrast enema in predicting the level of aganglionosis, with approximately 8% of children who have a rectosigmoid transition zone on contrast study having a more proximal transition zone on histology.[46] This step is particularly important for surgeons who do a different operation for long-segment disease than they do for rectosigmoid disease. The preliminary biopsy can be done using a laparoscopic approach, or through a small umbilical incision, both of which can also be used to mobilize the splenic flexure in children with higher transition zones.[47] The advantage of the umbilical approach is that it can be done by any surgeon, anywhere in the world, and does not require laparoscopic skills or equipment. Evidence would suggest that a preliminary biopsy to determine the pathologic transition zone does not have a deleterious effect on postoperative outcomes such as time to feeding, pain, or length of hospital stay.[45,48]

There is also controversy about whether the transanal pull-through is best done in the prone or supine position.[49] The prone position provides excellent visualization and is familiar to most pediatric surgeons because of their experience with it in the repair of anorectal malformations. The supine position has the advantage of access to the peritoneal cavity for initial colonic biopsy or for mobilization of the colon or a stoma if necessary. Finally, there is controversy about the length of the rectal cuff. The initial description of the transanal pull-through involved a long cuff, with a submucosal dissection extending into the peritoneal cavity. Many surgeons continue to do the operation this way, and most advocate division of the cuff to prevent narrowing. Other surgeons have modified the procedure by doing a short submucosal dissection for a few centimeters, and others have abandoned the submucosal dissection entirely and do what is essentially a transanal

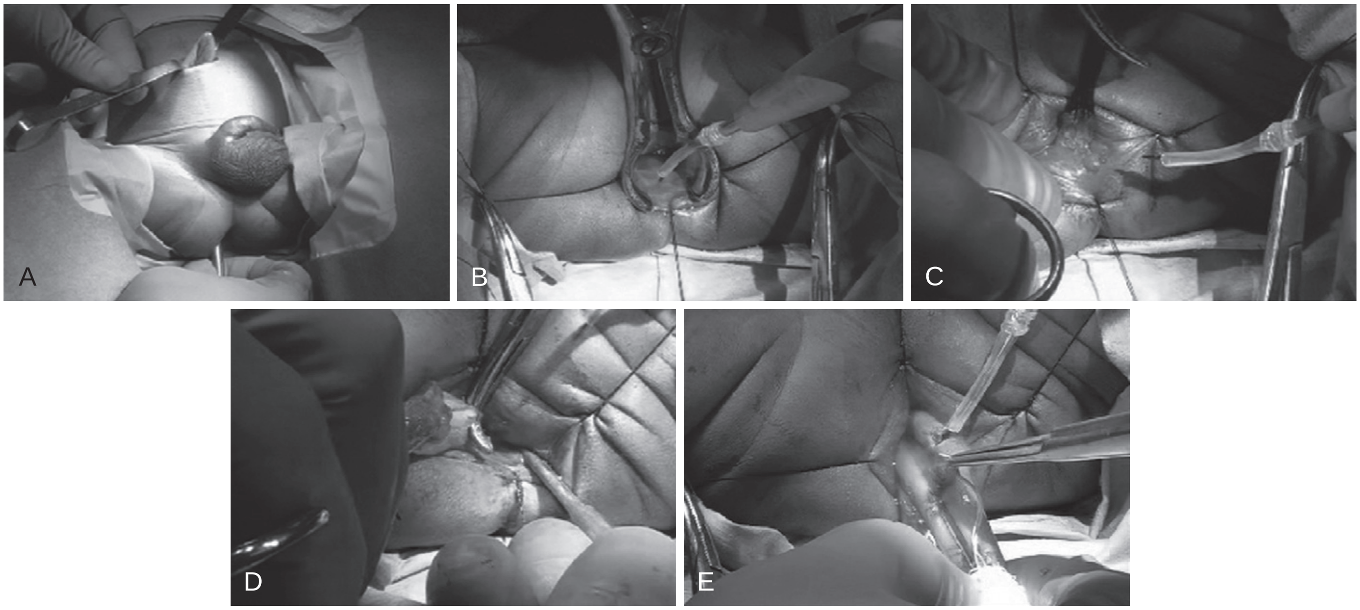

**FIGURE 101-6** The transanal Soave pull-through. **A,** An umbilical incision is used for a preliminary biopsy. A Heger dilator is used to push the sigmoid into the umbilical incision. **B,** Eversion sutures are placed, and a nasal speculum is used to provide exposure to the anal canal. A circumferential incision is made 5 mm from the dentate line. **C,** The submucosal dissection is carried 2 to 3 cm. **D,** Once the muscle cuff has been divided circumferentially, the dissection is carried proximally, staying right on the colonic wall. **E,** The bowel is divided at least 2 cm above the biopsy showing ganglion cells, and the anastomosis is performed. Care must be taken to do the anastomosis to the rectal mucosa, not to the transitional epithelium, or normal sensation will be lost and the risk of incontinence will be increased.

Swenson procedure.[50] The advantage of a shorter cuff is a lower rate of narrowing and potentially a lower risk of postoperative obstructive symptoms and enterocolitis.[48]

## Surgical Approach to Long-Segment Hirschsprung Disease

Long-segment Hirschsprung disease is usually defined as a transition zone that is proximal to the midtransverse colon. The most common is total colonic aganglionosis, which usually also includes some of the distal ileum. In rare cases most of or the entire small bowel is aganglionic. Long-segment disease is more likely to be associated with a positive family history[51] and is more likely to be diagnosed prenatally.[52] Contrast enema typically shows a shortened, relatively narrow colon ("question mark colon") (Fig. 101-7),[53] and there may also be a transition zone in the small bowel. The rectal biopsy shows absence of ganglion cells, but in many cases there are no hypertrophic nerves or abnormalities of acetylcholinesterase staining.

Early resuscitation and management is similar to that described for standard Hirschsprung disease. Sequential colonic biopsies are done looking for ganglion cells on frozen section. These can be done through a standard laparotomy, laparoscopically, or through an umbilical incision, which in a newborn can be used to access all parts of the colon. Traditionally, many surgeons started with an appendectomy, assuming that lack of ganglion cells in the appendix would be diagnostic of total colonic disease. However, this may result in a false-positive diagnosis of total colonic Hirschsprung disease because there may be a paucity of ganglion cells in the appendix in children with shorter segment disease.[54]

FIGURE 101-7 Contrast enema in a child with total colonic Hirschsprung disease. There is no transition zone in the colon, and the colon is foreshortened with a "question-mark" configuration.

Once the level of aganglionosis has been identified, most surgeons create a stoma, wait for permanent sections, and do a definitive reconstructive procedure at a later time. Although primary pull-through without ileostomy for total colonic disease has been reported, this approach requires a high degree of confidence in the pathologist because it requires doing a total colectomy on the basis of frozen sections alone. In addition, many surgeons believe that the results of pull-through surgery are better once the stool has thickened, which usually occurs in the first few months of life.

Three types of operations are available for reconstruction in children with long-segment Hirschsprung disease: straight pull-through, colon patch, and J-pouch construction. Straight pull-through procedures involve bringing the normally innervated ileum to just above the anal sphincter, using any one of the standard techniques (Swenson, Duhamel, or Soave). Colon patch procedures involve a side-to-side anastomosis between normally innervated small bowel and aganglionic colon, using the small bowel for motility and the colon as a reservoir for storage of stool and absorption of water. The Martin procedure consists of a Duhamel reconstruction that extends proximally to involve the entire left colon (Fig. 101-8, *A*). Kimura, using the rationale that the right colon is better at water absorption than the left colon, advocated a staged procedure, in which the right colon is anastomosed side-to-side to the ileum. The "ileo-colon" is then disconnected from the right colonic blood supply after several months and anastomosed above the anal sphincter (Fig. 101-8, *B*). The J-pouch procedure is done commonly for children and adults with ulcerative colitis and familial polyposis syndrome, and some pediatric surgeons have reported the use of this operation for children with long-segment Hirschsprung disease.[55]

There are no prospective or well-controlled series reporting long-term results of surgery for long-segment Hirschsprung disease. Although the colon patch procedures theoretically result in decreased stool output due to better water absorption, the aganglionic colon gradually tends to dilate and many of these patients develop severe enterocolitis, which requires removal of the patch or a permanent stoma. Children undergoing straight pull-through tend to experience gradually decreasing stool frequency over time, with an acceptable quality of life.[56–58]

### Near-Total Intestinal Aganglionosis

Rarely, almost the entire intestinal tract of a patient is aganglionic, usually leaving 10 to 40 cm of normally innervated jejunum. In most of these cases, there is not enough functional small bowel to support enteral nutrition and intestinal failure results. These children require total parenteral nutrition from birth, a situation that has been associated with a high risk of mortality from liver failure. The surgical approach at the time of the first laparotomy is to determine the extent of aganglionosis on the basis of frozen sections and to bring out a stoma at the most distal point that has normally innervated bowel. Some surgeons prefer to bring out a more distal stoma, but this approach may increase the risk of chronic intestinal obstruction and bacterial overgrowth. A central venous catheter should be inserted for parenteral nutrition, and a gastrostomy should be considered for continuous "trophic" feeding of breast milk or elemental formula.

The management of these children is similar to the management of any child with intestinal failure.[59] Strict attention to

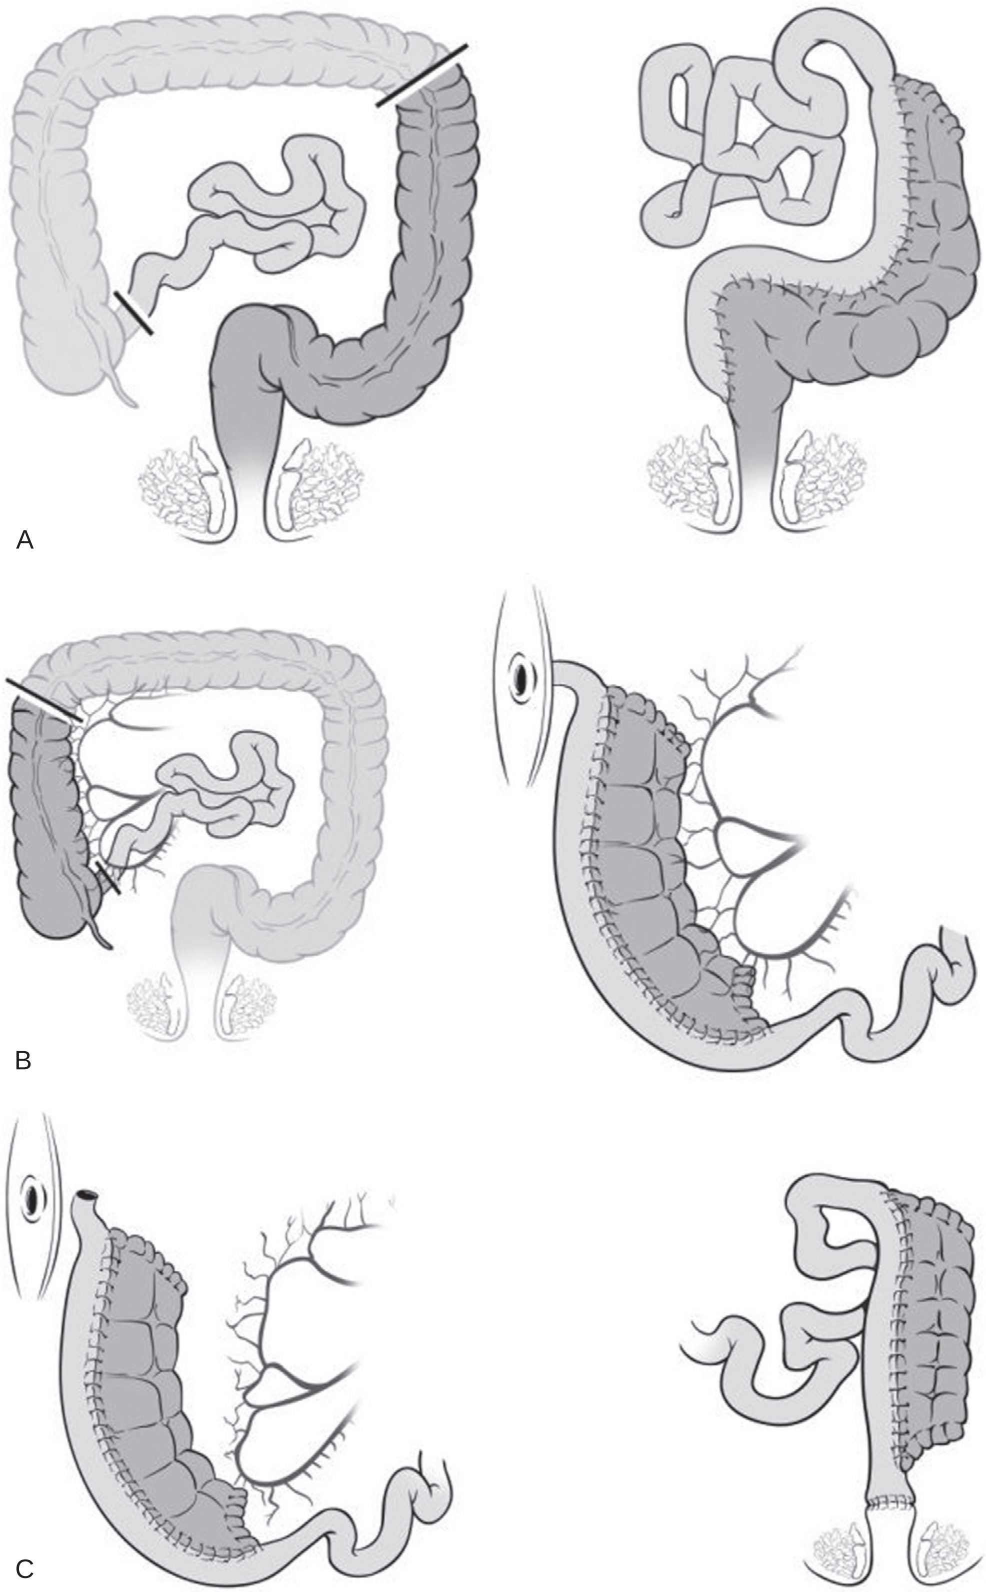

**FIGURE 101-8** Operations for long-segment Hirschsprung disease. **A,** Martin procedure. **B** and **C**, Kimura procedure.

prevention of sepsis, treatment of bacterial overgrowth, use of trophic feeds, and prevention of TPN-related cholestasis are all extremely important. Recent experience with omega-3 lipids has resulted in encouraging trends toward prevention and treatment of this problem.[60]

A number of surgical options are available for children with near-total aganglionosis.[61] For children who develop significant proximal dilatation of the normally innervated bowel, tapering, imbrication, or bowel-lengthening procedures such as the Bianchi or serial transverse enteroplasty (STEP)

procedure may be used.[62,63] Zeigler has popularized a technique known as “myectomy-myotomy,” in which a length of aganglionic small bowel distal to the transition zone undergoes myectomy.[64] Although a few successful cases using this technique have been reported, most surgeons have not found it to be successful and have noted high rates of postoperative complications. For children with ongoing liver failure, small bowel or combined small bowel-liver transplantation may offer the only chance for survival. A recent report from Paris documented extremely good results in 12 patients, many of whom underwent successful pull-through surgery following their intestinal transplant.[65]

# Postoperative Care

Most children undergoing a laparoscopic or transanal pull-through for standard Hirschsprung disease can be fed immediately, and most can be discharged within 24 to 48 hours. The anastomosis should be calibrated with an appropriately sized dilator or finger 1 to 2 weeks after the procedure. Although many surgeons instruct the parents to dilate the anastomosis on a daily basis, others have found it to be unnecessary in most cases and instead perform weekly calibration for a period of 4 to 6 weeks. It is important for the parents to protect the buttocks with a barrier cream because at least 50% of children will have frequent stools and perineal skin breakdown postoperatively. Fortunately, this problem tends to resolve over time.

As with any operation, children undergoing a pull-through may develop a wound infection or intra-abdominal bleeding. In addition, anastomotic complications such as leak or stricture may occur. Intestinal perforation can occur at a proximal biopsy site due to back pressure from anal sphincter spasm or due to unrecognized cautery injury. Bowel obstruction can result from intra-abdominal adhesions, a twist in the pull-through bowel, or a muscular cuff that has rolled down and constricted the pull-through bowel. In rare cases, rectovesical or rectovaginal fistulas have developed after pull-through surgery. Close monitoring for and early treatment of these complications is imperative. In addition, children with Hirschsprung disease can develop enterocolitis, even in the early postoperative period. The family and the primary care physician should be educated about the signs and symptoms of enterocolitis, and the family must be told to bring the child to the hospital if there are any signs suggestive of this problem because children can become very sick and even die from enterocolitis.[66]

# Long-Term Outcomes

Long-term problems in children with Hirschsprung disease include ongoing obstructive symptoms, soiling, and enterocolitis.[67] Quite often an individual child may have a combination of problems. Although early reports suggested that long-term issues were rare after surgical treatment of Hirschsprung disease,[68] it is now clear that these complications are more common than previously recognized.[31,69,70] It is important for the surgeon to follow these children closely, at least until they are through the toilet training process, in order to identify and provide early treatment for these problems.

## OBSTRUCTIVE SYMPTOMS

There are a range of obstructive symptoms that can be seen after a pull-through. Abdominal distension, bloating, vomiting, or ongoing severe constipation may be present immediately after surgery or may develop later after an initial period of normal bowel function. There are five major reasons for persistent obstructive symptoms following a pull-through: mechanical obstruction, recurrent or acquired aganglionosis, disordered motility in the proximal colon or small bowel, internal sphincter achalasia, or functional megacolon caused by stool-holding behavior (Table 101-2). The clinician will have much greater success in managing these difficult patients if an organized approach to this problem is taken. One proposed algorithm is shown in Figure 101-9.[71]

### Mechanical Obstruction

The most common cause of mechanical obstruction after a pull-through is a stricture, which usually occurs after a Swenson or Soave procedure (Fig. 101-10, *A*). Patients undergoing a Duhamel procedure may have a retained “spur” consisting of the anterior aganglionic bowel, which may fill with stool and obstruct the pulled-through bowel (Fig. 101-10, *B*). In other cases, there may be obstruction secondary to a twist in the pulled-through bowel (Fig. 101-10, *C*) or narrowing due to a long muscular cuff in children who have had a Soave procedure.

Obstruction can be identified using a combination of digital rectal examination and a barium enema. Initial management of anastomotic stricture consists of repeated dilatation using a finger, dilator, or radially dilating balloon. Some authors have advocated innovative techniques for recalcitrant strictures including antegrade dilatation over a string using Tucker dilators[72] and the use of intralesional steroid.[73] In some cases the stricture cannot be successfully dilated, and revision of the pull-through is necessary. This is best done using the Duhamel technique, although other operations have also been advocated.[74–76] Duhamel spurs can be resected from above or managed by extending the staple line from below, with or without laparoscopic visualization. Twisted pull-throughs and narrow muscular cuffs usually require surgical intervention, typically a repeat pull-through. In some cases, a muscular cuff can be divided laparoscopically without having to re-do the entire pull-through.

### Persistent or Acquired Aganglionosis

This rare problem may be due to pathologist error,[77] a transition zone pull-through,[78] or ganglion cell loss after a pull-through.[79] Repeat rectal biopsy, above the previous anastomosis (it must be posterior in the case of an initial Duhamel procedure), should be done to determine whether there are

normal ganglion cells present in all patients with persistent obstructive symptoms after surgery. The pathology from the original operation should be reviewed to ensure that there was normal innervation at the proximal margin, and in some cases further sections should be done circumferentially from the resection margin because the transition zone is often asymmetrical in children with Hirschsprung disease.[80] The best treatment for persistent or acquired aganglionosis in most cases is a repeat pull-through, which can be done using either a Soave or Duhamel approach.[75]

***Motility Disorder*** Children with Hirschsprung disease often have associated motility disorders including an increased incidence of gastroesophageal reflux and delayed gastric emptying,[81] small bowel dysmotility, and disordered colonic motility. Some cases are more focal, usually involving the left colon. In some cases the disordered motility may be associated with histological abnormalities such as intestinal neuronal dysplasia (discussed in greater detail later).

In children who have been shown not to have a mechanical obstruction and who have normal ganglion cells on rectal

biopsy, investigations for motility disorders should be undertaken. This can include a radiologic shape study, radionuclide colon transit study,[82] colonic manometry,[83] and laparoscopic biopsies looking for evidence of intestinal neuronal dysplasia.[84] If a focal abnormality is found, consideration should be given to resection and repeat pull-through using normal bowel. If the abnormality is diffuse, the appropriate treatment is bowel management and the use of prokinetic agents. Some children with particularly dysmotile colon will benefit from placement of a cecostomy for antegrade colonic enemas.[85]

***Internal Sphincter Achalasia*** This term refers to the lack of a normal RAIR that is present in all children with Hirschsprung disease (as described earlier in "Diagnosis"). It is unclear why only some children develop obstructive symptoms from this nonrelaxation, while others function normally in the postoperative period. It is also unclear why most children eventually "grow out" of this problem over time, usually by the age of 5 years. Internal sphincter achalasia is a diagnosis of exclusion, which is made after ruling out mechanical obstruction, aganglionosis, and dysmotility. The diagnosis can be confirmed by demonstrating a clinical response to intrasphincteric botulinum toxin.[86] However, the response to botulinum toxin is not related to the absolute value of the internal anal sphincter pressure (i.e., patients with a higher resting pressure are not necessarily more likely to benefit from botulinum toxin).

The standard treatment of internal sphincter achalasia has been internal sphincterotomy or myectomy,[87,88] but because this problem tends to resolve on its own in most children and there is concern about sphincter-cutting operations exacerbating future soiling issues, we prefer to use "chemical sphincterotomy" with intrasphincteric botulinum toxin.[86,89,90] In many cases repeated injection of botulinum toxin or applications of nitroglycerine paste or topical nifedipine are necessary while waiting for resolution of the problem.

***Functional Megacolon*** Functional megacolon is the result of stool-holding behavior, a common cause of constipation that some authors claim affects up to half of normal children at some time during their first few years of life.[91] This condition is probably even more common in children with Hirschsprung disease because of their predisposition to constipation, which leads to hard painful stools, withholding behavior, and a resulting vicious cycle.[92] The treatment for this problem is a bowel management regimen consisting of laxatives, enemas, and behavior modification including support for the child and family. In some severe cases of obstructive symptoms, the child may be best served by use of a cecostomy and administration of antegrade enemas, or even by the creation of a proximal stoma. In many cases the cecostomy or stoma can ultimately be reversed when the child reaches adolescence.

### Fecal Soiling

There are three broad causes of soiling after a pull-through: abnormal sphincter function, abnormal sensation, or "pseudo-incontinence" related to abnormal rectal function or obstipation (Table 101-3). Abnormal sphincter function may be due to sphincter injury during the pull-through or to a previous myectomy or sphincterotomy and can usually be identified using anorectal manometry. Two forms of abnormal sensation exist. The first is lack of sensation of a full rectum, which is also identifiable using anorectal manometry by expanding a balloon in the rectum and asking the child to state when he can feel it. The other type of sensation that may be abnormal is the ability to detect the difference between gas and stool, which is dependent on intact transitional epithelium in the anal canal. This sensation may be impaired if the anastomosis is done too low and the transitional epithelium is damaged. This problem is usually evident on simple physical examination. Neither sphincter weakness nor abnormal sensation is amenable to a surgical solution, and most of these children are best managed using a bowel routine that may include a constipating diet, rectal enemas, or antegrade enemas through a cecostomy. Biofeedback training has been advocated, especially for those children with sphincter weakness. In some cases the child is best served by a colostomy.

**TABLE 101-3**
**Causes of Soiling Following Surgery for Hirschsprung Disease**

| |
|---|
| Abnormal sensation |
| 1. Inability to feel rectal distension |
| 2. Loss of transitional epithelium |
| Abnormal sphincter function |
| "Pseudo-incontinence" |
| 1. Associated with severe constipation |
| 2. Associated with hyperperistalsis of the pulled-through bowel |

If both the sphincter and sensation are intact, the most common cause of soiling after a pull-through is "pseudo-incontinence."[93] Some patients have severe obstipation with a massively distended rectum and develop overflow of liquid stool around the fecal mass. Others simply leak small amounts of stool through the day, creating "skid marks" in the underwear on a constant basis. Other children suffer from hyperperistalsis of the pulled-through bowel, which results in inability of the anal sphincter to achieve control despite normal sphincter function.[83]

Successful management depends on a clear understanding of the underlying basis for the soiling, which requires a clear history and physical examination, as well as investigations such as abdominal radiograph, barium enema, anorectal manometry, and in some cases colonic manometry. Children with severe constipation will benefit from laxative therapy. However, if the sphincter or sensation, or both, are inadequate, passive laxatives such as lactulose or PEG 3300 will make the problem worse and the child should instead be treated with stimulant laxatives such as senna or enemas. On the other hand, children with stool-holding behavior who have a normal sphincter and sensation will often experience exacerbation of the behavioral problem by rectal enemas or any other kind of anal manipulation. Children without constipation who have hyperperistalsis of the pulled-through bowel or abnormal sphincter function or sensation will benefit from a constipating diet and medications such as loperamide. Children with slow transit constipation or stool-holding behavior, on the other hand, will benefit from a high-fiber diet and passive laxative therapy. The treatment of soiling must be based on a clear understanding of the child's underlying problem.

### Enterocolitis

Enterocolitis may be present both before and after surgical correction of the disease, and it can be severe or life threatening. HAEC is more common in children diagnosed at a younger age,[94] those with longer segment disease, and those with trisomy 21. The clinical features of HAEC are generally agreed on and include fever, abdominal distention, diarrhea, elevated white blood cell count, and evidence of intestinal edema on abdominal radiograph. Because there is overlap between HAEC and other conditions such as obstructive symptoms and gastroenteritis, there has been confusion in the literature as to the exact definition and the true incidence of the condition. A recently developed HAEC score may be useful in the future in both the clinical setting and in research into this area (Table 101-4).[95]

The treatment of postoperative HAEC involves nasogastric drainage, intravenous fluids, broad-spectrum antibiotics, and decompression of the rectum and colon using rectal stimulation or irrigations. The risk of HAEC can be minimized by using preventive measures such as routine irrigations[96] or chronic administration of metronidazole or probiotic agents, particularly in those who are thought to be at higher risk for this complication on the basis of clinical or histologic grounds. Because enterocolitis is the most common cause of death in children with Hirschsprung disease and can occur postoperatively even in children who did not have it preoperatively, it is extremely important that the surgeon educate the family about the risk of this complication and urge early return to the hospital if the child should develop any concerning symptoms.[66]

### Long-Term Outcomes

Despite the relatively common occurrence of postoperative problems, most children with Hirschsprung disease overcome these issues and do well. Obstructive symptoms, soiling, and enterocolitis, in the absence of an ongoing source of obstruction, usually resolve after the first 5 years of life. Studies of teenagers and adults with Hirschsprung disease suggest that sexual function, social satisfaction, and quality of life all appear to be normal in the vast majority of patients once they reach their late teens.[69,97]

Several populations of children have less optimistic outcomes. Children with long-segment disease appear to have a higher risk of enterocolitis, incontinence, and dehydration than children with shorter-segment disease. Children with Hirschsprung disease associated with Down syndrome have a greater risk of enterocolitis and incontinence.[98,99] Finally, prognosis may be poor in children with other types of comorbidity such as those with congenital central hypoventilation syndrome, congenital heart disease, and syndromes that are associated with mental retardation or other forms of disability.

## "Variant" Hirschsprung Disease

Some children present with signs and symptoms suggestive of Hirschsprung disease but have ganglion cells present on rectal biopsy.[100] There is a significant amount of controversy surrounding the definitions and features of many of these conditions,[101] and in some cases their existence has even been called into question.

### INTESTINAL NEURONAL DYSPLASIA

This condition was first described by Meier-Ruge in 1971. Two types are usually described.[102] Type A is less common and is characterized by diminished or absent sympathetic innervation of the myenteric and submucosal plexuses, as well as hyperplasia of the myenteric plexus. Type B consists of dysplasia of the submucous plexus with thickened nerve fibers and giant ganglia, increased acetylcholinesterase staining, and identification of ectopic ganglion cells in the lamina propria. Type B can occur on its own or can be present in the nonaganglionic bowel in children who also have Hirschsprung disease. In addition, intestinal neuronal dysplasia may be either diffuse or focal. The reported incidence of IND varies significantly from one center to another, largely due to differences in definition of the condition.

Despite multiple publications on the topic of IND, this topic still stimulates controversy among pediatric surgeons and pediatric pathologists.[103] The diagnostic criteria have changed over time, and there is disagreement among pathologists about the diagnosis both in general terms and with respect to individual patients.[104] Sophisticated histologic techniques including special stains and the use of thick sections are often believed to be necessary for an accurate diagnosis.[105] In addition, there is some evidence that the histologic finding of IND may in some cases be secondary to chronic obstruction rather than the cause of it, and in many cases there may not be good correlation between the histologic finding of IND and the motility function of the bowel.[106]

### Hypoganglionosis

This is a rare form of dysganglionosis, which is characterized by sparse and small ganglia, usually in the distal bowel, often associated with abnormalities in acetylcholinesterase distribution.

The appropriate treatment is to resect the abnormal colon and perform a pull-through procedure, much as one would do for a child with Hirschsprung disease.[107] It is important to differentiate this condition from immature ganglia, which is seen in preterm children who present with a picture of distal intestinal obstruction resulting from underdeveloped colonic motility. The colonic motility is self-limited and should not be treated surgically.[108]

## Internal Sphincter Achalasia

Some children have normal ganglion cells on rectal biopsy but lack the RAIR on anorectal manometry. These children will sometimes develop obstructive symptoms or severe constipation that mimics Hirschsprung disease. Similarly to the situation mentioned previously in which obstructive symptoms continue after surgery for Hirschsprung disease, this condition has been termed *internal sphincter achalasia*.[109] The diagnosis is made using anorectal manometry and rectal biopsy. The initial treatment is a bowel management regimen, consisting of diet, laxatives, and enemas or irrigations. If this is unsuccessful, many surgeons have advocated the use of anal sphincter myectomy.[110,111] Because the constipation associated with this condition usually improves over the first 5 years of life, the same rationale has been used to advocate temporary or reversible sphincter-relaxing measures such as botulinum toxin,[112] nitroglycerine paste,[113] or topical nifedipine.

## Ultrashort-Segment Hirschsprung Disease

There is much confusion in the literature regarding this condition and how it is defined. Some authors use this term to describe children with normal ganglion cells on rectal biopsy, but with absence of the RAIR (which is synonymous with the definition of internal sphincter achalasia). We prefer to reserve it for children who have a documented aganglionic segment of less than 1 to 2 cm. In children with this condition, the findings of hypertrophic nerves and abnormal cholinesterase staining may be absent.[114] The treatment of ultrashort-segment Hirschsprung disease is controversial. Some authors advocate simple anal sphincter myectomy,[115,116] and some prefer excision of the aganglionic segment and pull-through reconstruction.

## Desmosis Coli

This is a condition described by Meier-Ruge characterized by total or focal lack of the connective tissue net of the circular and longitudinal muscles and the connective tissue layer of the myenteric plexus, without any abnormality of the enteric nervous system.[117] Patients with this condition present with chronic constipation. In one family Hirschsprung disease and desmosis coli coexisted,[118] although in most cases they are completely separate entities.

CHAPTER 102

# Intestinal Dysganglionosis and Other Disorders of Intestinal Motility

Prem Puri

The typical patient with Hirschsprung disease (HD) is a newborn presenting with delayed passage of meconium and abdominal distension or a young child presenting with severe chronic constipation. The diagnosis is confirmed by the histologic and histochemical evaluation of suction rectal biopsies, which demonstrate absence of ganglion cells in the submucosa and increased acetylcholinesterase (AChE) activity in the lamina propria. However, there are a number of patients who clinically resemble HD despite the presence of ganglion cells in rectal biopsy. Various terms have been used to describe these conditions: "chronic idiopathic intestinal pseudo-obstruction," "pseudo-Hirschsprung disease," "neonatal intestinal pseudo-obstruction," and "intestinal hypoperistalsis syndrome." There is a growing interest to further investigate these relatively rare functional bowel disorders because the diagnosis and management of these patients continues to be a challenge for clinicians. Over the past 3 decades our group has focused its research interest into delineating variant HD on the basis of specific histochemical, immunohistochemical, and electron microscopic studies.

Between 1981 and 2009, full-thickness bowel biopsy or resected surgical specimens from 178 patients (75 boys and 103 girls) with clinical symptoms suggesting HD were examined in our research laboratory. Their ages ranged from 1 day to 9 years. One hundred and three patients had onset of symptoms in the neonatal period. Ninety-one patients were from Ireland, and in 87 patients biopsy material was sent to our laboratory from other countries. Table 102-1 shows various functional bowel disorders diagnosed using different histologic techniques. The vast majority of variant HD cases include intestinal neuronal dysplasia, isolated hypoganglionosis, internal sphincter achalasia, and megacystis-microcolon-intestinal hypoperistalsis syndrome (MMIHS). Rarer motility disorders include immature ganglia, absence of argyrophil plexus, and smooth muscle disorders.

## Intestinal Neuronal Dysplasia

### HISTORY AND PATHOGENESIS

Intestinal neuronal dysplasia (IND) was first described by Meier-Ruge in 1971 as a malformation of enteric plexus.[1] The first association between IND and HD was reported by my colleagues and me in a 5-year-old Arab boy who had rectosigmoid aganglionosis and IND of descending and transverse colon.[2] In 1983 Fadda and colleagues[3] classified IND into two clinically and histologically distinguished subtypes. Type A, which occurs in less than 5% of cases, is characterized by congenital aplasia or hypoplasia of the sympathetic innervation and presents acutely in the neonatal period with episodes of intestinal obstruction, diarrhea, and bloody stools. Type B is clinically indistinguishable from HD, is characterized by a malformation of the parasympathetic submucous and myenteric plexuses, and accounts for more than 95% of cases of IND.[4,5] IND occurring in association with HD is of type B. Since its original description, little has been written about IND type A. IND has become synonymous with IND type B.

Many investigators have raised doubts about the existence of IND as a distinct histopathologic entity.[6,7] It has been suggested that the pathologic changes seen in IND may be part of normal development or may be a secondary phenomenon induced by congenital obstruction and inflammatory disease.[6,8] On the other hand, the literature contains several familial cases of IND suggesting that genetic factors may be involved in this condition. Martuccielo and colleagues[9] observed three families with multiple IND cases, and Moore and colleagues[10] and Kobayashi and colleagues[11] reported IND in monozygotic twins. The strongest evidence that IND is a real entity stems from the animal models. Hox11L1 is a homeobox gene involved in peripheral nervous system development and is reported to play a role in the proliferation or differentiation of neural crest cell lines. Two different Hox11L1 knockout mouse models have been generated. In both cases, homozygous mutant mice were viable but developed megacolon at the age of 3 to 5 weeks. Histologic and immunohistochemical analysis showed hyperplasia of myenteric ganglia, a phenotype similar to that observed in human IND type B.[12,13]

However, the mutation screening of this gene in 48 patients with IND did not show any sequence variant, either causative missense mutation or neutral substitution.[14]

In 2002 Von Boyen and colleagues[15] reported abnormalities of the enteric nervous system in heterozygous *EDNRB*-deficient rats resembling IND in humans. They showed that a heterozygous 301-base-pair deletion of the *EDNRB* gene led to abnormalities of the enteric nervous system. Malformations of the enteric nervous system observed in +/sl rats included hyperganglionosis, giant ganglia, and hypertrophied nerve fibers in the submucous plexus resembling the histopathologic features of IND type B in humans. These findings support the concept that IND may be linked to a genetic defect. However, no mutations of the *EDNRB* gene were detected in a small series of IND patients.[16]

## INCIDENCE

Intestinal neuronal dysplasia is the most commonly encountered variant of HD.[5] The incidence of isolated IND has varied from 0.3% to 40% of all suction rectal biopsies in different centers.[5,17] The incidence varies considerably among different countries. IND immediately proximal to a segment of aganglionosis is not uncommon and often presents as persistent obstructive symptoms after a pull-through operation for HD.[18] Some investigators have reported that 25% to 35% of patients with HD have associated IND.[3] However, others have rarely encountered IND in association with HD. The uncertainty regarding the incidence of IND has resulted from the considerable confusion regarding the essential diagnostic criteria. The diagnostic difficulty is centered on a wide variability encountered in the literature, not only in terms of age of the patient, the type of specimen examined, and the stains performed but also in the diagnostic criteria used.

## CLINICAL PRESENTATION

The characteristic clinical pattern of IND can be found in infants younger than 1 year old with a history of constipation and abdominal distention, thus mimicking HD. Montedonico and colleagues[19] classified IND according to the severity of histochemical changes in rectal biopsies. The criteria used for the diagnosis of severe IND included hyperplasia of submucous plexus, giant ganglia, ectopic ganglia, and increased acetylcholinesterase (AChE) activity in the lamina propria or around submucosal blood vessels. Any biopsy that showed giant ganglia of the submucous plexus with only one of the other criteria was considered mild. Montedonico and colleagues reported that the patients with severe IND begin their symptoms at an earlier age than those with mild IND (5.2 ± 112 months vs. 17.5 ± 23 months).

The incidence of associated anomalies in IND has been reported to be between 25% and 30%.[9,19] The common associated anomalies include anorectal malformations, intestinal malrotation, MMIHS, congenital short bowel, hypertrophic pyloric stenosis, necrotizing enterocolitis, and Down syndrome.

## DIAGNOSTIC CRITERIA

Since the first description in 1971, most controversy surrounding IND has been regarding which histologic diagnostic criteria are required for definitive diagnosis. The presently recognized diagnostic criteria, previously reported by our group and supported by others, are hyperganglionosis and giant ganglia, in addition to the presence of at least one of the following on suction rectal biopsy: ectopic ganglia in the lamina propria and increased AChE-positive nerve fibers around submucosal blood vessels and in the lamina propria.[4,5,17,20] However, Lumb and Moore[21] believe that giant ganglia can be a normal feature in normal bowel, having identified them in segments of adult bowel removed during surgery for colorectal carcinoma. To overcome the confusion in diagnostic criteria, Borchard and colleagues[4] produced guidelines for identifying IND in mucosal rectal biopsies. These comprised two obligatory criteria (hyperplasia of the submucous plexus and an increase in AChE-positive nerve fibers around submucosal blood vessels) and two additional criteria (neuronal heterotopia and increased AChE activity in the lamina propria). In our experience, hyperganglionosis and giant ganglia are the most important features for the diagnosis of IND in suction rectal biopsies, except in the newborn, when hyperganglionosis is a normal finding.[22]

## DIAGNOSIS

Suction rectal biopsy is the principal method for the diagnosis of disorders of intestinal innervation. It is necessary to include a sufficient amount of submucosa in the suction biopsy specimens. Traditionally, hematoxylin and eosin and AChE histochemical staining (Figs. 102-1 and 102-2) in suction rectal biopsy specimens have provided the basis for the diagnostic evaluation of IND. However, there has been discussion about whether AChE histochemistry is sufficient for the accurate diagnosis of IND and other additional staining techniques have been proposed. Meier-Ruge and colleagues suggest lactate dehydrogenase histochemistry.[5,23] In my laboratory, neuronal markers currently being used are reduced nicotinamide-adenine dinucleotide phosphate (NADPH) diaphorase histochemistry and immunohistochemistry using antibodies raised against neural cell adhesion molecule, protein gene product 9.5 (PGP9.5), S-100, peripherin, and synaptophysin.[5,17] Ganglion-cell counting can be difficult. Standard immunohistochemical techniques, using antibodies raised against neuron-specific enolase or PGP9.5, which are commonly used to display the enteric nervous system, are less suitable for cell counting because they stain not only the cell bodies but also the axonal processes. Cuprolinic blue staining has been proposed as the method that stains the largest number of ganglion cells.[5] Furthermore, this method stains only the cell bodies and not the axons, which makes it relatively easy to distinguish the individual cells.

Barium enema in IND does not show any specific radiologic features other than rectosigmoid distention. Similarly,

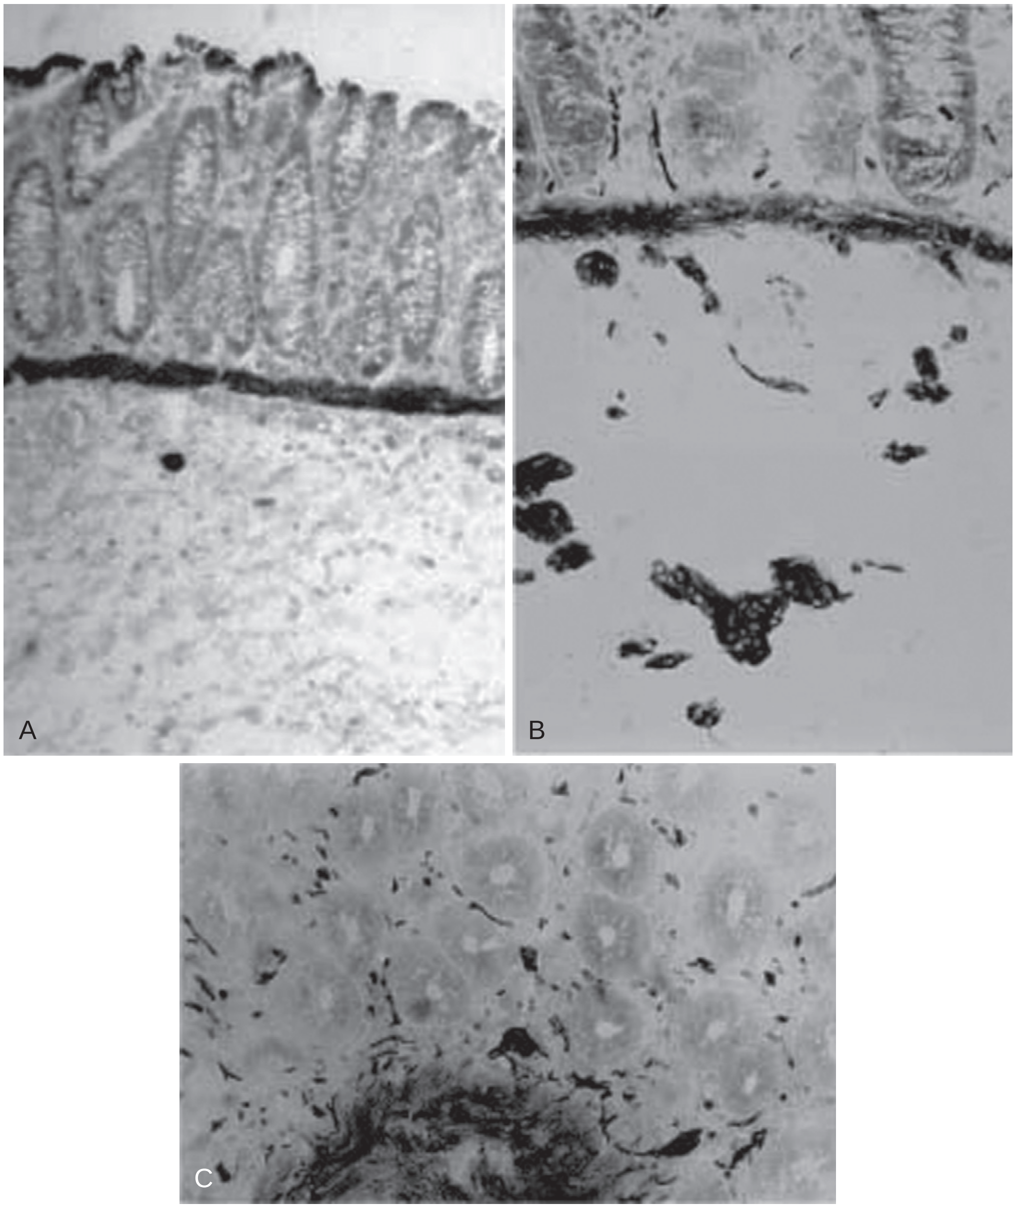

**FIGURE 102-1** Acetylcholinesterase staining of suction rectal biopsy. **A,** Normal biopsy showing a submucosal ganglion. **B,** Biopsy from a patient with intestinal neuronal dysplasia showing hyperganglionosis and giant ganglia. **C,** Ectopic ganglia in the lamina propria and increased AChE activity in the lamina propria in a biopsy specimen from a patient with intestinal neuronal dysplasia.

anorectal manometry may show the rectosphincteric reflex to be present, absent, or atypical.

### CORRELATION BETWEEN HISTOLOGIC FINDINGS AND CLINICAL SYMPTOMS

Several investigators have raised doubts about the existence of IND as a distinct histopathologic entity.[6,7] One reason for this has been the weak correlation found between the severity of clinical symptoms and the histologic findings. It has been suggested that the histologic findings of IND can be a part of normal development or secondary to prolonged constipation. Recently, Montedonico and colleagues[19] correlated specific clinical, radiologic, and manometric findings with the severity of histopathologic findings in 44 patients with IND treated at their institution over 20 years. They classified IND according to the severity of histochemical alteration into two groups: mild IND and severe IND. The criteria used for the diagnosis of severe IND included hyperplasia of the submucous plexus, giant ganglia with more than seven ganglion cells, increased AChE activity in the lamina propria or surrounding submucosal blood vessels, and heterotopic neuronal cells in the lamina propria. Any biopsy specimen that showed giant ganglia of the submucous plexus with only one of the other elements was considered mild IND. According to their results, the characteristic clinical pattern of severe IND can be found in infants younger than 1 year old with a history of constipation and abdominal distention, thus mimicking HD, with absence of internal sphincter relaxation in anorectal manometry but who have a normal barium enema. The median age at presentation of severe IND was 5 months, and similar results have been reported in other series.[3] These authors found a correlation between the histologic severity of IND and the clinical symptoms, suggesting that IND is a distinct entity. Although many cases of IND are clinically indistinguishable from HD, barium enema findings in IND are often equivocal or show slight to moderate rectosigmoid distention but lack the typical narrow segment of aganglionosis.

### MANAGEMENT

Current treatment of IND type B is in the first instance conservative, consisting of laxatives and enemas. In the majority of patients the clinical problem resolves or is manageable in this way because maturation of nerve cells is often observed in IND. If bowel symptoms persist after at least 6 months of treatment, internal sphincter myectomy should be considered. Resection and a pull-through operation are rarely indicated in IND. The indication for pull-through should not be determined on the basis of histopathologic findings alone; rather, the decision must be based on the individual patient's clinical symptoms.

### OUTCOME

Gillick and colleagues[24] reported results of treatment in 33 patients with IND observed for periods ranging from 1 to 8 years (mean 2.4 years). Twenty-one (64%) patients had a good response to conservative management and currently have normal bowel habits. Twelve patients (36%) underwent internal sphincter myectomy after failed conservative management. Seven of these patients now have normal bowel habits. Two patients were able to stay clean with regular enemas. Three patients who continued to have persistent constipation after myectomy and underwent resection of redundant and dilated sigmoid colon now had normal bowel habits.

## Isolated Hypoganglionosis

Isolated hypoganglionosis (IH) has been classified as a "hypogenetic type" of intestinal innervation disorders.[4] Clinically, IH resembles classical HD: Patients present with severe constipation or pseudo-obstruction. Due to the fact that IH is one of the rarest subtypes of intestinal innervation disorders, accounting for only 5% of all cases,[4] the number of reported cases in the literature is limited. Dingemann and Puri recently reviewed 92 patients with IH reported in the English literature between 1978 and 2008 and critically analyzed the current state of the epidemiologic, diagnostic, and therapeutic features of this rare neuronal intestinal disorder.[25]

### EPIDEMIOLOGY

In the reported review the overall male-to-female ratio of IH was 3:1. This is similar to the overall male-to-female ratio of HD, which is commonly considered to be 4:1. Although 29 (32%) patients were diagnosed in the newborn period, the median age at diagnosis of the reported patients with IH was 4.85 years. This is due to the fact that, in some patients, diagnosis was made as late as the age of 17 years. This differs significantly from HD. Although late diagnosis is also possible in HD, more than 90.6% of patients are diagnosed in the newborn period. This late diagnosis of IH might reflect the difficulties in diagnosing IH in rectal suction biopsies but also the rareness of the disease.

### CLINICAL PRESENTATION

Even though the median age at diagnosis is significantly higher in patients with IH than in those with HD, the symptoms of IH resemble classical aganglionosis. The symptoms reported in all IH included intractable constipation, ileus, and enterocolitis. As in HD, enterocolitis of the newborn remains the most serious complication of IH, as 6 of the 7 reported IH related deaths were neonates with enterocolitis.

### HISTOPATHOLOGIC APPROACH

The diagnosis of IH by means of rectal suction biopsy is difficult.[26] As recommended by the interdisciplinary consensus conference,[27] a full-thickness bowel is essential for the diagnosis of IH. Besides standard hematoxylin and eosin staining, histochemical evaluation of AChE was performed by 91% of the authors in the review by Dingemann and Puri to visualize the characteristic changes for IH such as low mucosal activity of AChE, deficiency of nerve cells in the myenteric plexuses, and hypertrophy of muscularis mucosae and circular muscle layers. Morphometric measurements in IH using AChE staining, as suggested by Meier-Ruge and colleagues,[23] represent one of the cornerstones of diagnostic criteria for the disease. It has been shown that plexus area and nerve cell number are dramatically decreased, and the distance between ganglia is almost doubled.

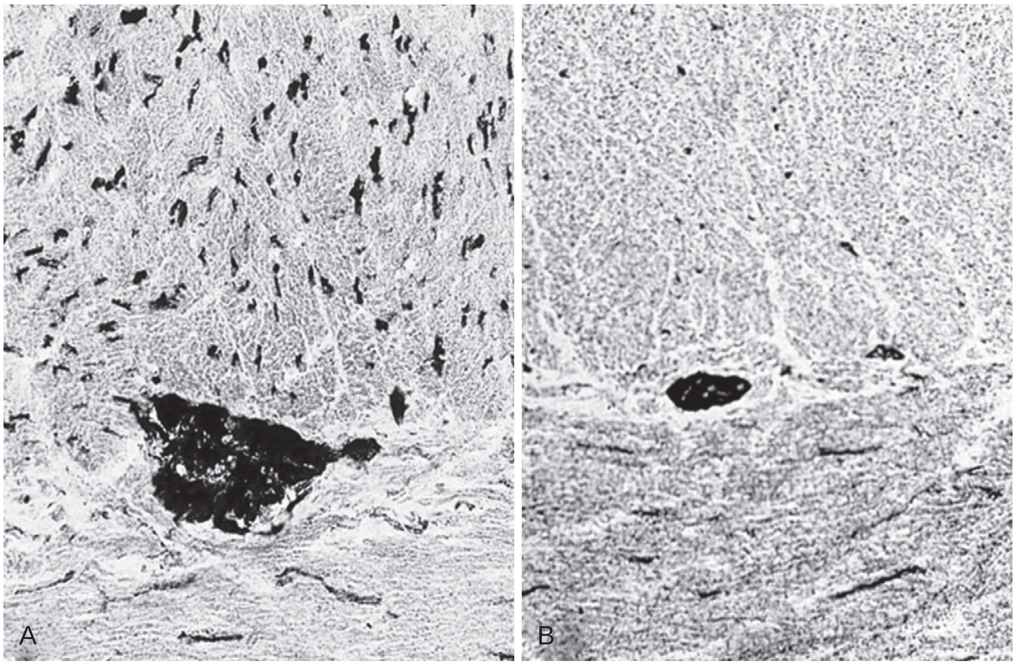

**FIGURE 102-3** Nicotinamide-adenine dinucleotide phosphate—diaphorase staining of the myenteric plexus. **A,** Normal colon showing normal myenteric ganglia and a large number of nitrergic nerve fibers in the circular and longitudinal muscle. **B,** Rectal biopsy in isolated hypoganglionosis patient showing small myenteric ganglia and reduced nitrergic innervation.

Several additional neuronal markers have been used to diagnose IH. Rolle and colleagues used NADPH diaphorase staining, which not only allows one to characterize the nitrergic innervation of the muscle but also differentiates mature fully developed ganglia from the immature ganglia in IH (Fig. 102-3).

## SURGICAL MANAGEMENT

According to literature, the treatment of hypoganglionosis is similar to HD involving resection of the affected segment and pull-through operation. In the review of 92 patients with IH reported by Dingemann and Puri, 54 patients received resection of affected bowel and pull-through procedures of different types; 11 underwent ileostomy, colostomy, or jejunostomy alone; and 2 underwent sphincter myectomy. In 25 patients, the operative treatment was not clearly stated. The treatment of choice remains resection of the affected segment. The exact method used must always be tailored to the extent of affected bowel, the localization of the disease, and presumably it will also depend on the surgeon's preference in this rare disease.

## OUTCOME AND COMPLICATIONS

The overall mortality of the patients included in this review was 8%. Six of the seven patients who died were newborns suffering from severe enterocolitis. The other patient died due to total parenteral nutrition–associated complications during follow-up. During a postoperative follow-up of 7 months to 12 years, typical complications reported were similar to those in HD. Enterocolitis, chronic constipation, overflow encopresis, and the need for redo pull-through for residual disease were reported.

# Internal Anal Sphincter Achalasia

The internal anal sphincter (IAS), a specialized smooth muscle continuation of the circular muscle layer of rectum, plays a significant role in the maintenance of anorectal continence and in the pathophysiology of incontinence and constipation.[28] The IAS relaxes in response to rectal distension, a phenomenon called the *rectosphincteric inhibitory reflex,* which is mediated by intramural nerves descending from the rectum to the IAS. The IAS receives adrenergic, cholinergic, and nonadrenergic noncholinergic (NANC) innervations.[29] Several investigators have reported that IAS relaxation is brought about by the activation of intramural NANC nerves. Nitric oxide (NO) is now recognized as a potent mediator of nonadrenergic noncholinergic inhibitory nerves, which regulate smooth muscle relaxation in the mammalian gastrointestinal tract including IAS.

Internal anal sphincter achalasia (IASA) is a clinical condition with presentation similar to HD but with the presence of ganglion cells on suction rectal biopsy. The diagnosis of IASA is made on anorectal manometry, which shows the absence of rectosphincteric reflex on rectal balloon inflation. Previously, IASA has been referred to as ultrashort segment HD. The ultrashort segment HD, which is a rare condition, is characterized by an aganglionic segment of 1 to 3 cm long and normal acetylcholinesterase (AChE) activity in the lamina propria and increased AChE activity in the muscularis mucosae.[30] Many patients who are considered to have ultrashort HD on abnormal anorectal manometric findings show presence of ganglion cells and normal acetylcholinesterase (AChE) activity in suction rectal biopsies. Many investigators have therefore suggested that the term IASA is more suitable

because it reflects more accurately failure of relaxation of the internal sphincter, which is the causative factor in this condition.[31]

## INCIDENCE

The exact incidence of isolated internal anal sphincter achalasia is not known. De Caluwe and colleagues[30] reported an incidence of 4.5% among 332 children who were investigated for severe chronic constipation.

## PATHOGENESIS

The exact pathogenesis and pathophysiology of IASA is not fully understood. Altered intramuscular innervation has been reported in IASA, and this is believed to be responsible for the motility dysfunction seen in these patients. Hirakawa and colleagues[32] reported absence of nitrergic innervation within the IAS muscle in patients with IASA and suggested that nitrergic nerve depletion may play an important role in the development of IASA (Fig. 102-4). Because nitrergic nerves regulate smooth muscle relaxation, their deficiency or absence in IASA may be responsible for the spasm or increased tone in the IAS in these patients.[33] Oue and Puri reported defective innervation of the neuromuscular junction (NMJ) of the IAS in patients with IASA. If the NMJ is abnormal, the neurotransmitter chemicals synthesizing neurons cannot be transmitted to muscle cells, thereby causing motility dysfunction.[29]

Altered distribution of c-kit positive interstitial cells of Cajal (ICCs) has been reported in the internal sphincter of patients with internal sphincter achalasia, which may further contribute to motility dysfunction in these patients. Piotrowska and colleagues reported deficiency or absence of ICCs in the IAS myectomy specimens obtained from patients with IASA at the time of internal sphincter myectomy.[34] The functions of ICCs include the generation of electrical pacemaker activity, generation of slow waves, and neurotransmission between the enteric nervous system and smooth muscle cells. It has been proposed that ICCs in certain regions of the gut may not act as pacemakers, but as stretch receptors.[32,35] The lack or deficient expression of NO and ICCs in the IASA may lead to defective generation of nitric oxide–mediated pacemaker activity causing motility dysfunction.

## DIAGNOSIS

Patients with IASA have clinical presentation similar to HD. The vast majority of patients present with severe constipation with or without soiling. About one third of the patients give history of abdominal distension. Laxatives usually fail to improve constipation in patients with IASA. Definite diagnosis of IASA is based on anorectal manometry, which shows absence of rectosphincteric reflex on rectal balloon inflation and the presence of marked rhythmic activity of the internal anal sphincter presence of ganglion cells and normal acetylcholinesterase activity in the suction rectal biopsy.

## TREATMENT

Posterior internal sphincter myectomy has been recommended as the treatment of choice for patients with internal sphincter achalasia. The myectomy is performed posteriorly starting at the level of the pectinate line, and a 5- to 10-mm wide strip of smooth muscle is resected extending proximally for varying lengths ranging from 15 to 50 mm.[30] De Caluwe and colleagues reported bowel function in 15 consecutive patients with IASA 2 to 6 years after posterior internal sphincter myectomy. At the time of follow-up, seven patients had regular bowel motions and were not on any laxatives. Six patients had normal bowel habits but were on small doses of laxatives. One patient was able to stay clean with a regular enema regimen. One patient required resection of dilated and redundant sigmoid colon and now has normal bowel habits with laxatives.

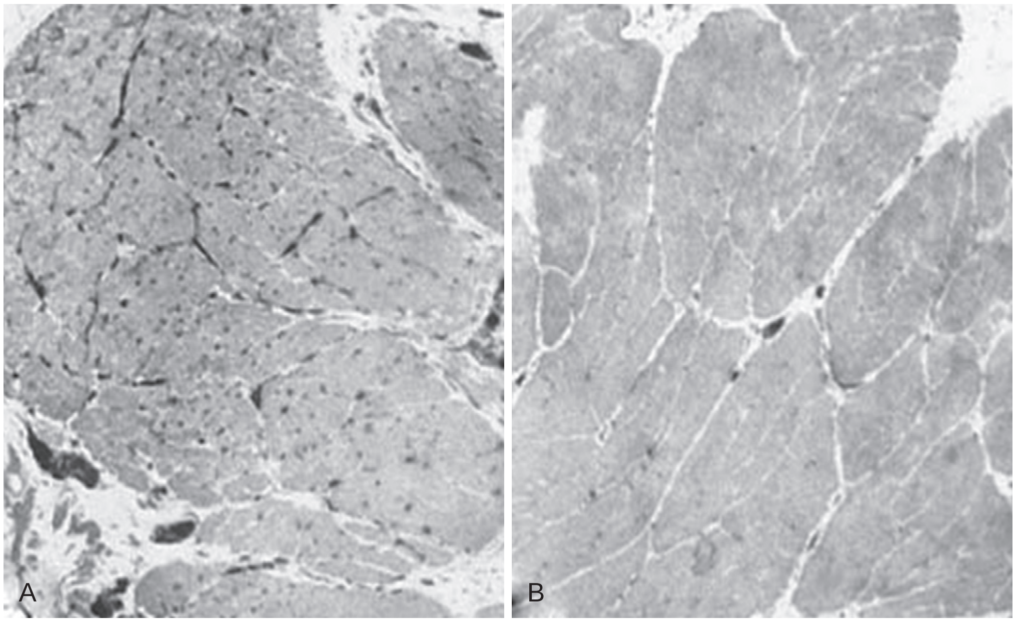

FIGURE 102-4 Nicotinamide-adenine dinucleotide phosphate–diaphorase staining of the internal sphincter. **A,** Normal specimen showing a large number of nitrergic nerve fibers. **B,** Internal sphincter achalasia patient showing nitrergic nerve depletion in the sphincter muscle.

Recently Heikkinen and colleagues[36] reported long-term follow-up in 10 IASA patients, 7 to 16 years after internal sphincter myectomy. Three of the ten patients in their study needed laxatives at the time of follow-up, and one patient had required resection of the dilated and redundant rectosigmoid 2½ years after myectomy. The remaining six patients had one to two bowel motions daily without the help of laxatives. Four of their patients suffered from soiling-related social problems.

Recently intrasphincteric injection of botulinum toxin has been used to treat patients with IASA. This is thought to work by interfering with the Ach release at the neuromuscular junction (NMJ) and thus inhibiting sympathetic stimulation to the IAS. Intrasphincteric injection is thought to produce a local and transient chemical denervation of the sphincter. This treatment modality has been found to be safe, but the effects are transient.[37] The IAS is injected in four quadrants, 25 i.u. per quadrant at the level of the dentate line. Irani and colleagues injected Botox in 24 patients with IASA and found that the duration of response following Botox injection was variable, ranging from 1 month to longer than 1 year. Foroutan and colleagues[38] compared efficacy of intrasphincteric Botox injection and internal sphincter myectomy in patients with IASA and found that Botox injection was as effective as myectomy. Further studies with longer follow-up are necessary to determine the effectiveness of this treatment modality in the management of internal sphincter achalasia.

## MEGACYSTIS-MICROCOLON-INTESTINAL HYPOPERISTALSIS SYNDROME

MMIHS is a rare congenital and generally fatal cause of functional intestinal obstruction in the newborn. This syndrome is characterized by abdominal distension caused by a distended nonobstructed urinary bladder, microcolon, and decreased or absent intestinal peristalsis.[27] Usually incomplete intestinal rotation and shortened small bowel are associated.

## PATHOGENESIS

MMIHS was first described in 1976 by Berdon and colleagues[27] and, to date, 182 cases have been reported in the literature.[39] The etiology of this syndrome remains unclear. Several hypotheses have been proposed to explain the pathogenesis of MMIHS: genetic, neurogenic, myogenic, and hormonal origin.

Histologic studies of the myenteric and submucosal plexuses of the bowel of MMIHS patients have found normal ganglion cells in the majority of the patients, decreased in some, hyperganglionosis, and giant ganglia in others.[39] Recently, Piotrowska and colleagues[34] reported absence of interstitial cells of Cajal (ICCs) in the bowel and urinary bladder of patients with MMIHS. ICCs are pacemaker cells that assist active propagation of electrical events and neurotransmission, and their absence may result in hypoperistalsis and voiding dysfunction in MMIHS. Puri and colleagues[40] showed, in 1983, vacuolar degenerative changes in the smooth muscle cells (SMCs) with abundant connective tissue between muscle cells in the bowel and bladder of patients with MMIHS and suggested that a degenerative disease of smooth muscle cells could be the cause of this syndrome. Several subsequent reports have confirmed evidence of intestinal myopathy in MMIHS. Other investigators have reported absence or marked reduction in α-smooth muscle actin and other contractile and cytoskeletal proteins in the smooth muscle layers of MMIHS bowel.[41] Contractile and cytoskeletal proteins are important structural and functional components of SMCs and play a vital role in the interaction of the filaments in smooth muscle contraction.

## PRENATAL DIAGNOSIS

Puri and Shinkai reviewed 182 cases of MMIHS reported in the literature.[39] In 54 cases ultrasound findings associated with MMIHS were described. The most frequent finding was enlarged bladder (88%), with hydronephrosis seen in 31 patients (57%). Normal amniotic fluid volume was revealed in 32 cases (59%), increased volume occurred in 18 (33%), and volume decreased in 4 (7%). In three cases (5%) abdominal distention caused by dilated stomach was detected. Three cases of oligohydramnios during the second and early third trimesters were reported, probably related to the functional bladder obstruction.

Serial obstetrical ultrasonography showed that the earliest finding in MMIHS is enlarged bladder, detectable from 16 weeks of gestational age. A later finding is hydronephrosis, caused by the functional obstruction of the bladder. Usually polyhydramnios develops late, appearing during the third trimester.

## CLINICAL PRESENTATION

Of the 182 cases reported in the literature, sex of the patient was mentioned in 149 patients. Ninety-eight were females and 43 were males. In four cases, pregnancy was terminated after ultrasonography detected MMIHS, which was confirmed at autopsy in all cases. The duration of pregnancy was reported in 98 cases. Fifty-eight patients (59%) were born at term, 25 (25.5%) at 36 to 39 weeks of gestation, 12 (12%) at 32 to 35 weeks, and 3 (3%) at 31 weeks and less. Dystocia delivery caused by abdominal distention was reported in eight cases. In four cases Caesarean section was required, and in four cases the bladder was so distended that the baby could only be delivered vaginally after removal of 250, 500, 650, 500 mL of urine, respectively, from fetal bladder by paracentesis. The mean birth weight was normal (3 kg) for gestational age.

The clinical symptoms of MMIHS are similar to other neonatal intestinal obstructions. Characterized by abdominal distention, bile-stained vomiting, and absent or decreased bowel sounds, abdominal distention was a constant and early finding. A consequence of the distended, nonobstructed urinary bladder was relieved by catheterization. Of 182 cases 61 had bilious vomiting, and failure to pass meconium was clearly reported in only 23 cases. The majority of patients were not able to void spontaneously.

In the review by Puri and Shinkai,[39] 19 sets of siblings affected with MMIHS were reported. Eighteen families had two affected siblings and one had three. Four sets of affected siblings occurred to consanguineous parents. In another case an affected child was born to a member of the family reported by Penman, and consanguinity was also present in these parents. In three further cases an elder sibling of the affected child died just after birth because of intestinal obstruction[30] or

multiple abnormalities; in another case a sibling of the patient was affected by prune-belly syndrome. The occurrence of MMIHS in 19 sets of affected siblings and consanguinity in four sets of parents suggest an autosomal recessive pattern of inheritance.

## RADIOLOGIC FINDINGS

In the vast majorities of the 182 cases, radiologic evaluation usually suggested the diagnosis of MMIHS. Plain abdominal films showed either dilated small bowel loops or a gasless abdomen with evident gastric bubble. An enlarged urinary bladder was present in all patients who had cystography or ultrasonography (Fig. 102-5). Intravenous urography or ultrasonography detected unilateral or bilateral hydronephrosis in 84 patients. Forty-four patients had an upper gastrointestinal series both before and after laparotomy: hypoperistalsis or aperistalsis in stomach, duodenum, and small bowel was a constantly detected symptom. In three cases reverse peristalsis from small bowel into the stomach was also observed. In two cases hypoperistalsis was associated with gastroesophageal reflux, and in one case the esophagus was aperistaltic. Barium enema showed microcolon in all 71 patients in whom this study was performed; in 39 cases malrotation was associated (see Fig. 102-5).

## SURGICAL OR AUTOPSY FINDINGS

Megacystis and microcolon were the two most frequent findings at surgery or autopsy and were present in all patients. In the review by Puri and Shinkai,[39] short-bowel syndrome was found in 37 cases, dilated proximal small bowel in 19, segmental stenosis of the small bowel in 3, duodenal web in 1, and Meckel diverticulum in 1. Malrotation was found in a total of 81 cases. Although surgical management was not mentioned in several reports, 93 patients (70%) underwent one or more surgical procedures. A variety of interventions were performed: gastrostomy, jejunostomy, ileostomy, cecostomy, segmental resection of jejunum and ileum, lysis of adhesions, and internal sphincter myectomy. Surgical manipulation of the gastrointestinal tract has generally been unsuccessful, and in most patients total parenteral nutrition was required. In 37 patients vesicostomy was performed to decompress the urinary tract and to preserve renal function.

## HISTOLOGIC FINDINGS

Histologic studies of the myenteric and submucous plexuses were reported in 93 out of 182 cases. In 72 the ganglion cells were normal in appearance and number, and in the remaining 21 cases the various neuronal abnormalities reported included hypoganglionosis, hyperganglionosis, and immature ganglia.

The majority of reports do not mention the histologic findings in the muscle layers of bowel and bladder wall. Nevertheless, some authors found significant abnormalities in SMCs. In nine cases thinning of the longitudinal muscle was found on light microscopy. Electron microscopy showed vacuolar degeneration in the center of the smooth muscle of the bowel in 11 cases and of the bladder in 8 cases. Connective tissue proliferation was found in the bowel in nine cases and in the bladder in eight cases. In three more cases the bladder showed elastosis. In two patients electron microscopy revealed vacuolar degeneration of smooth cells in the muscle layers of the bowel and the bladder in addition to neuronal abnormalities. Other investigators have reported absence or marked reduction in α-smooth muscle actin and other contractile and cytoskeletal proteins in the smooth muscle layers of MMIHS bowel.[41]

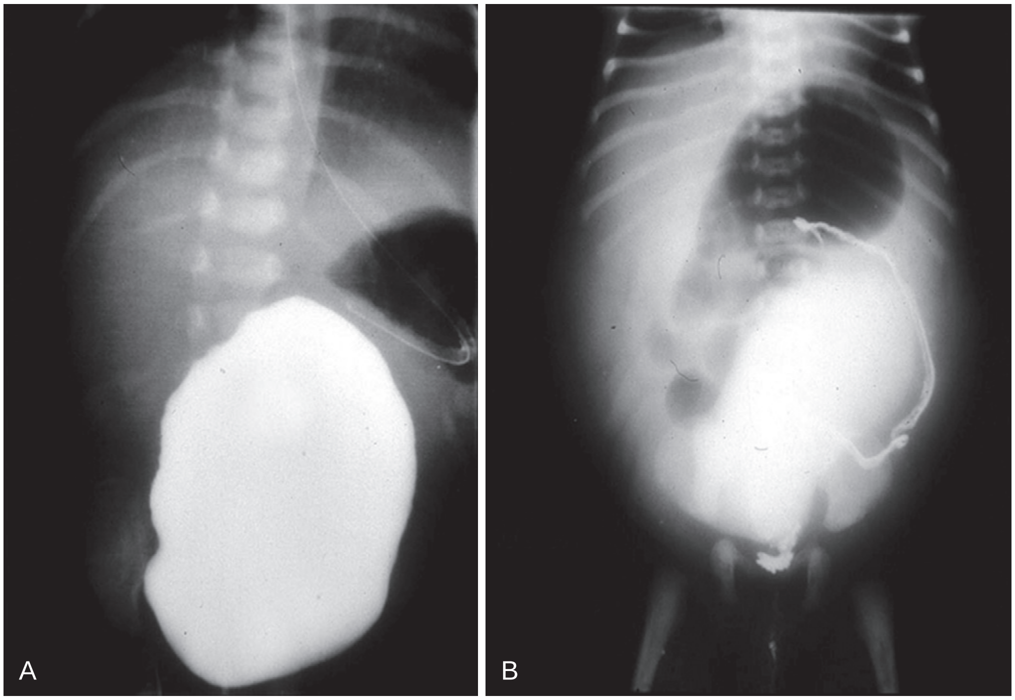

**FIGURE 102-5** Megacystis-microcolon-intestinal hypoperistalsis syndrome patient. **A,** Voiding cystourethrogram showing enlarged urinary bladder. **B,** Contrast enema showing microcolon.

## OUTCOME

The management of patients with MMIHS is frustrating. A number of prokinetic drugs and gastrointestinal hormones have been tried without success. Surgical manipulation of the gastrointestinal tract has generally been unsuccessful. The outcome of this condition is generally fatal: Only 23 of the 182 reported patients were alive, the oldest being 18 years old. Twenty-one of the 23 patients were being maintained by total or partial parenteral nutrition. The need for surgical intervention should be made carefully and individualized, in that most explorations have not been helpful and are probably not necessary.

# CHAPTER 103

# Anorectal Malformations

Marc A. Levitt and Alberto Peña

## History

Throughout history, surgeons have attempted to treat infants and children with anorectal malformations. The written accounts describe few patients, so it is likely that most patients died without treatment.[1–2] Successful maneuvers involved rupturing an obstructing membrane with a finger or the point of a knife[3] and evolved to making an incision to find the bowel in the perineum[4] or in the hollow of the sacrum. The first inguinal colostomy was performed in 1783,[5–6] but most infants died, and colostomy was thought of as a method of last resort. In 1835 Amussat mobilized the bowel through a perineal incision and sutured it to the skin, thus performing the first anoplasty[7] and avoiding the strictures that were common with earlier procedures. In the 1700s and 1800s, several authors suggested that the peritoneum be opened if the bowel was not encountered from below.[8–11] In the mid-1900s, single-stage abdominoperineal procedures became popular[12–13] and usually involved resection of the rectosigmoid. Shortly after these reports, Stephens described a procedure that emphasized passage of the rectum within the puborectalis sling.[14] Until the early 1980s, this approach with its modifications was used, but it involved blind dissection near the posterior urethra. A progressive increase in the length of the perineal incision to gain exposure eventually led to the posterior sagittal anorectoplasty,[15,16] which was rapidly adopted because it allowed full visualization of the sphincteric complex and more clearly showed the relationship of the rectum to the urologic system and the surrounding structures.

## Incidence

No specific cause of anorectal malformation has been described. The average incidence worldwide is 1 in 5000 live births,[17] although the condition is more common in certain geographic areas. Some families have a genetic predisposition, with anorectal malformations being diagnosed in succeeding generations.[18] In addition, imperforate anus occurs in association with several syndromes.[19–20] A slight male preponderance exists.

The most common defect in females is rectovestibular fistula, whereas the most common defect in males is rectourethral fistula. Cloacal malformations are more common than formerly thought, most likely because they were previously misdiagnosed as rectovaginal fistulas.[21] Imperforate anus without fistula occurs in 5% of patients, but interestingly, half of them also have Down syndrome. Patients with Down syndrome and anorectal malformations have this type of defect 95% of the time.[20]

## Classification

The classification system shown in Table 103-1 is anatomically descriptive with therapeutic and prognostic implications.

## Embryology

The cloaca in the embryo is a cavity into which opens the hindgut, tailgut, allantois, and later, the mesonephric ducts. The cloaca is first formed at around 21 days' gestation; it is U shaped, with the allantois lying anteriorly and the hindgut posteriorly. The septum in the middle grows downward and fuses with lateral folds (Rathke plicae) until it joins the cloacal membrane. In this 6-week process, a urogenital cavity anteriorly and an anorectal cavity posteriorly are created. Rapid growth of the genital tubercle changes the shape of the cloaca and the orientation of the cloacal membrane, which is displaced posteriorly. The cloacal membrane breaks down at 7 weeks' gestation, thereby creating two openings: the urogenital and anal openings.[22–24] The muscles that surround the rectum develop at the same time and are seen in the sixth and seventh weeks of gestation,[25] and by the ninth week, all relevant structures are in place. At this stage, differentiation into male or female external genitalia has not yet occurred.

## Associated Malformations

Most babies (50% to 60%) with anorectal malformations have one or more abnormalities that affect other systems.[26] Higher abnormalities are associated with more malformations. Many are incidental findings, but others, such as cardiovascular defects, may be life threatening.

## CARDIOVASCULAR ANOMALIES

Cardiovascular anomalies are present in approximately one third of patients,[27–29] but only 10% of these require treatment. The most common lesions are atrial septal defect and patent ductus arteriosus, followed by tetralogy of Fallot and ventricular septal defect. Transposition of the great vessels and hypoplastic left heart syndrome are rare.

## GASTROINTESTINAL ANOMALIES

A wide spectrum of associated gastrointestinal anomalies has been described. Tracheoesophageal abnormalities occur in about 10% of cases.[26–27] Duodenal obstruction caused by atresia or malrotation has been reported to have an incidence of 1% to 2%.[27,30] Hirschsprung disease has been found in only 3 patients in our series of 2100. Overdiagnosis of this association is probably due to the high incidence of constipation seen in patients with anorectal malformations.[31]

## SPINAL, SACRAL, AND VERTEBRAL ANOMALIES

Lumbosacral anomalies such as hemivertebrae, scoliosis, butterfly vertebrae, and hemisacrum are common. The most frequent spinal problem is tethered cord,[32–35] but spinal lipomas, syringomyelia, and myelomeningocele are also commonly seen. The more complex the anorectal anomaly is, the more likely is the presence of an associated spinal and vertebral anomaly. These problems are found by ultrasound or magnetic resonance imaging in one third to half of patients with anorectal malformations.[4,36–38] It is still unclear how many of these lesions are clinically significant and which lesions require prophylactic surgery.[35,39] A sacral defect, particularly hemisacrum, in association with imperforate anus and a presacral mass is known as the Currarino triad[40] and has a strong familial tendency.[41–43] The sacral ratio is a valuable prognostic tool (Fig. 103-1) because it quantifies the degree of sacral hypodevelopment. Patients with ratios less than 0.4 are universally incontinent. Ratios that approach 1.0 usually predict a good prognosis.

## GENITOURINARY ANOMALIES

Urologic abnormalities predominate.[44–45] Improved imaging has shown an increasing range of upper and lower urinary tract anomalies. The incidence ranges from one third to half of patients in several series and increases with increasing complexity of anorectal defect.[30,46] Vesicoureteric reflux is the most common anomaly found, and renal agenesis and dysplasia are the next most frequent findings.[46–47] Cryptorchidism is reported in up to 20% of males with imperforate anus,[47–48] and hypospadias occurs in approximately 5%.[48]

## GYNECOLOGIC ANOMALIES

Associated gynecologic anomalies have emerged as a significant concern in patients with anorectal malformations.[33,49–50] In the newborn period, hydrocolpos can lead to urinary obstruction or can cause pyocolpos. Müllerian anomalies may become manifest later when teenagers have obstruction of menstrual flow. Large intra-abdominal collections and peritonitis can develop, or patients may have amenorrhea because of absence of the müllerian structures. Asymmetric obstruction to menstrual flow can occur as a result of an anatomic abnormality at any level such as an obstruction of the tube, atresia of the cervix, or a blind hemivagina.[33,51] Uterine malformations (predominantly bicornuate uterus and uterus didelphys), vaginal abnormalities (particularly a vaginal septum), and associated vaginal atresia[33,49] occur in approximately one third of patients. A search for hydrocolpos needs to be performed in the newborn period. During definitive repair or at the time of colostomy closure, inspection of the intra-abdominal gynecologic structure is vital to prevent immediate and long-term sequelae. The full obstetric impact of these anomalies is not yet known.

# Anorectal Anatomy and Pathophysiology

Bowel control implies the ability to detect and retain flatus and stool until the appropriate time for evacuation. It is the result of a complex interplay among sphincter function, anorectal sensation, and colonic motility. All these factors are affected in children with anorectal malformations.[52]

## SPHINCTER MECHANISM

The muscle groups of the sphincter mechanism form a funnel-like structure in the pelvis. These muscles are innervated by the pudendal nerve, both motor to the voluntary muscles and sensory to the skin around the anus and anal canal. They are derived from the sacral plexus roots S2 to S4, as well as the autonomic nervous system via the nervi erigentes, from the same segments of the spinal cord. The exposure afforded by the posterior sagittal approach shows that the junction of the levator musculature with the fibers about the anal dimple is defined by a vertical group of striated muscle fibers called the *muscle complex.* Electrical stimulation of the upper end of the levator group pulls the rectum forward. Stimulation of the muscle complex (vertical fibers) elevates the anus, and stimulation of the parasagittal fibers closes the anus. Children with anorectal malformations have varying degrees of striated muscle development from almost normal-appearing muscle to virtually complete absence.

## SENSATION AND PROPRIOCEPTION

Under normal circumstances, the anal canal is an exquisitely sensitive area. It allows the individual to discriminate solids, liquids, and gas. The overwhelming majority of children with anorectal malformations is born without an anal canal and therefore lacks this anal canal sensation. There is, however, proprioception, which is described as a vague feeling that is perceived when the rectum is distended, simultaneous with stretching of the voluntary muscle that surrounds the rectum. Proprioception seems to be present to a variable degree in most patients. Thus these patients lose control when they suffer an episode of diarrhea but have the ability to be toilet-trained when they form solid stool and learn to perceive it.

## COLONIC AND RECTOSIGMOID MOTILITY

Normally it takes between 3 and 6 hours for the gastric contents to reach the small bowel. The intestinal contents reach the cecum in a liquid state. It then takes about 20 to 24 hours for that fecal material to reach the rectum and become formed stool with the absorption of water that occurs in the colon. The rectosigmoid acts as a reservoir and holds the fecal material for a variable period of time. The anal canal (below the pectinate line) is usually empty because of the action of the surrounding sphincteric mechanism. Occasionally, however, there are peristaltic waves in the colon that push the fecal material toward the anus. The rectal contents move distally and touch the exquisitely sensitive tissue of the anal canal, thereby providing valuable information related to the nature of the rectal contents (solid, liquid, or gas).

Depending on the surrounding social circumstances, the individual may contract the sphincteric mechanism to push stool or gas back into the rectum and then voluntarily relax at the appropriate time. Distention of the rectum produces a vague sensation of fullness or even colicky pain (proprioception) but does not provide specific information concerning the physical characteristic of the contents. Little is known about the mechanism that triggers peristalsis of the rectosigmoid to defecate, but it is clear that the degree of rectal fullness has an important role. Thus when the time comes, the rectosigmoid generates waves of peristalsis aimed at emptying the lumen. Individuals can restrain this process temporarily by using their voluntary sphincter. With a conscious decision made to allow the stool to come out, the sphincter is relaxed and the individual waits for the next peristaltic wave. Normal defecation allows massive emptying of the rectosigmoid, followed by another resting period of about 24 hours, during which the rectosigmoid again acts as a reservoir.

Children with anorectal malformations have a spectrum of rectosigmoid motility disorders. Those patients subjected to surgical techniques that preserve the rectosigmoid usually suffer from constipation. Constipation, one of the most important functional sequelae, is probably the result of hypomotility of the rectosigmoid, which is self-perpetuating and self-aggravating to the point that if left untreated, megasigmoid develops.[31] In extreme cases, fecal impaction and encopresis, or overflow pseudoincontinence, may develop. It seems that constipation is worse with lower defects. Knowing this and the fact that hypomotility can begin a vicious cycle leading to megasigmoid, it is vital that the clinician avoid the cycle of hypomotility, constipation, and megasigmoid, with aggressive patient follow-up plus dietary, mechanical, and pharmacologic treatment.

Children with anorectal malformations who have lost their rectosigmoid suffer from the opposite problem (i.e., tendency to have diarrhea). These children have no reservoir capacity, are highly sensitive to certain foods, and frequently suffer from incontinence.

# Clinical Findings and Initial Management

Figure 103-2 shows the decision-making algorithm for the initial management of male patients.

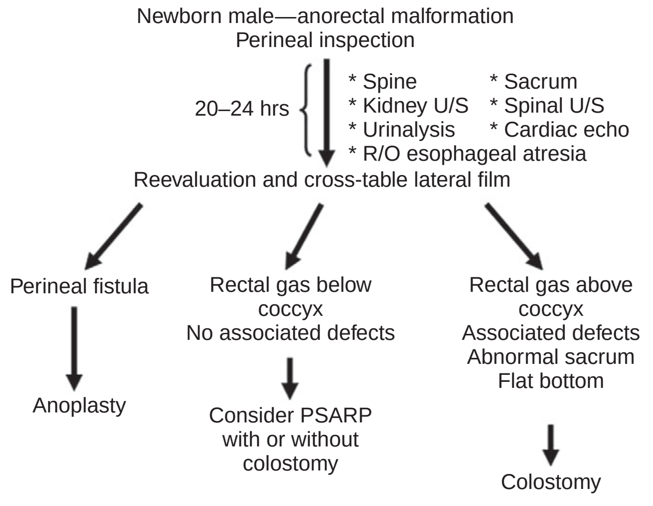

**FIGURE 103-2** Algorithm for the treatment of a male newborn with an anorectal malformation.

A clinician is called to see a newborn male with an anorectal malformation. First the clinician must perform a thorough perineal inspection, which usually provides the most important clues about the type of malformation that the patient has (Fig. 103-3). It is important to not make a decision about a colostomy or a primary operation before 20 to 24 hours of age. The reason for waiting is that significant intraluminal pressure is required for meconium to be forced through a fistula, which is the most valuable sign of the location of distal rectum in these babies. If meconium is visualized on the perineum, it is evidence of a rectoperineal fistula. If there is meconium in the urine, the diagnosis of a rectourinary fistula is obvious.

Radiologic evaluations do not show the real anatomy before 24 hours because the rectum is collapsed by the muscle tone of the sphincters that surround its lower part. Therefore radiologic evaluations done too early (before 24 hours) will likely reveal a "very high rectum" and therefore yield a false diagnosis.

During the first 24 hours, the newborn should receive intravenous fluids, antibiotics, and nasogastric decompression to prevent aspiration. The clinician should use these hours to evaluate for the presence of associated defects such as cardiac malformations, esophageal atresia, and urologic problems. An echocardiogram can be performed, and the baby should be checked for the presence of esophageal atresia. A plain radiograph of the lumbar spine and sacrum should be taken to evaluate for hemivertebrae and sacral anomalies. A spinal ultrasound helps screen for tethered cord and other spinal problems. Ultrasonography of the abdomen evaluates for the presence of hydronephrosis.

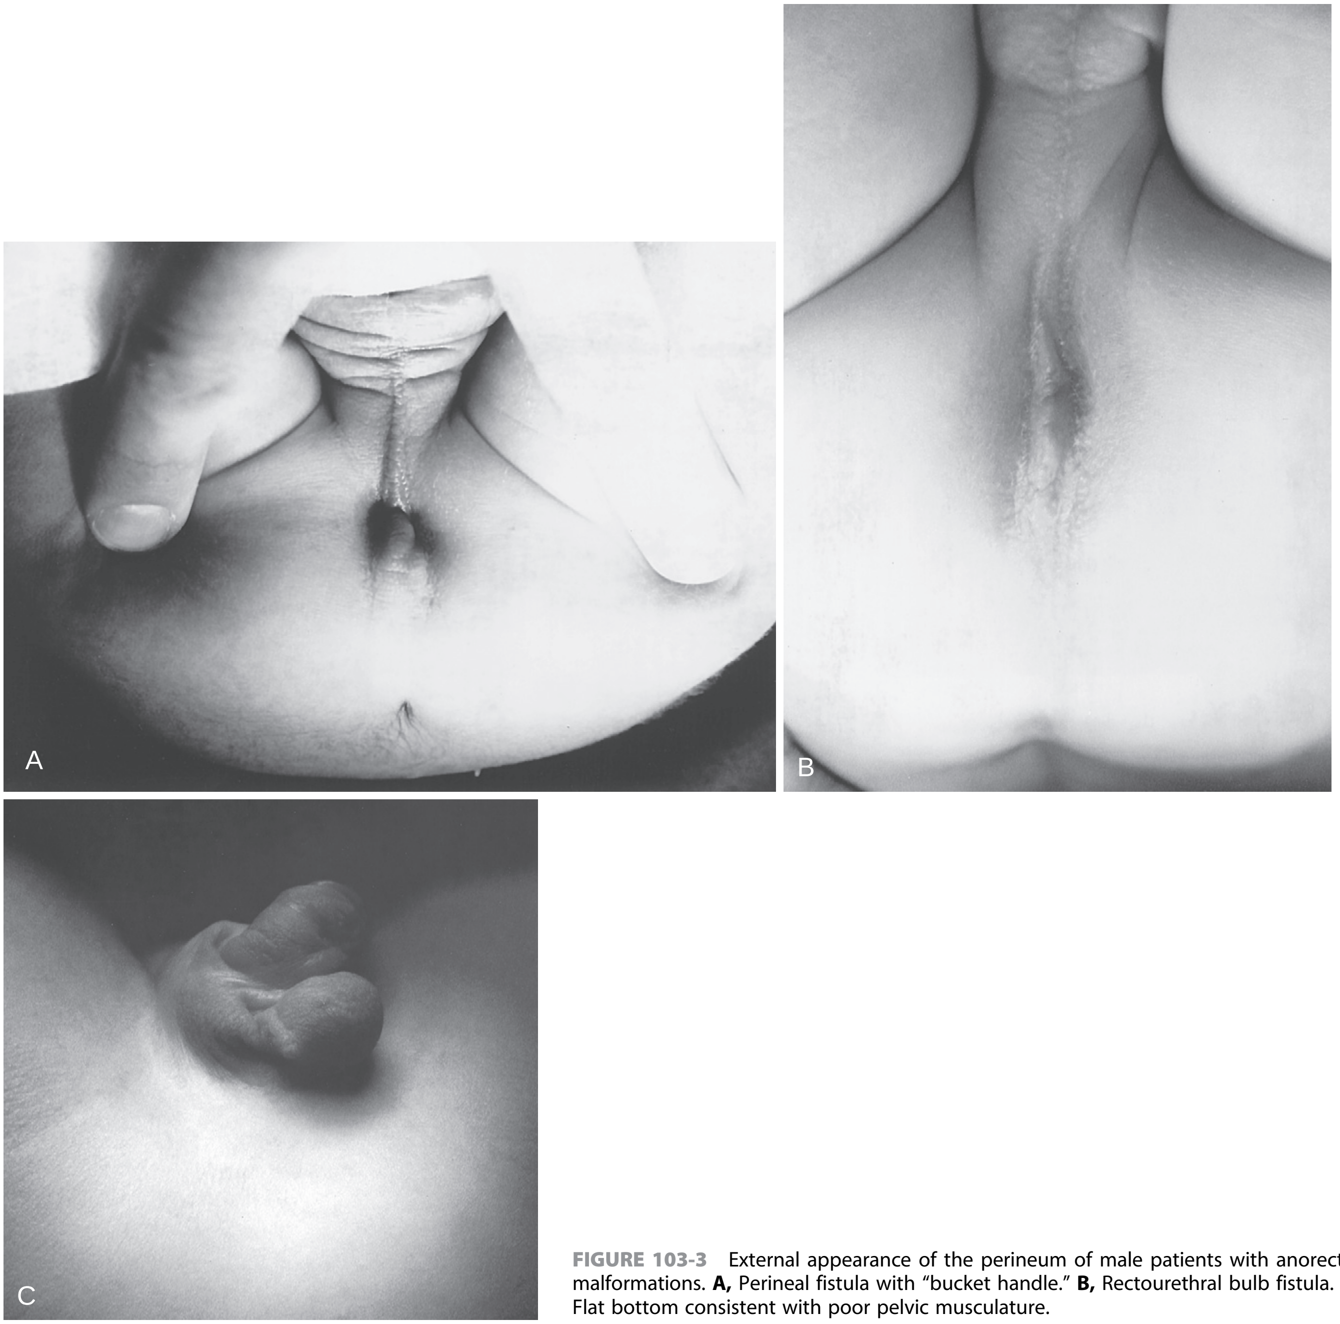

**FIGURE 103-3** External appearance of the perineum of male patients with anorectal malformations. **A,** Perineal fistula with "bucket handle." **B,** Rectourethral bulb fistula. **C,** Flat bottom consistent with poor pelvic musculature.

If the baby has signs of a perineal fistula, an anoplasty can be performed without a protective colostomy in the newborn period. If the baby is ill from associated problems, is very premature, or if the clinician chooses to wait until the baby is a little older, the fistula can be gently dilated. The repair in such cases should not be delayed more than several months. After 24 hours, if no meconium is seen on the perineum or in the urine, a cross-table lateral x-ray film with the baby in prone position should be obtained. If the gas in the rectum is located below the coccyx (Fig. 103-4) and the baby is in good condition with no significant associated defects, depending on the surgeon's experience, a posterior sagittal operation without a protective colostomy can be considered. A more conservative alternative would be to perform a colostomy, with the definitive repair planned for a second stage.

If rectal gas is seen above the coccyx (Fig. 103-5) or the patient has meconium in the urine, significant associated defects, and/or an abnormal sacrum or a flat bottom, a colostomy is recommended with postponement of the main repair for a subsequent operation. This can be performed 2 to 3 months later after a distal colostogram delineating the anatomy is performed, provided that the baby is gaining weight normally.

Performing the definitive repair at 2 to 3 months of age has important advantages for the patient including less time with an abdominal stoma, less size discrepancy between the proximal and distal bowel at the time of colostomy closure, easier anal dilation, and no recognizable psychologic sequelae from painful perineal maneuvers. In addition, at least theoretically, placing the rectum in the right location early in life may provide an advantage in terms of the potential for acquired local sensation.

The potential advantages of an early operation must be weighed against the possible disadvantages of an inexperienced surgeon unfamiliar with the minute anatomic structures of an infant's pelvis.

A trend to repair these defects without a protective colostomy[53–55] must be balanced against the concern that such a repair without a colostomy is done without precise anatomic information about the patient's specific type of anorectal defect. The most catastrophic complications seen in patients operated on without a colostomy occur in patients in whom the surgeon did not have a properly done preoperative distal colostogram. While looking for the rectum, the surgeon might inadvertently find and injure the urethra, an ectopic ureter, the bladder neck, the vas deferens, or the seminal vesicles.[56]

**FIGURE 103-4** Cross-table lateral radiograph, reachable rectum.

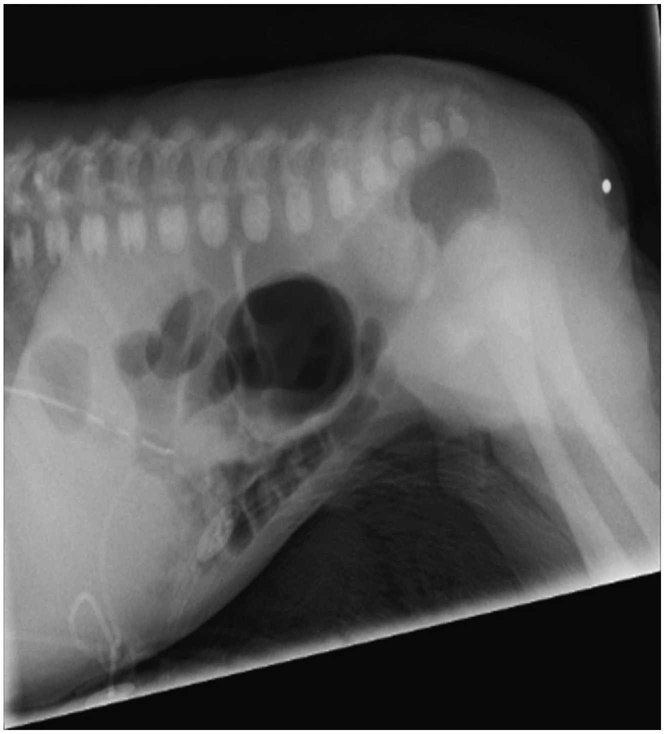

**FIGURE 103-5** Cross-table lateral radiograph, high rectum.

Figure 103-6 shows a decision-making algorithm for the initial management of female patients. As in males, the most important step in diagnosis and decision making is the perineal inspection (Fig. 103-7). The first 24 hours should also be used to rule out serious associated defects. Perineal inspection may disclose the presence of a solitary perineal orifice. This finding establishes the diagnosis of a cloaca. The clinician should know that such a patient has a high likelihood of a urologic defect. The presence of hydrocolpos should be ruled out by ultrasound.

Such a baby requires a colostomy. It is important to perform the colostomy proximally enough in the sigmoid to allow repair of the malformation without interference from the colostomy. In other words, the surgeon must leave enough redundant, distal rectosigmoid to allow for the pull-through and even a vaginal replacement if that is necessary. During opening of the colostomy, it is mandatory that the hydrocolpos be drained when present. If the hydrocolpos is not large enough to reach the abdominal wall above the bladder, to be sutured to the skin, it can be drained with a curled rubber tube. Because a significant number of these patients have two hemivaginas, the surgeon must be certain that the tube inserted into the hydrocolpos is draining both hemivaginas. Occasionally, one has to open a window in the vaginal septum to drain both with a single tube. At times the hydrocolpos is so large that it may even produce respiratory distress. Rarely, some patients with cloaca are unable to empty their bladder because the common channel is almost atretic. In such rare circumstances, the baby may require a vesicostomy. Endoscopy is best done outside of the

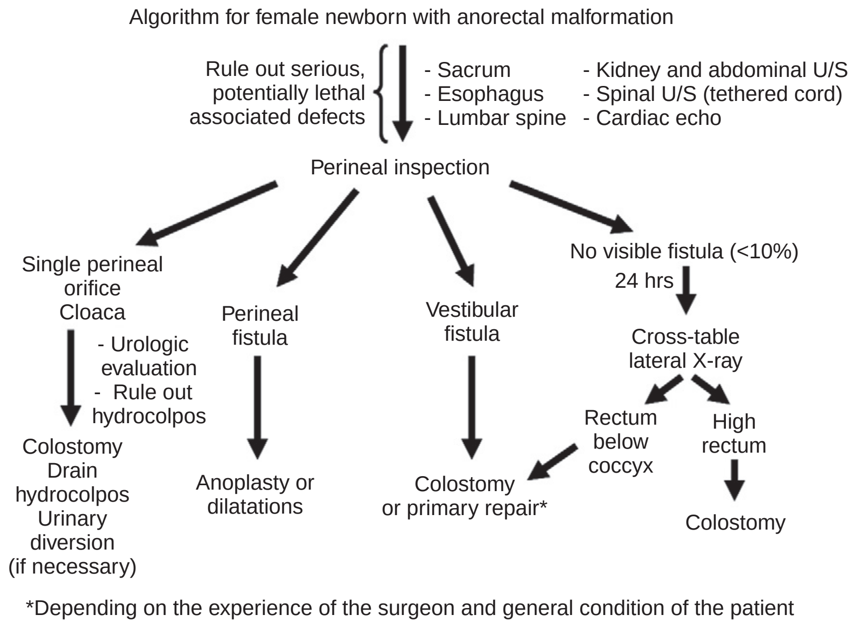

**FIGURE 103-6** Algorithm for the treatment of a female newborn with an anorectal malformation.

newborn period when the baby is larger and the perineum is less swollen, to determine the anatomy, particularly the length of the common channel, which helps with surgical planning.

Perineal inspection may show the presence of a perineal fistula, and an anoplasty can be performed without a colostomy.

The presence of a vestibular fistula is the most common finding in female patients. This malformation may be repaired during the neonatal period without a protective colostomy; however, these operations represent the most common source of complications in such patients. The decision to repair this malformation primarily or to open a colostomy should be based on the experience of the surgeon. Colostomy is still the most effective way to protect these patients from a perineal infection of dehiscence.

Occasionally (<10% of cases), no fistula is visible and there is no meconium apparent even after 24 hours of observation. This small group of patients requires a cross-table lateral radiograph. If the radiograph shows gas in the rectum located near the skin, the patient probably has imperforate anus with no fistula. If the patient is in good condition, one can perform a primary operation without a colostomy. Many of these patients with no fistula also have Down syndrome.[20]

When patients are subjected to primary repair of a vestibular fistula or perineal fistula later in life, strict preoperative bowel irrigation 24 hours in advance should be performed. Our routine is to keep such patients with nothing by mouth, on parenteral nutrition, for 7 days to decrease the passage of stool.

With emerging advancements in perinatology and prenatal ultrasound techniques, anorectal malformations are more commonly being suspected.[57] Sonographic findings such as a dilated rectum or hydrocolpos or demonstration of an associated anomaly such as an absent kidney, a vertebral anomaly such as a hemisacrum, or an orthopedic problem such as a missing radius can make the perinatologist suspicious that the fetus may in fact have an anorectal malformation. With improving technology, it is likely that this area of diagnosis and even fetal intervention for, perhaps, a massive hydrocolpos will continue to advance.[58–59]

Abdominal ultrasonography to evaluate for associated urologic problems and echocardiography should be performed during the initial newborn evaluation. It is also convenient at this time to perform a spinal ultrasound to evaluate for associated spinal anomalies such as myelomeningocele or a tethered cord. Such an ultrasound is an excellent screening examination for these anomalies, but it must be performed before sacral ossification, which occurs at 3 months of age. If screening is done later, magnetic resonance imaging is required. From a plain anteroposterior and lateral radiograph of the sacrum, a sacral ratio can be calculated (see Fig. 103-1), which can be helpful in predicting the prognosis for fecal continence with low ratios predictive of poor potential for bowel control and high ratios (>.7) predictive of good potential. If a hemisacrum is identified, a presacral mass may be present and must be looked for by magnetic resonance imaging. During the assessment conducted before performance of either anoplasty or colostomy, the baby is maintained on intravenous fluids, with a nasogastric tube in place to decompress the stomach. No oral feeding is allowed. Antibiotics are given at the time of surgery.

## LIMITED POSTERIOR SAGITTAL ANORECTOPLASTY

When a low anomaly (perineal fistula) is diagnosed, the fistulous track to the perineum is always located anterior to the sphincter mechanism. A limited posterior sagittal anorectoplasty can be performed in the newborn period. In newborns who cannot undergo such a procedure because they are ill, have significant associated anomalies, or the surgeon prefers to wait, dilatation of the fistulous tract is appropriate with a plan for repair in the future preferably within 2 to 3 months. Occasionally, such babies escape detection in the newborn period and delayed primary repair is then appropriate. It is advantageous to perform this operation in the first 48 hours of life because the meconium is sterile. When such an operation is delayed and performed at several months of life,

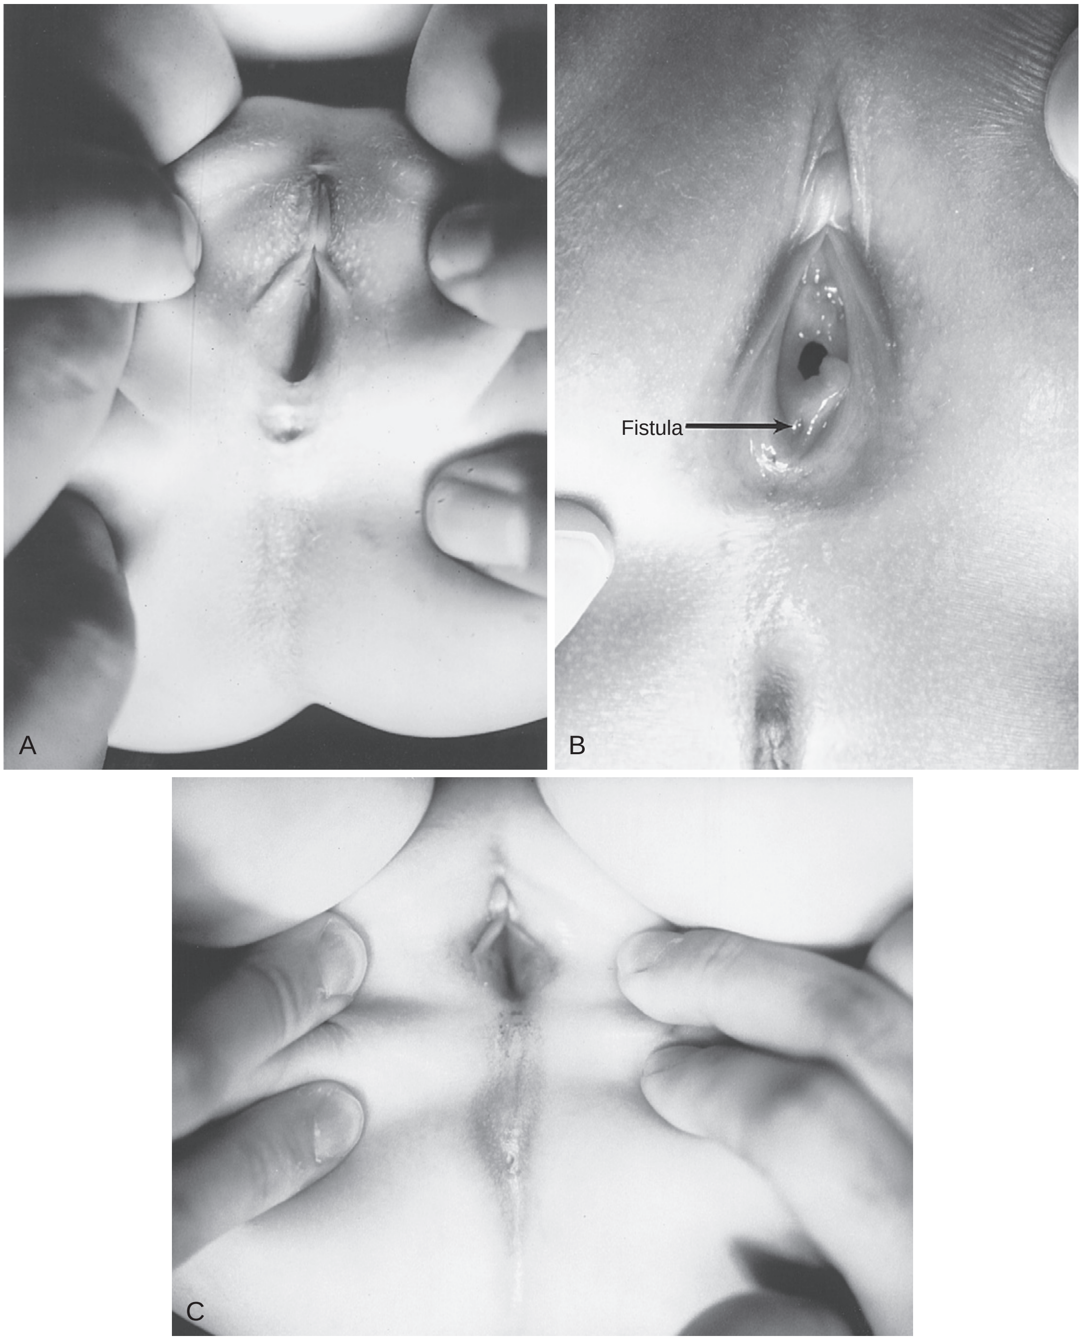

FIGURE 103-7 External appearance of the perineum of female patients with anorectal malformations. **A,** Perineal fistula. **B,** Vestibular fistula. **C,** Cloaca.

a complete bowel preparation including a postoperative period of parenteral nutrition without oral intake is recommended to reduce the risk of perineal infection.

For a limited posterior sagittal anorectoplasty, the baby is placed prone. In males, a urinary catheter is inserted. The distal end of the rectum is intimately attached to the posterior urethra, and urethral injury must be avoided. Multiple 6-0 silk sutures are placed at the mucocutaneous junction around the fistula orifice. An incision divides the posterior sphincter in half and is continued circumferentially around the fistula. While traction is maintained on the bowel, a circumferential dissection is performed to mobilize the bowel and reposition it within the limits of the sphincter. Mucosa is sutured to skin with fine, absorbable sutures under slight tension. The perineal body is reconstructed.

## COLOSTOMY

Colostomy is usually performed as a first stage in a newborn with a high anomaly. A descending colostomy is a relatively trouble-free stoma (Fig. 103-8). It also leaves the sigmoid colon entirely free for reconstruction. It is fashioned by making an oblique left lower quadrant incision. The stoma is divided, with the bowel openings placed at opposite ends of the

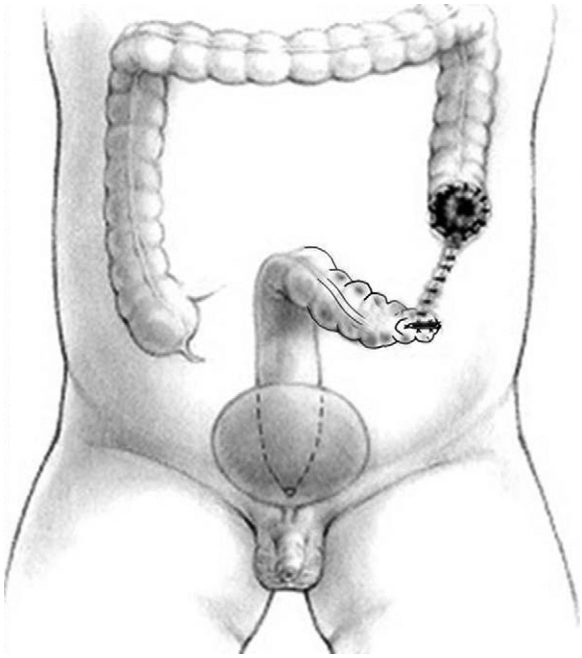

FIGURE 103-8 Descending colostomy.

FIGURE 103-9 Distal colostogram showing a rectourethral bulbar fistula.

FIGURE 103-10 Distal colostogram showing a rectobladder neck fistula.

wound. The proximal part of the stoma is at the start of the sigmoid colon, just after the colon comes off its left retroperitoneal attachment. The distal part of the stoma, in the upper sigmoid, is made intentionally small in an attempt to prevent prolapse. The distal segment should be copiously irrigated to remove all meconium. It should be placed far enough away from the functional stoma so that the stoma bag does not cover it. This way no spillage downstream can occur, and the stoma bag stays on more easily.

A colostomy can result in significant morbidity, so it is vital to construct it meticulously.[60] Transverse colostomies often lead to prolapse, make cleaning the distal segment difficult, and make delineation of the downstream rectourinary anatomy during the distal colostogram challenging.[61] Such colostomies also lead to megarectosigmoid and a left microcolon in the defunctionalized segment, particularly when the colostomy is left in place for many months. A colostomy that is placed too low in the sigmoid can limit the pull-through. A loop colostomy leads to distal contamination of the urinary stream if there is a fistula and to a dilated megarectosigmoid from stool spillage.

### MANAGEMENT AFTER COLOSTOMY

Before proceeding with definitive reconstruction, the anatomy of the anorectal malformation is delineated by high-pressure distal colostography (Figs. 103-9 and 103-10).[61] Patience is required when performing this study as the rectum is slowly distended with contrast. The muscles of the pelvis are normally contracted, and thus the distal rectum is compressed and can at first appear flat at the pubococcygeal line. With gentle pressure, this flat line begins to bulge, and it is at this point that the examiner can visualize the true extent of the rectum and the presence of a rectourinary fistula.

## Anorectal Reconstruction

### BASIC PRINCIPLES

All defects can be repaired using a posterior sagittal approach. Approximately 10% of male patients (those with a rectum-bladder neck fistula) and about 40% of female patients with a cloaca may, in addition, require an abdominal approach for mobilization of a high rectum or vagina. The patient is placed in a prone position with the pelvis elevated. A Foley catheter is inserted into the bladder before the patient is

positioned. A coudé catheter is ideal. The catheter sometimes goes into the rectum through the fistula rather than into the bladder. To avoid misplacement, the surgeon can direct the catheter with a lacrimal probe inserted in the tip of the Foley catheter to function as a guide. Occasionally, the catheter must be positioned intraoperatively once the fistula is exposed. Special care must be taken to cushion all the pressure areas of the baby's body (Fig. 103-11). Two small bolsters are used in front of each deltopectoral groove to avoid hyperextension of the neck and shoulders. Electrical stimulation of the perineum allows evaluation of the strength of the sphincter contraction. A midline incision is made, and the sphincteric mechanism is divided exactly in the midline, with equal amounts of muscle on each side. The rationale for this approach is based on the fact that important nerves or vessels do not cross the midline. Sharp Weitlaner retractors are used to achieve good exposure. The retractors should be placed superficially to avoid pressure damage to the muscles.

## POSTERIOR SAGITTAL ANORECTOPLASTY FOR ANOMALIES IN MALES

### Rectourethral Fistula (Bulbar and Prostatic)

The size of the incision must be adapted to the specific anatomy of the patient (Fig. 103-12). No deleterious effects are caused by extending the incision, provided that it remains in the midline. The incision usually extends from the lower portion of the sacrum through the center of the anal dimple and sometimes extends to the perineal body. Below the skin and running parallel to the midline are the parasagittal muscle fibers. Medial to these muscle structures and located within the limits of the anal dimple are other muscle structures that run perpendicular. These structures extend from the skin to the levator muscle and are called the *muscle complex*. Deeper to the parasagittal fibers, the ischiorectal fat becomes evident. Below this is the levator, which is also divided in the midline. The crossing of the muscle complex fibers with the parasagittal muscle structures defines the anterior and posterior limits of the new anus. These limits can be determined most clearly with use of an electrical stimulator.

**FIGURE 103-11** Patient in prone position with proper padding.

In boys with a rectourethral bulbar fistula, on opening the incision the bowel is evident. In boys with a rectoprostatic fistula, the rectum is much smaller and located much higher in the incision just under the coccyx. The distal colostogram provides information that is valuable at this point for determining where the rectum can be found (see Fig. 103-9). In the case of a rectobladder neck fistula, the rectum is not visible through a posterior sagittal approach and should not be searched for (see Fig. 103-10).

Temporary silk sutures are placed in the posterior rectal wall for traction, and the rectum is opened exactly in the midline. The incision in the rectal wall is extended distally. As the rectum is being opened, more sutures are placed to hold the edges of the rectal wall and improve exposure of the rectal lumen. The incision must be extended distally until the fistula site is found (Fig. 103-13).

Because there is no distinct plane of separation between the rectum and urethra, the surgeon must be extremely careful while separating the rectum from the urinary tract. Multiple 6-0 silk sutures are placed above the fistula site in a semicircular fashion (Fig. 103-14). These sutures allow the surgeon to exert uniform traction on the rectum while dissecting and separating it from the urethra. Dissection of the lateral aspects of the rectum first helps to delineate the anterior plane. The dissection then proceeds in the submucosal plane, anteriorly, for approximately 5 to 7 mm until the rectum and urethra gradually separate and become independent. The surgeon must be careful in this anterior plane because this is where the vas deferens and seminal vesicles can be injured if the dissection is too deep. A single suture is placed at the fistula site so that it can easily be identified and closed later. Once the rectum is fully separated from the urinary tract, circumferential perirectal dissection is performed to gain enough rectal length to reach the perineum. To achieve this, the fascia that surrounds the rectum must be divided including blood vessels and nerves attached to the rectum. This is a key plane to identity. While the surgeon is applying traction to the rectum, the dissection continues in a circumferential manner. The vessels that hold the rectum are coagulated and divided until enough rectal length has been achieved. The rectum has an excellent intramural blood supply; even with a high prostatic fistula, sufficient length can be obtained without making the rectum ischemic. When the rectal wall is injured, however, this blood supply is damaged and ischemia may occur. Therefore every effort must be made to perform this dissection as close as possible to the rectal wall but without interfering with the intramural blood supply. Once enough length has been achieved to perform a tension-free bowel-to-skin anastomosis, the size of the rectum must be evaluated and compared with the available space. If necessary, the rectum can be tapered by removing part of its posterior wall and reconstructed by closing the posterior incision with two layers of long-term absorbable interrupted sutures. The anterior rectal wall that used to be attached to the posterior urethra may require a few stitches to reinforce the wall by bringing the seromuscular layer together. The urethral fistula is closed with interrupted absorbable suture.

The perineal body is reconstructed by bringing together the anterior limits of the external sphincter, which was previously marked with temporary silk sutures. The levator muscle is sutured behind the rectum (see Figs. 103-12 and 103-15), and the posterior edge of the muscle complex is sutured together

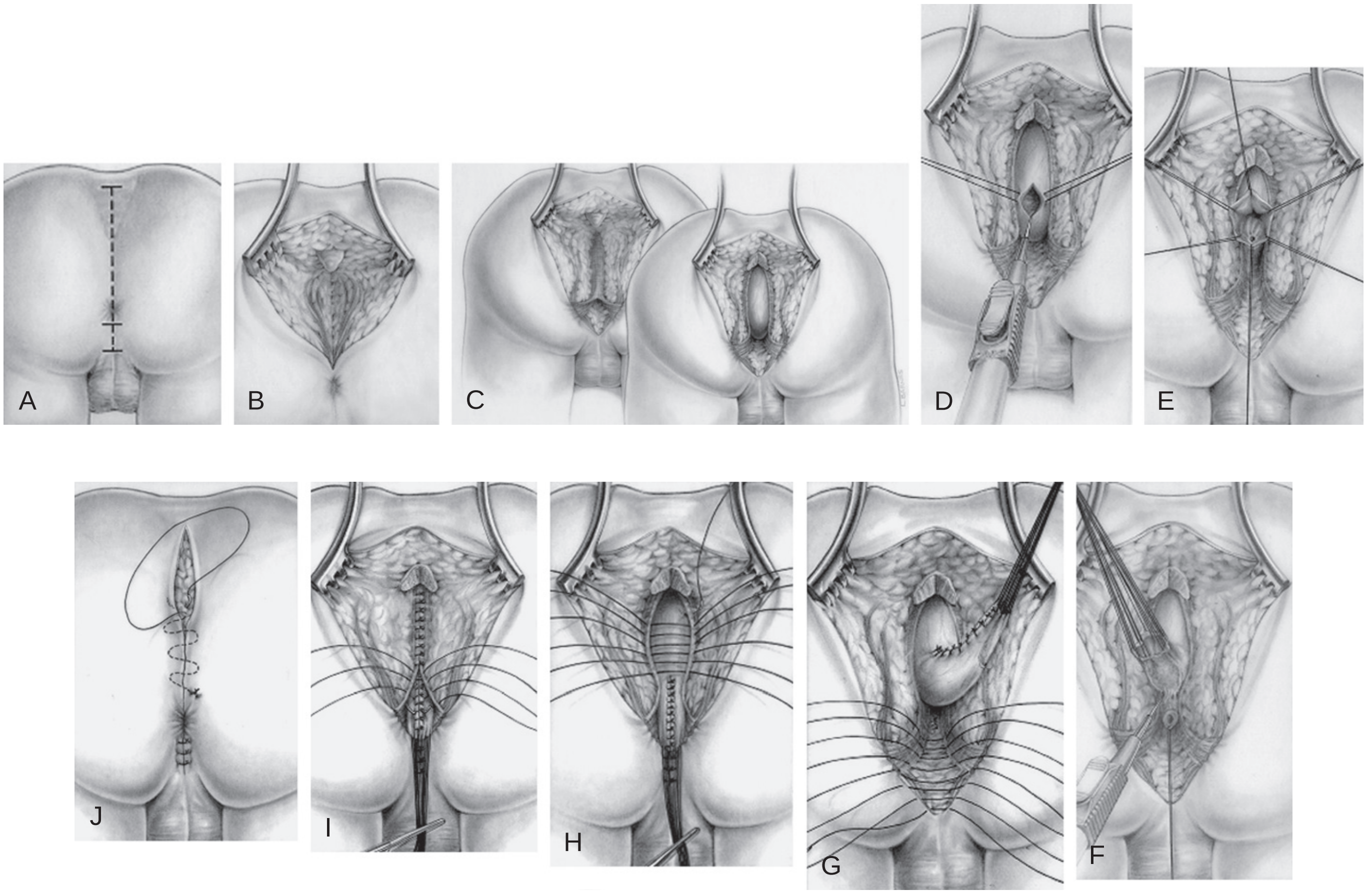

**FIGURE 103-12** Essential steps for posterior sagittal anorectoplasty in male patients. **A,** Planned posterior sagittal incision. **B,** Posterior sagittal approach with the parasagittal fibers and ischiorectal fat split in the midline. **C,** Posterior rectal wall exposed. **D,** Posterior rectal wall opened in the midline. **E,** Posterior rectal wall opened going anteriorly until the rectourethral fistula is identified. **F,** Separation of the rectum from the posterior urethra with dissection above the fistula. **G,** The rectum fully mobilized and in this case tapered. Sutures are placed anteriorly to close the perineal body. **H,** The rectum pulled through and placed within the limits of the sphincter mechanism. **I,** Closure of the levator and tacking of the posterior edge of muscle complex to the posterior rectal wall. **J,** Closure of the posterior sagittal incision and completed anoplasty.

in the midline while taking, with the same stitches, part of the posterior rectal wall to anchor the rectum. This helps to prevent prolapse (Fig. 103-16). The ischiorectal fossa and the subcutaneous tissue are then reapproximated, and the skin is closed. The anoplasty is performed by placing the rectum within the limits of the sphincter with the use of interrupted long-term absorbable sutures (Fig. 103-17).

### Rectobladder Neck Fistula

In patients with a rectobladder neck fistula, an abdominal approach via either laparoscopy or laparotomy, in addition to the posterior sagittal approach, is necessary to mobilize the rectum. The fistula is separated from the back of the bladder neck. Laparoscopy is well suited for this stage. The challenge thereafter is often mobilization of adequate rectal length to reach the perineum. Such mobilization, plus the bulbous distension of the rectum, makes the laparoscopic stage technically demanding. In general, for higher lesions such as a rectoprostatic urethral fistula, a laparoscopic approach has utility[62,63] because sufficient mobilization is often a challenge through the posterior sagittal incision. Lower lesions, however, such as a rectourethral bulbar fistula or the no-fistula defect, can be more safely repaired with a posterior sagittal approach without laparoscopic assistance because the rectum lies below the peritoneal reflection.

Before beginning operation on higher lesions, the entire body surface from chest to toes is prepared so that the surgeon can work simultaneously in the abdomen and the perineum. The abdomen is entered via either laparoscopy or laparotomy (Fig. 103-18). The sigmoid is identified and dissected down to the bladder neck. The distal rectum is usually located approximately 2 cm below the peritoneal floor and therefore requires minimal pelvic dissection. It is important to remember that the vas deferens and ureters run close to the rectum; thus the dissection must be carried out as close as possible to the rectal wall. The rectum narrows rapidly and opens into the bladder neck in a T-shaped manner. It is relatively easy to separate the rectum from the urinary tract because the fistula forms less of a common wall the higher the malformation. The rectum is divided at its most distal part, and the fistula is closed with absorbable suture.

In this type of high defect, mobilization of the rectum is sometimes limited by branches of the inferior mesenteric vessels. To gain length surgeons have traditionally been advised to divide the inferior mesenteric vessels at their origin from the aorta. This technique is contraindicated here because this is often the only blood supply of the rectosigmoid—the

FIGURE 103-13 Operative view, posterior sagittal approach. The rectourethral fistula is seen with a metallic probe in it.

FIGURE 103-15 Levator muscle sutured behind the rectum.

FIGURE 103-16 Sutures on the posterior edge of the muscle complex anchor the rectum.

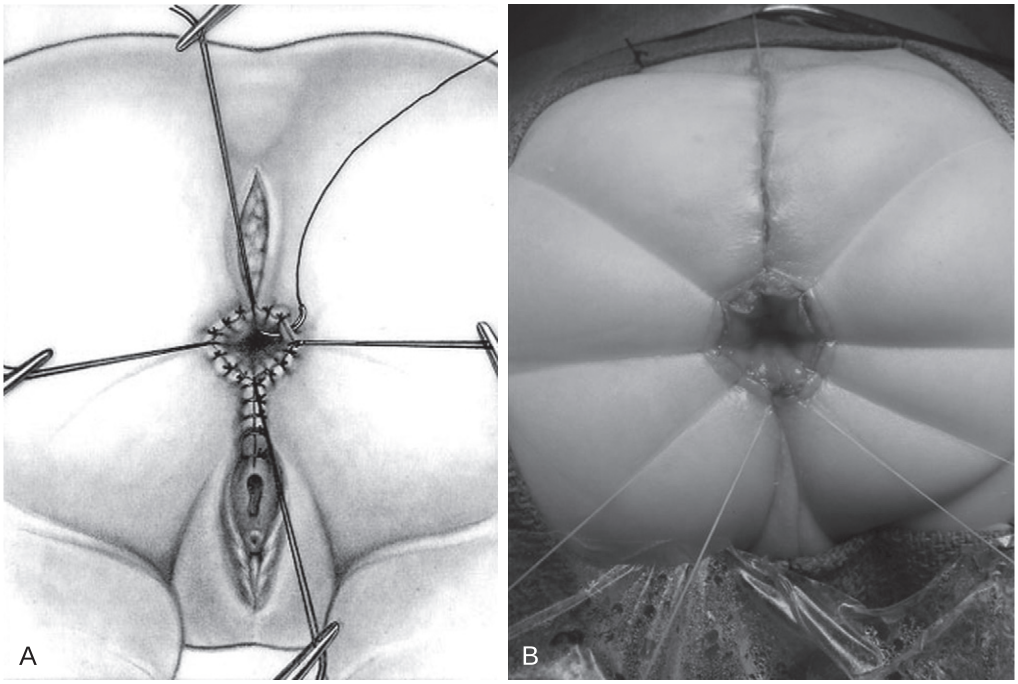

FIGURE 103-17 A, Repair of perineal body and anoplasty. B, Anoplasty performed with 16 long-term absorbable sutures.

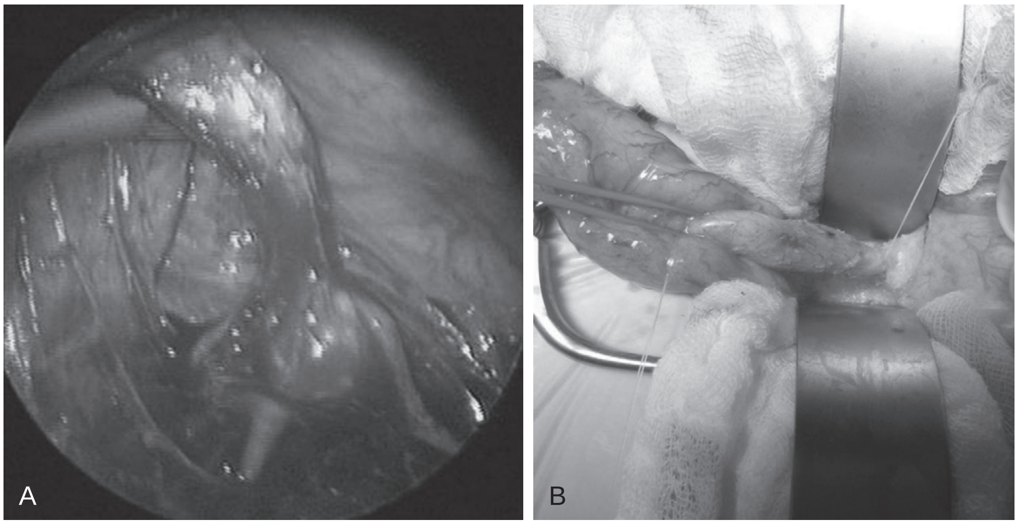

FIGURE 103-18 Operative view of a rectobladderneck fistula showing the rectosigmoid ending at the bladder neck. **A,** Laparoscopic view. **B,** View via laparotomy.

opening of the colostomy may have interfered with the continuity of the arcade that connects the middle colic vessels with the inferior mesenteric vessels. Therefore the blood supply of the distal part of the rectum may depend solely on the inferior mesenteric vessels, and therefore preservation of the main trunks is crucial to preserve the intramural blood supply of the rectum. Meticulous dissection along the rectum is required to gain length (Fig. 103-19). In extremely high defects, the rectum can be elongated by rectoplasty. Sometimes the distal rectum is wide and must be tapered. With the legs lifted up, a midsagittal incision is made and the presacral space dissected. Then the rectum is pulled through. An anoplasty should be performed as previously described. Tacking of the rectum to the muscle complex is important because these patients have poor pelvic musculature and are particularly prone to prolapse.

### Imperforate Anus Without a Fistula

In patients with an imperforate anus and no fistula, the blind end of the rectum is located at the same level as in a patient with a bulbar urethral fistula. Because the rectum is still intimately attached to the posterior urethra, separation from the urethra requires careful dissection. The rest of the repair is performed as described for rectourethral fistulas.

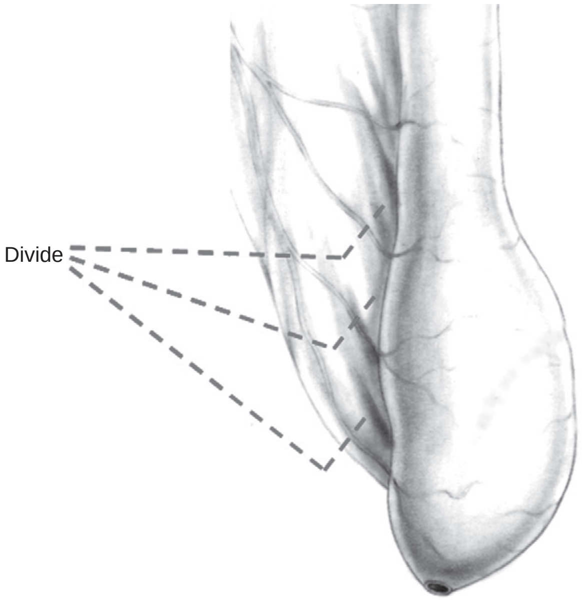

**FIGURE 103-19** Ligation of the peripheral branches of the inferior mesenteric vessels with preservation of the main trunks, in order to gain length on a high rectum.

### Rectal Atresia and Stenosis

Repair of rectal atresia and stenosis involves connecting the blind dilated end of the rectum proximally with the anal canal distally. Both structures are usually separated by a few millimeters of fibrous tissue. The rectum must be sufficiently mobilized to allow the performance of an end-to-end anastomosis to the anal canal. The wound is then closed by reconstructing all the muscle structures, as previously described. Because the anal canal is normal, these patients have excellent potential for bowel control. This defect in particular is associated with a presacral mass, often a teratoma; full evaluation is essential.

## POSTERIOR SAGITTAL ANORECTOPLASTY FOR ANOMALIES IN FEMALES

### Vestibular Fistula

The complexity of this defect is frequently underestimated. Patients with a vestibular fistula are born with excellent potential for bowel control. Thus every effort should be directed at successful reconstruction with a single operation; wound dehiscence and infection may compromise the final functional result. A protective colostomy minimizes these complications, but if the surgeon has adequate experience with this malformation, a primary repair can be performed in the newborn period. Occasionally, such patients escape detection in the newborn period and undergo reconstruction several months or even years later. A primary repair without colostomy under these circumstances can also be performed. However, to avoid a perineal infection, meticulous technique, excellent bowel preparation, 1 week without oral intake, and parenteral nutrition postoperatively are vital.

With the patient in prone position, a midline incision is performed, but it is not usually necessary to extend the incision as high as the middle portion of the sacrum. The midline incision continues around the fistula into the vestibule and multiple 5-0 sutures are placed circumferentially at the fistula site. While traction is placed on these sutures, the rectum is dissected in a circumferential manner. The posterior rectal wall can easily be identified, and the dissection must start from the posterior aspect and be extended laterally. The last step, separation of the rectum from the vagina, is the most delicate part of the dissection. The common wall between the rectum and vagina in this kind of defect is long and extremely thin. Once fully separated, the surgeon finds an areolar plane between the two structures. At this point branches of the hemorrhoidal vessels found on the lateral aspects of the rectum can be ligated with cautery, thereby mobilizing the rectum as previously described, to gain enough length to perform a tension-free bowel-to-skin anastomosis. The limits of the sphincteric mechanism are electrically determined and marked with temporary silk sutures. The perineal body is then reconstructed by bringing together the anterior limit of the sphincter complex. The anterior edge of the muscle complex is reapproximated taking bites of rectal wall, as described previously for males. The levator muscle is not usually exposed and thus does not need to be reconstructed. The anoplasty and wound closure are performed as described for males. For the extremely unusual case of a rectovaginal fistula, the technique is the same except that the rectum requires more mobilization to reach the perineum.

### Cloaca

This female malformation is managed by a variation of the posterior sagittal anorectoplasty. It is considered separately because of its complexity. The reconstruction requires a delicate, meticulous technique, as well as creativity, imagination, and a resourceful, experienced surgeon. Repair of this defect has three main goals: achievement of urinary control, bowel control, and sexual function. Because a spectrum of defects exists, these goals are achieved in some cases; in others, however, the defect is repaired anatomically, but the patients are left with functional sequelae that require extensive medical assistance to provide a good quality of life. During surgical exploration, the surgeon must be prepared to find bizarre anatomic arrangements of the rectum, vagina, and urinary tract (Fig. 103-20). A long midsagittal incision is made, extending from the middle portion of the sacrum through the sphincter mechanism and down into the single perineal opening.

Before undertaking repair of a cloaca, the surgeon should perform an endoscopy with the specific purpose of determining the length of the common channel. A contrast study of each of the three systems is valuable and can be done in three dimensions (Fig. 103-21). There are two well-characterized groups of patients with a cloaca.[64] These two groups represent different technical challenges and must be recognized preoperatively. The first group consists of patients with a common channel shorter than 3 cm; fortunately, this represents the majority. These patients can usually be repaired via a posterior sagittal approach alone, without laparotomy.

The second group consists of patients with longer common channels. These patients usually need laparotomy, followed by a decision-making process that usually requires intricate vaginal maneuvers or vaginal replacement, tricks to mobilize a high rectum, knowledge of bladderneck anatomy, and decision making related to ectopic ureters if found. This group should be cared for at centers with special dedication to the repair of these defects.

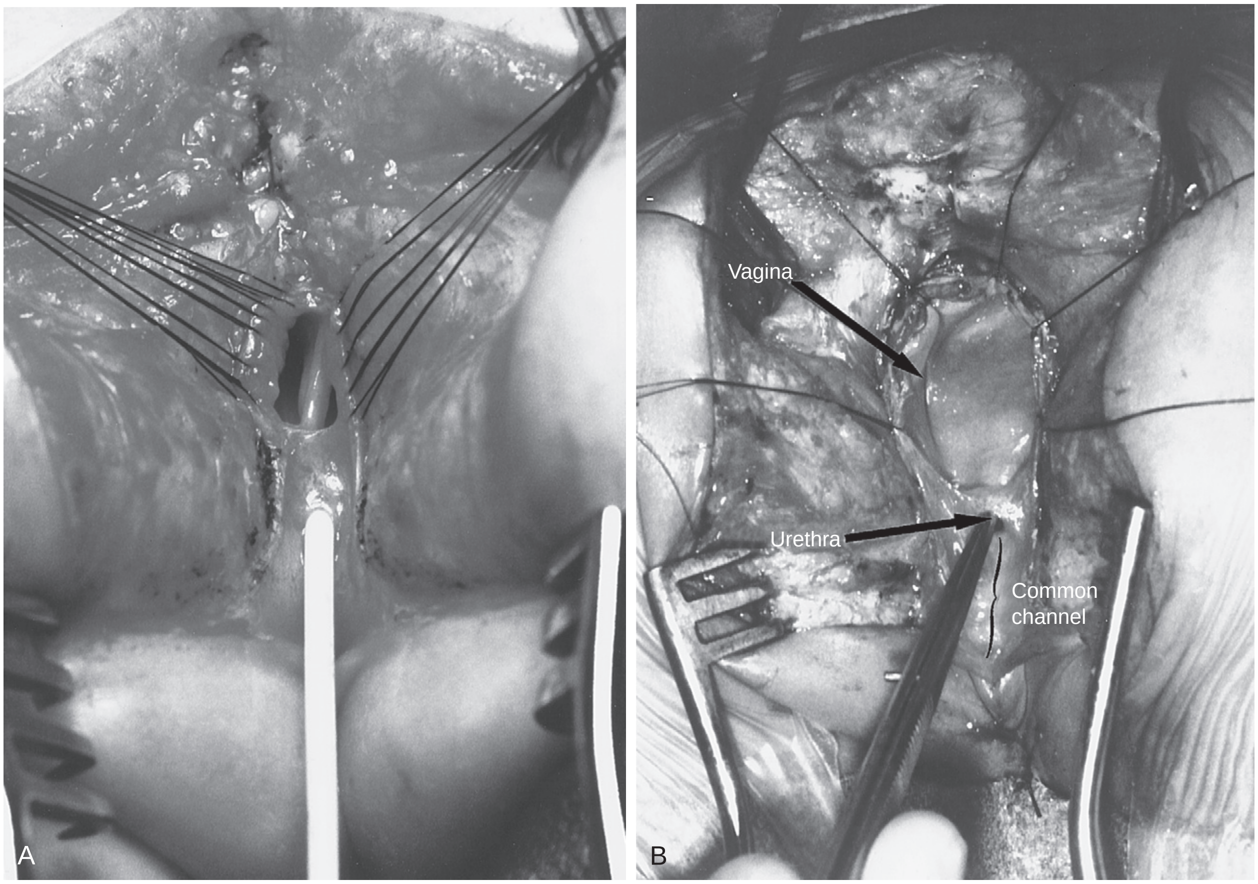

**FIGURE 103-20** **A,** Posterior sagittal view of a typical cloaca with a common channel of 2 cm with a visible vaginal septum. **B,** A cloaca with a very large vagina (hydrocolpos). The rectum opens higher in the vagina and is not seen here.

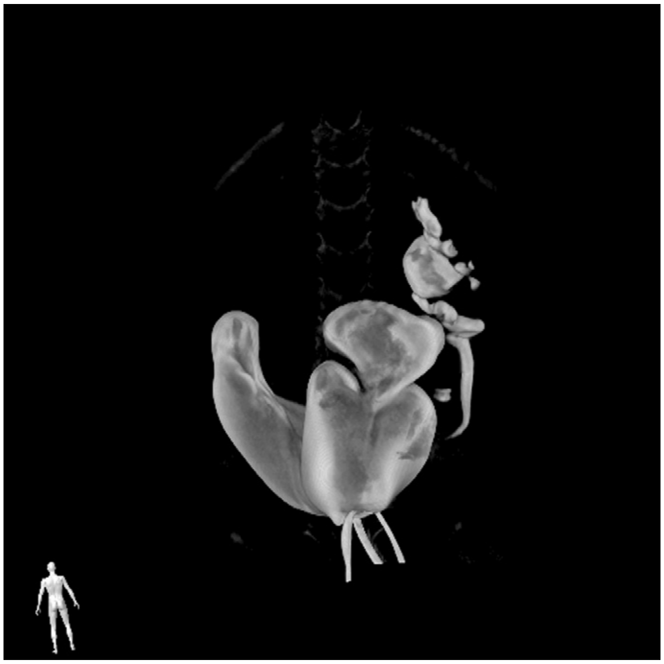

**FIGURE 103-21** Three-dimensional cloacagram.

***Cloacas with a Common Channel Shorter than 3 cm*** The incision extends from the middle portion of the sacrum down to the single perineal orifice. The sphincter mechanism is divided in the midline. The first structure that the surgeon will find after division of the sphincter mechanism is the rectum. The rectum is opened in the midline, and silk stitches are placed along the edges of the posterior rectal wall. The incision is extended distally through the posterior wall of the common channel. The entire common channel is exposed to allow confirmation of its length under direct vision (Fig. 103-22). The rectum is then separated from the vagina (see Fig. 103-22). This is performed in the same way as for repair of a rectovestibular fistula because the rectum and vagina share the same common wall already described. In patients with a vaginal septum, the rectum must be searched for at the posterior aspect of this septum.

Once the rectum has been completely separated from the vagina, a maneuver called *total urogenital mobilization* is used.[65] Before this advance, the vagina was separated from the urinary tract, which was a technically challenging maneuver associated with significant morbidity.

Total urogenital mobilization consists of mobilization of both the vagina and urethra as a unit without separating them. After the rectum has been separated, multiple silk stitches are placed through the edges of the vagina and the common channel to apply uniform traction on the urogenital sinus (see Fig. 103-22). Another series of fine stitches are placed

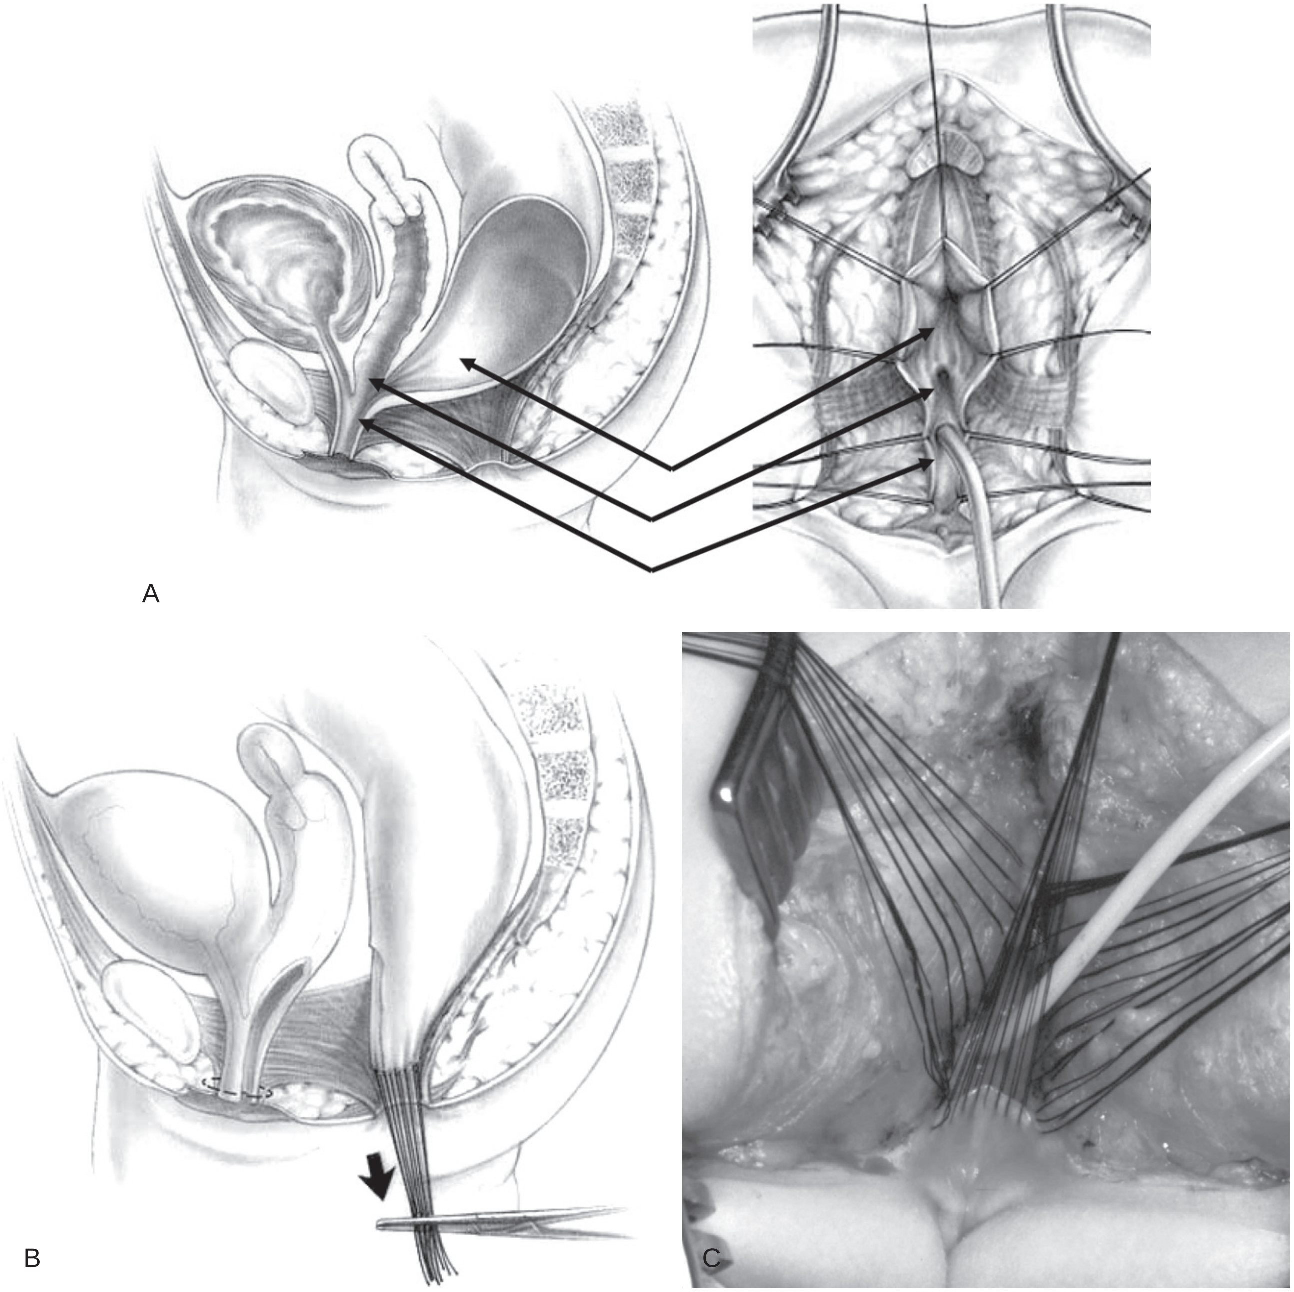

**FIGURE 103-22** **A,** Total urogenital mobilization (cloaca with a short common channel, <3 cm). **B,** The rectum is separated from the urogenital sinus. **C,** Sutures are placed around the urogenital complex for uniform traction to facilitate mobilization of the urogenital sinus.

across the urogenital sinus approximately 5 mm proximal to the clitoris. The urogenital sinus is transected between the last row of silk stitches and the clitoris. The dissection takes advantage of the fact that there is a natural plane of separation from the pubis. Rapidly and in a bloodless field, one can reach the upper edge of the pubis. There, a fibrous, avascular structure that gives support to the vagina and bladder is identified.

This structure is called the *suspensory ligament* of the urethra and bladder. This ligament is divided, which immediately provides significant mobilization (between 2 and 3 cm) of the urogenital complex. One can then dissect the lateral and dorsal walls of the vagina to gain an extra 5 to 10 mm. This dissection is enough to repair about 60% of all cloacas and is a reproducible maneuver. It has the additional advantage of preserving an excellent blood supply to both the urethra and vagina. It places the urethral opening in a visible location and provides a smooth urethra that can easily be catheterized. What used to be the common channel is divided in the midline to form two lateral flaps that are sutured to the skin to create the new labia. If a vaginal septum is present, it is removed. The vaginal edges are then mobilized to reach the skin to create the introitus. The limits of the sphincter are electrically determined. The perineal body is reconstructed by bringing together the anterior limit of the sphincter. The rectum is placed within the limits of the sphincter in the manner previously described. Patients can eat the same day, and the pain is usually easily controlled. Patients are discharged 48 hours postoperatively.

***Cloacas with a Common Channel Longer than 3 cm*** When endoscopy and a cloacagram show that the patient has a long common channel, the surgeon must be prepared to face several significant technical challenges.

Patients with a long common channel should receive a total-body preparation because it is likely that laparotomy will be required. The rectum is separated from the vagina and urethra via a posterior sagittal incision or via laparotomy when it is located very high. The presence of a long common channel (>5 cm) indicates there is no way that total urogenital mobilization will be sufficient to repair the malformation, and therefore it is advisable to leave the common channel in place, which can be used as urethra for intermittent catheterization. In this situation the vagina should be separated from the urinary tract by placing multiple 6-0 silk sutures through the vaginal wall to try to create a plane of dissection between the vagina and the urinary tract. This is best done through the abdomen when the vagina(s) are high. In such a high common channel case, when the vaginas are low and closer to the perineum, the surgeon may need to do a total urogenital mobilization and then deliver that mobilized urogenital complex into the abdomen. Sometimes dissection in the abdomen then allows this complex to reach the perineum. Often, though, at this point, the urinary tract and vaginas must be separated and the neourethra tubularized. These are delicate maneuvers. Often, the bladder must be opened in the midline, and feeding tubes placed into the ureters to protect them. In these types of malformations there is an extensive common wall between vagina and bladder. Both ureters run through that common wall, and therefore during separation of the vagina from the urinary tract, the ureters must sometimes be skeletonized and thus need to be protected. Once the separation has been completed, if the vagina does not reach, the surgeon has to make decisions about the vaginal reconstruction on the basis of specific anatomic findings.

Within the abdomen, the patency of the müllerian structures are investigated by passing a No. 3 feeding tube through the fimbriae of the fallopian tubes and injecting saline. If one of the systems is not patent, the atretic müllerian structure should be excised, with great care taken to avoid damage to the blood supply of the ipsilateral ovary. When both müllerian structures are atretic, they should be left in place. The patient must be monitored closely and further investigated with ultrasound when she enters puberty.

***Vaginal Switch Maneuver*** A specific group of patients are born with hydrocolpos and two hemivaginas. The hemivaginas are large and the two hemiuteri are separated, the distance between them being longer than the vertical length of both hemivaginas. In these cases it is ideal to perform a maneuver called a "vaginal switch" (Fig. 103-23).

One of the hemiuteri and the ipsilateral fallopian tube is resected with particular care taken to preserve the blood supply of the ovary. The blood supply of the hemivagina of that particular side is sacrificed. The blood supply of the contralateral hemivagina is preserved and provides for both hemivaginas. The vaginal septum is resected, and both hemivaginas are tubularized into a single vagina by taking advantage of the long lateral dimension of both hemivaginas. Then, what used to be the dome of the hemivagina where the hemiuterus was resected is turned down to the perineum. This is a useful maneuver that can be performed only when these specific anatomic characteristics are encountered.

***Vaginal Replacement*** In a patient with a small vagina(s) or in the rare case of an absent vagina, a vaginal replacement is required. In such cases the choices are rectum, colon, or small bowel. When the patient has internal genitalia or an upper blind vagina, the upper part of the bowel used for replacement should be sutured to the vaginal cuff. When the patient has no internal genitalia (no vagina and no uterus), a vagina is created and left with its upper portion blind and used only for sexual purposes.

*Rectum:* This form of vaginal replacement is feasible only in patients who have a good size rectum that is large enough to be able to divide it transversely or longitudinally into a portion with its own blood supply that will form a new vagina and another portion with enough circumference to reconstruct an adequately sized rectum (Fig. 103-24). The blood supply of the rectum will be provided transmurally from branches of the inferior mesenteric vessels. This can also work for patients with a rectosigmoid long enough to allow the distal portion to be used as a new vagina with its own blood supply and the upper portion to be pulled down as the new rectum.

*Colon:* The colon is an ideal substitute to replace the vagina (Fig. 103-25). However, sometimes the location of the colostomy interferes with this type of reconstruction. The left colon or sigmoid work well because their arcades reach the perineum nicely. Sometimes taking the colostomy down and using its distal segment for the vaginal graft is a helpful maneuver.

*Small Bowel:* When the colon is not available, the most mobile portion of the small bowel is used for vaginal reconstruction. The mesentery of the small bowel is longest in an area located approximately 15 cm proximal to the ileocecal valve, which is the best portion of the small bowel for vaginal replacement. A portion of the ileum is isolated and pulled down while preserving its blood supply (Fig. 103-26).

In the highest type of cloaca one may find two little hemivaginas attached to the bladder neck or even to the trigone of the bladder. In these cases the rectum also opens in the trigone (Fig. 103-27). Separation of these structures is done abdominally. Unfortunately, when the separation is completed, the patient is frequently left with either no bladder neck or a severely damaged one. At that point the surgeon must have enough experience to make a decision whether to reconstruct the bladder neck or close it permanently. In the first situation, most patients will require intermittent catheterization to empty the bladder. A vesicostomy is created in such cases, and the patient will require a continent diversion type of procedure and possibly a bladder neck procedure and/or bladder augmentation, done at the age of urinary continence (3 to 4 years old). In this particular type of malformation, the patient usually also needs a vaginal replacement, which should be performed in one of the ways previously described.

At the time of colostomy closure, endoscopy should be performed to be sure that the repair is intact and that there is no prolapse, stricture, or urethrovaginal fistula. If the cloaca repair did not require laparotomy, the time of colostomy closure is the opportunity to investigate the patency of the müllerian structures.

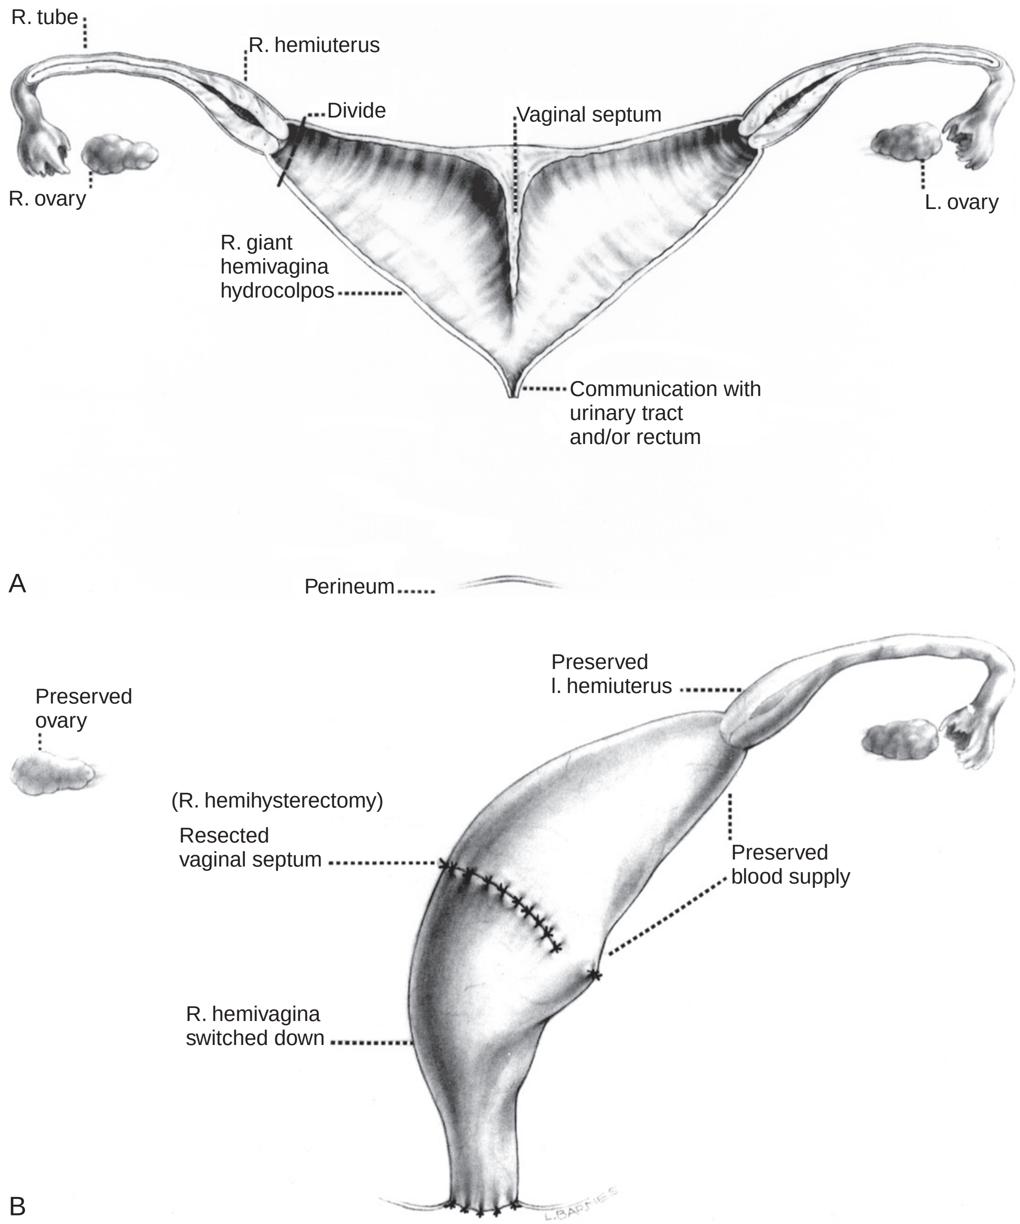

**FIGURE 103-23** **A,** Very large hemivaginas with a vaginal septum and long common channel. **B,** Vaginal switch maneuver.

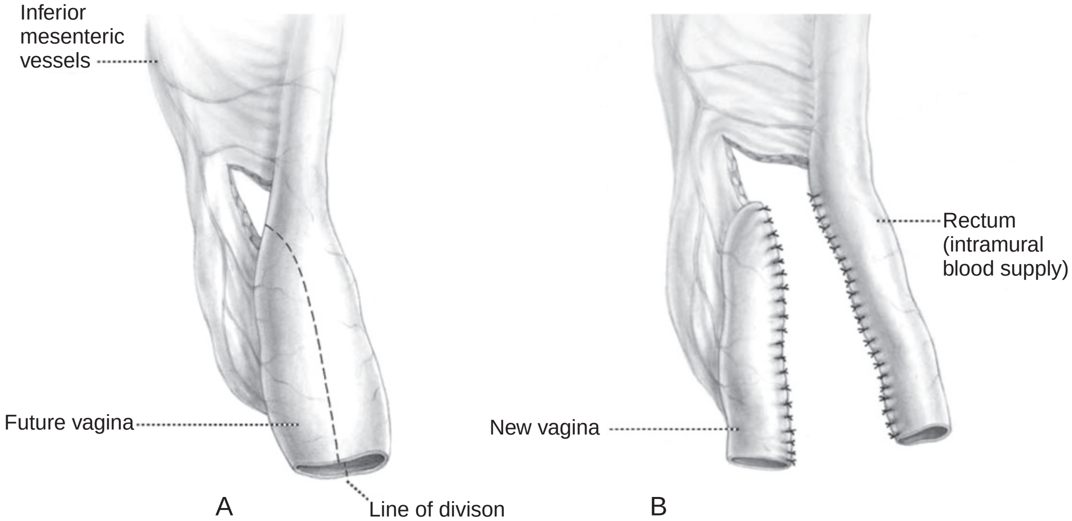

**FIGURE 103-24** **A** and **B,** Vaginal replacement with the rectum.

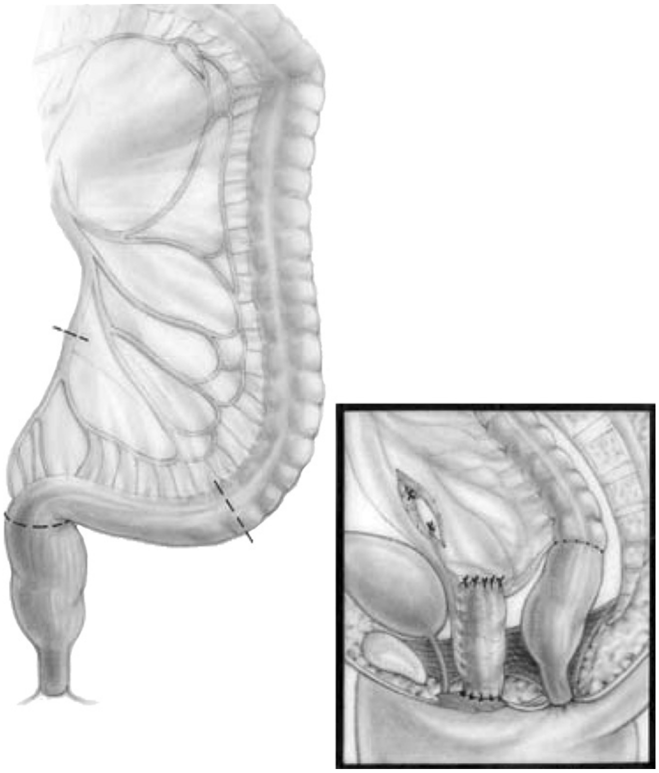

**FIGURE 103-25** Vaginal replacement with the sigmoid colon.

## GENERAL PRINCIPLES OF POSTOPERATIVE CARE

In the absence of a laparotomy, oral feedings may begin when the child is awake. Antibiotics are given for 48 hours. In males who had a rectourethral fistula, the urinary catheter should be left in place for 7 days. In patients who have undergone cloaca repair, the urethral catheter is left in place for 2 to 3 weeks until the urethral orifice is visible.

A dilatation program is begun 2 weeks after surgery. The anus is calibrated, and a dilator that fits snugly is initially used to dilate the anus twice a day. Every week, the size of the dilator is increased by one unit until the desired size is reached. The optimal size of dilator is shown in Table 103-2. Once the correct size is reached, the colostomy can be closed, which is usually 8 to 12 weeks after the reconstruction.

Dilatations must continue after closure. Once the dilator can be inserted easily, the schedule is reduced to once a day for 1 month, twice a week for 1 month, once a week for 1 month, and then once a week for 3 months.

After the colostomy is closed, the patient may have multiple bowel movements and perineal excoriation may develop. A constipating diet may be helpful in the treatment of this problem. After several weeks the number of bowel movements decreases, and most patients will essentially become constipated. This constipation must be anticipated and proactively treated.[31] After 3 to 6 months, a more regular bowel movement pattern develops. A patient who has one to three bowel movements per day remains clean between bowel movements

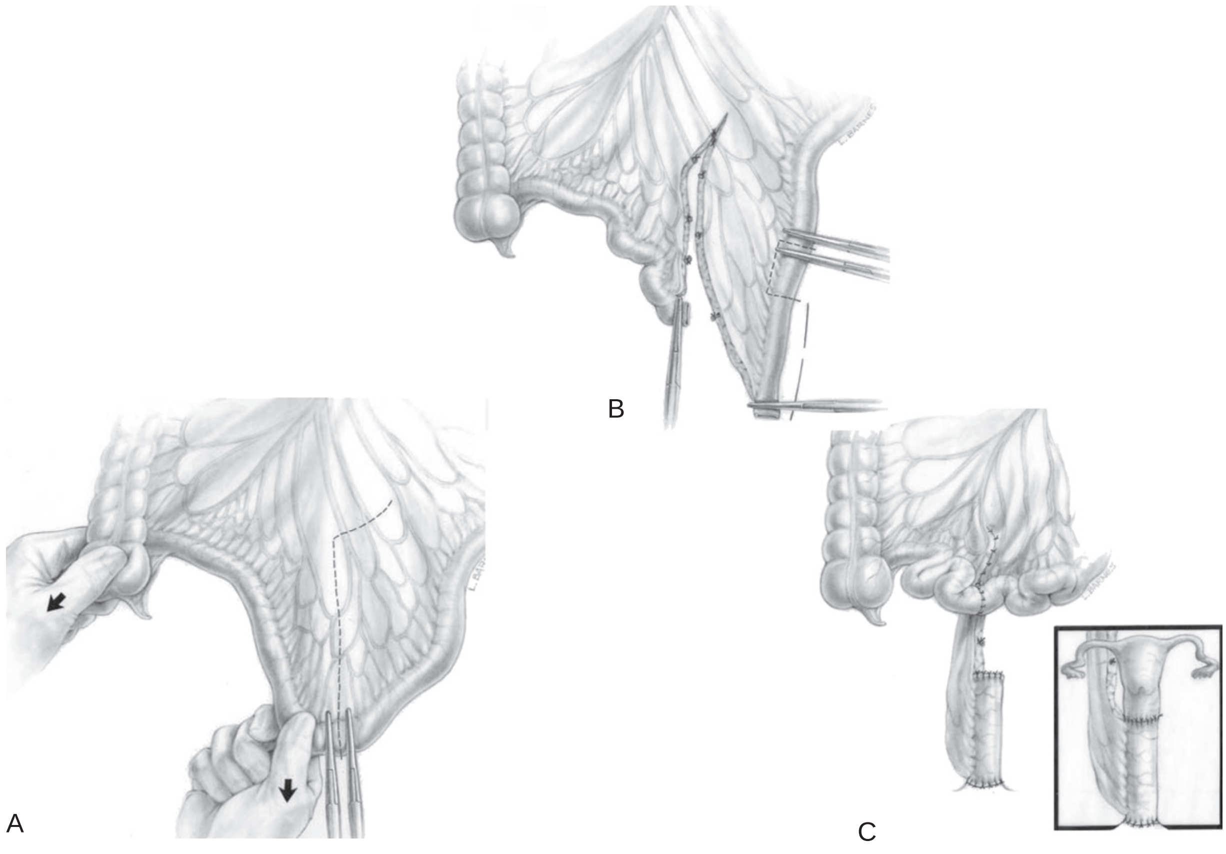

**FIGURE 103-26** Vaginal replacement with small bowel. **A** and **B,** Using the portion of ileum with the longest mesentery. **C,** Pulling the small bowel down as a neovagina (the *insert* shows an anastomosis to the upper part of the vagina).

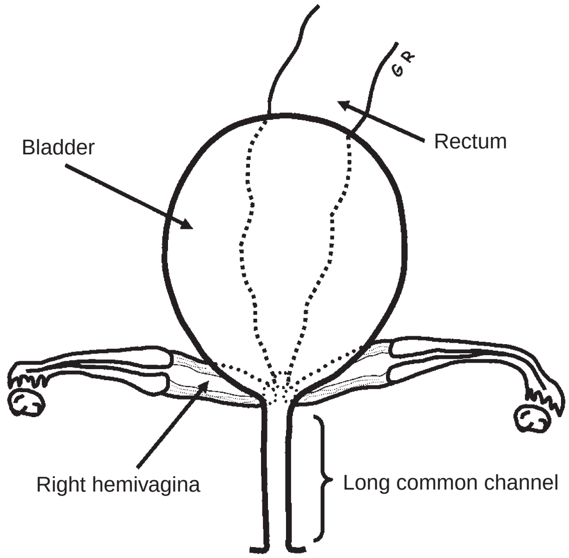

**FIGURE 103-27** Extremely long common channel–hemivaginas and rectum connected to the bladder neck.

and shows evidence of a feeling of pushing during bowel movements. This type of patient has a good bowel movement pattern, generally has a good prognosis, and is trainable. A patient with multiple bowel movements or one who passes stool constantly without showing any signs of sensation or pushing typically has a poor functional prognosis for bowel control. The original malformation type, as well as the quality of the sacrum and spine, predict the potential for voluntary bowel movements.

In cloacas the baby is watched to see whether she is capable of emptying her bladder. If she cannot pass urine and efficiently empty the bladder, she needs intermittent catheterizations.

# Outcomes

## COMPLICATIONS

All the usual postoperative complications may occur after surgery of this nature. In addition, some specific problems develop both early in the postoperative course and later.[66]

Wound infection and retraction are known to occur. When the infection affects only the superficial layers of the wound, is not accompanied by dehiscence of the structures pulled through, and is promptly treated, it is likely that no functional sequelae will result. On the other hand, infection accompanied by dehiscence may reach catastrophic proportions

**TABLE 103-2**
**Anal Dilatation Program**

| *Patient Age* | *Hegar Dilator* |
|---|---|
| 1-4 mo | Size No. 12 |
| 4-8 mo | Size No. 13 |
| 8-12 mo | Size No. 14 |
| 1-3 yr | Size No. 15 |
| 3-12 yr | Size No. 16 |
| >12 yr | Size No. 17 |

and leave sequelae that include incontinence, strictures, acquired atresias, recurrent fistulas, and severe pelvic fibrosis. We have reoperated on many such patients who suffered these kinds of complications at another institution and were referred to us for a secondary procedure.[67–68]

Infections and dehiscence have occurred mainly in patients operated on primarily, without a colostomy. Therefore although there is the benefit to operate earlier, primarily, and without a colostomy, it must be remembered that a colostomy is a valuable adjunct in the management of these defects. Surgeons must make decisions regarding this issue on the basis of their personal experience.

Determining the precise causes of these complications is difficult; however, it seems the main contributing factors are fecal contamination, ischemia, and suture line tension (often from the incomplete mobilization of structures).

Rectal or vaginal strictures (or both) are usually due to the previously mentioned complications, although they may occur independently. An anal dilatation program is recommended to avoid strictures; however, these maneuvers prevent only minor, ringlike strictures. Difficult anal dilatations usually reflect a major problem related to ischemia or tension that will result in a long narrow stricture or even acquired atresia.

Rectal mucosal prolapse is not uncommon after reconstruction. The rate of prolapse after posterior sagittal anorectoplasty in the authors' series was less than 5%.[69] Mucosal prolapse is uncommon after posterior sagittal anorectoplasty, probably because of several key technical steps: (1) tacking of the posterior rectal wall to the posterior edge of the muscle complex, (2) tapering a dilated rectum if necessary, and (3) performing the anoplasty under slight tension so that after the sutures of the anoplasty are cut, the rectum retracts slightly with no mucosa being visible. Mucosal prolapse is managed by full-thickness trimming and is performed when prolapse causes excess mucus production or ulceration or interferes with anal sensation.

A review of patients operated on at other institutions has revealed significant urologic injuries in male patients who underwent repair of anorectal malformations.[56] The posterior sagittal approach, when performed without a good preoperative distal colostogram, was the most important source of these complications. Urethral, ureteral, vas deferens, and seminal vesicle injuries can occur. The laparoscopic approach when done for malformations in which the rectum ends below the peritoneal reflection risks leaving behind a posterior urethral diverticulum (the original distal rectum). Postoperative neurogenic bladder in male patients who undergo a technically correct operation for the treatment of anorectal malformations must be extremely unusual because in our series it happens only in patients with an abnormal sacrum or spine.[70] Otherwise, we believe that it may reflect a poor surgical technique with denervation of the bladder and bladder neck during the repair.

Constipation is the most common sequela after surgical repair of anorectal malformations.[31] The lower the malformation, the more likely the development of constipation. A vicious cycle ensues with megarectosigmoid leading to more constipation. Constipation that is not properly managed will lead to more megarectosigmoid, resulting in overflow pseudoincontinence. Patients appear to be incontinent, but if their constipation is managed appropriately, they become

continent. Such patients sometimes benefit from sigmoid resection to reduce their laxative requirement.[71–74]

Every effort must be made to avoid this cycle and maintain a collapsed and clean bowel from the moment the baby is born. Transverse colostomies left for a long period of time lead to severe megarectosigmoid. Loop colostomies may also contribute to distal fecal impaction, dilation, and subsequent constipation. Adequate treatment of constipation starting after colostomy closure is vital.

## CONTINENCE

Long-term follow-up of our series suggests that good bowel control is achieved in about 75% of patients.

Our results according to the type of abnormality are shown in Tables 103-3 through 103-6. Patients with low anomalies have done extremely well; those with high lesions and those with associated spinal or sacral problems have done less well.

All patients with anorectal malformations, regardless of the complexity of the defect, can be kept completely dry of urine and clean of stool after the age of 3, either because they achieve bowel and urinary control or because we implement a program to keep them artificially dry and clean. The majority can have voluntary bowel movements, sometimes with the help of laxatives. For the others, we implement a bowel management program that uses enemas to ensure adequate emptying for a 24-hour period of cleanliness. With the rational administration of bowel irrigation, diet, and drugs, most patients, including those with inherent fecal incontinence, are able to remain clean for 24 hours.[75–76] Only patients with loose stool secondary to an absent or a short colon need a permanent colostomy.

Patients suffering from fecal incontinence are evaluated and classified into those with constipation or those with increased motility (tendency to have diarrhea). In the first group the saline enema must be of large volume, with additives (e.g., glycerin, soap, phosphate) to help empty the colon. This program takes advantage of the decreased bowel motility in constipated patients; they remain clean for the next 24 hours. No laxatives or diets are given as part of this protocol. The second group (patients who suffer from increased bowel motility because of loss of the rectal reservoir) require a constipating diet,

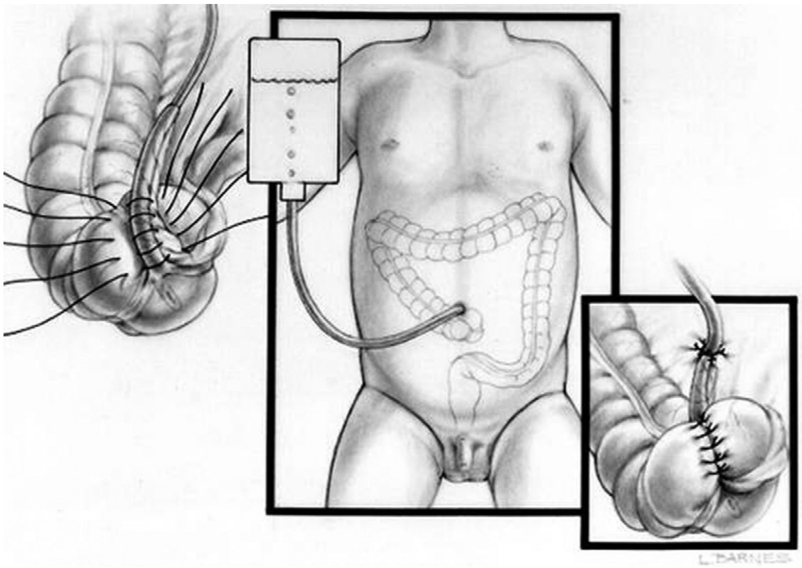

FIGURE 103-28 Diagram showing appendicostomy.

medication to decrease bowel motility, and a smaller daily saline enema.

The treatment is adjusted by trial and error over a period of 1 week, with 95% of patients remaining clean.[75] Bowel management is started just before the patient has to go to school and join his or her classmates, who are already wearing regular underwear. Most patients and parents are happy with the implementation of this program, but when the patient reaches the age of 7 to 12 years or sometimes younger, more independence is usually desirable.

At that point, creation of a continent appendicostomy (Malone procedure) is beneficial.[77–79] This operation creates a communication between the abdominal wall and the cecum through the patient's appendix. A valve mechanism is created by plicating the cecum around the appendix, which allows catheterization of the cecum but prevents leakage of stool. Patients can administer their own enema while sitting on the toilet. The operation consists of the plication and then the connection of the appendix to the umbilicus to make it inconspicuous. This is accomplished with a V-to-V anastomosis between the appendix and the umbilical skin (Fig. 103-28). A significant number of patients do not have an appendix. In such cases we make an appendix with a tubularized flap of the cecum and then plicate the cecum around it (Fig. 103-29). The stoma is also exteriorized through the umbilicus. Most patients who have undergone this operation express a great deal of satisfaction.

Some patients benefit from an enema program early on, but if they have potential for bowel control, when they are a little older, a laxative trial can be used to help their colon empty, with careful radiologic monitoring. This may allow them to demonstrate the capacity for voluntary bowel movement and thus eliminate the need for enemas.

FIGURE 103-29 Neoappendix made from a tabularized flap of colon.

Certain patients in whom the rectum was mislocated during the original operation may be candidates for a reoperation. This is recommended only in patients who were born with a good sacrum, good sphincters, and a malformation with a good prognosis. The results of this procedure vary, with worthwhile continence achieved in more than half of patients.[68,80–81]

Urologic problems in male patients and in female patients without cloacas are rare.[82] In patients with a cloaca, those with a common channel shorter than 3 cm require intermittent catheterization one third of the time. Patients with common channels longer than 3 cm require intermittent catheterization or a continent diversion 70% to 80% of the time.[64]

CHAPTER 104

# Other Disorders of the Anus and Rectum, Anorectal Function

Risto J. Rintala and Mikko P. Pakarinen

## Anatomy

The anal canal measures 2.5 to 4 cm in length (Fig. 104-1).[1] It is the area between the anal verge and the junction of the stratified cuboidal and columnar epithelium (dentate line).[2] It is lined by squamous epithelium in the lower anal canal below which sebaceous glands and hair follicles arise but changes to stratified cuboidal and, finally, columnar epithelium of the rectum. Sensitive sensory receptors in this epithelium and in the more proximal anal mucosa respond to a variety of stimuli, permitting discrimination of solid, liquid, and gas. The mucosa of the rectum meets the epithelial lining of the anal canal at the dentate or pectinate line, marking the oral extension of the anal columns and valves. High in the anal canal, the mucosa forms four to six longitudinal folds.

The smooth muscle of the internal anal sphincter (IAS) is continuous with the inner circular muscle of the rectum. It becomes more prominent low in the anal canal. It is approximately 3 cm long and 5 mm thick.[3] IAS is bound to voluntary external sphincter and perianal skin by muscular strands. It is involuntarily in a tonic state of contraction, providing at least 85% of the resting anal canal pressure that keeps the anal canal closed.[4] The IAS can increase contraction only slightly, but it relaxes completely by reflex in response to rectal distention.[5] This reflex, mediated by the myenteric plexus, is intrinsic and thus remains independent from extrinsic innervation.

Both sympathetic and parasympathetic nerves innervate the internal sphincter.[6] Sympathetic innervation is primarily excitatory, contracting the IAS, and is supplied by the lumbar splanchnic nerves from L2 to L4 ganglia and by the hypogastric nerves from the inferior mesenteric ganglion. $\alpha$-Adrenergic stimulation is excitatory, but $\beta$-adrenergic stimulation is inhibitory. The continuous tonic state of IAS appears to be mediated by excitatory fibers of both adrenergic and cholinergic innervation. Parasympathetic innervation comes from the S2 to S4 ganglia through the pelvic nerves and is generally inhibitory, causing the IAS to relax.[7,8]

The IAS also has an important intrinsic innervation, which is responsible for reflex relaxation in response to rectal distention. These intrinsic nerves lie in intramural plexuses and in the myenteric (Auerbach), deep submucosal (Henke), and submucosal (Meissner) plexuses and are nonadrenergic and noncholinergic in origin.[6,7]

The external anal sphincter is a striated muscle that is partially under voluntary control. The muscle surrounds the anus below the dentate line and is attached anteriorly to the perineal body and posteriorly to the anococcygeal raphe. The external anal sphincter has traditionally been divided in three anatomic components: subcutaneous, superficial, and deep. It is innervated by rami of the pudendal and perineal nerves, which originate from sacral roots 2 to 4.[9]

Although capable of phasic contraction, the external anal sphincter may also have tonic contraction.[10] Unlike the IAS, the tonic contraction of the external sphincter depends on extrinsic efferent innervation. The phasic contractions are born voluntary and involuntary; thus the external anal sphincter provides part (10% to 15%) of the resting anal sphincter tone.[11]

The pelvic floor muscles consist of the levator ani muscle group, one part of which, the puborectal muscle, forms a sling around the anorectal junction. Although a striated muscle, the puborectalis remains in tonic contraction.[12] This creates an angle between the anus and the rectum, the anorectal angle, which is 80 to 90 degrees at rest and during defecation more obtuse, at 100 to 105 degrees.[13] With coughing, straining, or other sudden increases in intra-abdominal pressure, the puborectalis automatically increases its tonic contraction, hereby maintaining the sharp anorectal angle that plays a significant role in fecal continence.[12] The levator ani muscle complex that contracts in a vertical plane is shaped like a funnel that surrounds the rectum and tapers down to the anal canal, where its fibers merge with the voluntary anal sphincter.

## Physiology of Anal Continence

The adaptive compliance of the colon with the retentive mechanism of the anorectum is required for fecal continence. The simple anatomic impedence to the descending fecal mass occurs because the distal end of the gastrointestinal tract is

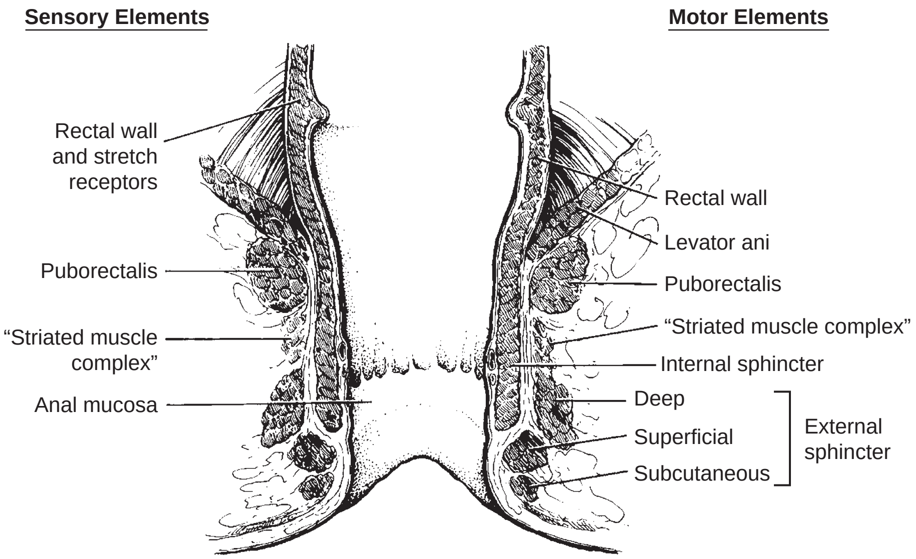

**FIGURE 104-1** The main anatomic components of the rectum and anus.

not a straight tube. The angulations in the sigmoid colon and the valves of Houston in the rectum impede the caudal movement of fecal contents. The 80-degree anorectal angle also assists fecal continence.[14] The longitudinal mucosal folds in the anus also contribute to continence of semisolid or fluid feces by the way they fold together, even when the internal sphincter partially relaxes.

The anal sphincters play an important role in maintaining continence, and both the voluntary external sphincter and the involuntary internal sphincter have a resting tone. Fecal continence requires a normally functioning IAS, external sphincter complex, and levator funnel, as well as intact sensory input from the rectum and anal canal.[15,16] The rectum has stretch receptors, which have an increasing sensitivity the more distal they are sited. The anal canal is richly endowed with sensory receptors for most modalities of sensation.[17] These receptors allow us to distinguish between flatus, fluid, and feces.

Gross continence, the ability to hold large volumes of solid or liquid feces, is a function of the intact anorectal angle and tonic contraction of both external and internal sphincter systems. Fine continence—the control of small volumes of feces or flatus—is the function of the coordinated action of the sphincters. The distal 2 cm of the anal canal above and at the dentate line is the critical site of fine continence.[18] This is the site where the "sampling reflex," discrimination between solid stool, liquid, or gas, is initiated.[19]

## Physiology of Defecation

The defecation sequence is a complex combination of involuntary actions and voluntary accomplishments that are controlled by higher cerebral centers. The rectum fills gradually by colonic action. The distension of the rectum stimulates stretch receptors in the rectal wall and levator and induces an initial contraction of the voluntary sphincter complex, retrograde emptying of the distal rectum, and relaxation of the IAS. This causes a sensation to desire to defecate that increases in intensity as the rectum fills. Stool is temporarily allowed to contact the sensitive mucosa of the anal canal and is sampled by the exquisitely sensitive sensory receptors in the anal mucosa, which allows evaluation of stool consistency and recognition of flatus. The need to defecate is appreciated, but this urge can be voluntarily inhibited. The external anal sphincter and puborectalis can be contracted voluntarily to abort the fecal expulsion. The rectum and colon stretch compliantly, decreasing the intrarectal pressure and the urge to stool.

As more stool is delivered to the rectum, the sensation increases and rectal waves intensify. The urge to defecate is increased, and the reflex inhibition of the sphincters becomes greater. The reflex suppression of the tonic contraction of the external anal sphincter and puborectalis begins; if time and place are appropriate, voluntary defecation can occur.

Young children have a shorter intestinal transit time than older children, and this correlates with the more frequent bowel movements in infants.[20] Infants who are fed by breast milk or cow's milk–based formula have one to seven bowel movements per day.[21] In children between 1 and 4 years of age, 85% pass stool once or twice per day.[22] Normal English school children[23] have mean transit times of 26 hours and constipated children of 80 hours. Healthy young adults have transit times from 30 to 48 hours.[24]

## Constipation

Constipation in children is a common condition, especially in the Western world. Unresolved constipation can lead to fecal retention and impaction, and finally to overf1ow incontinence. In the overwhelming majority of patients the exact cause of constipation remains obscure; in this case the condition is called *functional constipation.*

### DEFINITIONS

The consensus Rome III classification is most commonly used in the diagnosis of functional constipation in children.[25] Functional constipation in children is defined as constipation not associated with congenital abnormalities, acquired

diseases, or medication. The following criteria apply for children of all ages:

*Two or more* of the following must exist:

1. Two or fewer defecations in the toilet per week
2. At least one episode of fecal incontinence per week (after acquisition of toileting skills)
3. History of retentive posturing or excessive volitional stool retention
4. History of painful or hard bowel movements
5. Presence of a large fecal mass in the rectum
6. History of large-diameter stools that may obstruct the toilet

Both constipation and soiling are common. Soiling has been reported in approximately 3% of children older than 4 years of age, and constipation accounts for at least 3% of all medical and 25% of pediatric gastroenterology referrals.[26–29] More than 50% of constipated children have a familial incidence, and most studies suggest a male predominance. The reported ratios range between 1.5:1 and 3:1.[30,31]

Because constipation during the neonatal period, usually associated with distention and vomiting, is never functional, anatomic or mechanical obstruction must be suspected. Most (94% to 98%) full-term and most (76%) preterm normal babies pass meconium during the first 24 hours after birth. All normal babies (100% of full-term and 99% of preterm) have a first stool with the first 48 hours of life.[32] During the first year of life, symptomatic constipation warrants an evaluation and organic causes for constipation should be ruled out.

During infancy, constipation is often initiated after dietary manipulations, often the change from breast-feeding to bottle-feeding or the introduction of solid foods.[33] Specifically, in children anal fissure or perianal dermatitis with group A *Streptococcus* causes a vicious cycle of stool withholding and painful defecation and chronic constipation. A suggested alternative etiology is cow's milk protein intolerance.[34] Dietary fiber is poorly associated with constipation except in older children.[35] Constipated parents are more likely to have constipated children.[36] Slow transit constipation is a major problem in adults and is probably important in a subset of children with constipation.[37,38] Psychologic problems are common in constipated children, but they are secondary to constipation in the majority of cases.[30,39]

## ACUTE CONSTIPATION

Acute constipation may be secondary to inactivity, changes of environment or diet, or an anal fissure. Presentation as acute abdominal pain is common. Acute constipation presenting with abdominal pain is usually relieved by one single enema. The management of acute constipation is usually straightforward, especially in infants and toddlers. Adding more water to the diet and restriction of cow's milk intake usually relieve the symptoms. Older children and those who have an acute anal fissure require bulk laxatives for a variable period of time.

## CHRONIC CONSTIPATION

Persistent constipation, which does not rapidly respond to dietary manipulation or simple laxative treatment, can be defined as chronic. A child with chronic constipation commonly presents with fecal soiling. Organic causes that should be taken into account in the diagnostic workup for chronic constipation are summarized in Table 104-1.

**TABLE 104-1**

**Differential Diagnosis of Chronic Constipation: Organic and Acquired Causes**

| |

| Anticonvulsive drugs |
| Psychiatric drugs |
| Anticholinergic drugs |

Studies of children with constipation and overflow soiling show that 40% were never completely toilet trained and that enuresis is an associated problem in more than 30%.[28] Chronic constipation and soiling typically present between ages 2 and 4 years[40]; however, up to 40% of the patients have the onset of symptoms during the first year of life. The diagnosis of chronic constipation relies on history and clinical examination. A detailed bowel history should focus on the age at which constipation first occurs; the frequency and description of stools; and therapeutic interventions previously attempted including any medications taken. Anticonvulsants, diuretics, antacids, and supplemental iron preparations are frequently associated with constipation. Family history can be important, particularly a history of Hirschsprung disease, cystic fibrosis, or familial constipation. The incidence of clinical findings in patients with chronic constipation is summarized in Table 104-2.

On clinical examination the child's abdomen is usually nontender and rarely distended. Stool masses are frequently palpable above the pubic symphysis and in the lower left abdomen. The perineum must be inspected carefully for the position and condition of the anus and the perianal skin, as well as for soiling marks. The normal position of the anus must be defined because malpositioning is a well-recognized cause of constipation.[41,42] Reisner and colleagues[43] defined normal values by using a ratio of the midanal to fourchette distance and the fourchette to coccyx distance in the female and midanal to posterior scrotum distance and the posterior scrotum to coccyx distance in the male. If the ratio is less than 0.34 in the female (usual values: newborn, 0.44; age 4 to 18 months, 0.40)

TABLE 104-2
Clinical Features of Severe Functional Constipation

| *Age at Onset* | |
|---|---|
| 0-1 yr | 20-25% |
| 1-5 yr | 70% |
| > 5 yr | 10-15% |
| Boys-to-girls | 1-3:1 |
| Previous attempts to treat | 80-90% |
| Soiling | 70-75% |
| Unsuccessful toilet training | 70-80% |
| Pain at defecation | 70-80% |
| Abdominal pain | 50-60% |
| Occasional blood in stool | 25-30% |
| Poor appetite | 20-30% |
| Wetting | 20-30% |
| Primary psychopathology | 15-20% |
| Rectal prolapse | 3% |

Data from references 28, 30, 36, 52, and 53.

and less than 0.46 in the male (usual values: newborn, 0.58; age 4 to 18 months, 0.56) the child should be investigated carefully, especially if constipation is present. To differentiate between anterior anus and perineal ectopic anus is often difficult, especially if the anterior position of the anus is associated with stenosis. Final diagnosis may require muscle stimulation in general anesthesia.

Perianal sensation to rule out neurologic disorders can be evaluated by stroking the perianal tissue gently with a cotton-tipped applicator, watching for the anal puckering, and ascent of the perineum. The child's underwear should also be examined for soiling.

It is advisable to perform a digital rectal examination at least once in a child with chronic constipation to rule out organic obstructing causes. The fecal mass that fills the rectum may have developed to a fecaloma that can be stone hard. The rectorectal space must be examined to feel masses within the hollow of the sacrum. The closing reflex should be seen when the finger is withdrawn. The absence of either the perineal cutaneous or closing reflexes suggests an underlying neurologic disorder.

If the clinical history and physical examination do not suggest organic etiology, a trial of medical treatment can be initiated. A small infant with a history of neonatal symptoms and early onset constipation should undergo barium enema without bowel preparation. An abnormal barium enema should be followed by rectal biopsy and possibly anorectal manometry to rule out Hirschsprung disease and allied disorders. In an older child without any history of significant neonatal constipation a primary barium enema or biopsies are not necessary[44,45] before the onset of medical management. Barium enema and other imaging such as plain abdominal radiography, transit time studies, or magnetic resonance imaging (MRI) are indicated in patients who have poor response to appropriate medical treatment or abnormal clinical findings such as neurologic symptoms. Patients who have a poor response to optimal medical therapy should undergo also rectal biopsy and anorectal manometry to rule out rare forms of dysganglionoses such as hypoganglionosis, intestinal neuronal dysplasias, and internal sphincter achalasia.

Barium enema usually shows dilatation of the rectosigmoid that extends to the anal canal. This rules out classic Hirschsprung disease but not internal sphincter achalasia.[46,47] Plain abdominal radiography may reveal spinal vertebral anomalies in patients who have clinical findings suggesting a neurologic disorder. In case of vertebral anomalies an MRI study should be performed to rule out intraspinal pathology such as tethering and intraspinal lipomas.[48] Transit time studies by radiopaque markers[37,49] or radioisotopes[38] have been used to assess colonic motility in patients with poor response to standard medical management. These studies have revealed that slow-transit constipation occurs in a significant proportion of patients with recalcitrant constipation. The main methodological problem with transit studies in children is the lack of standardized methods and normal values in healthy children.

Anorectal manometry is useful only for the diagnosis of Hirschsprung disease and internal sphincter achalasia. In both these conditions the rectoanal relaxation reflex is missing. In patients suffering from functional constipation, anorectal manometry does not improve diagnostic or therapeutic accuracy. Some constipated children with normal histology also have manometric evidence of anal outlet obstruction and paradoxically contract the sphincter complex with straining, so-called rectoanal dyssynergy.[46,50–52]

## MANAGEMENT OF CHRONIC IDIOPATHIC CONSTIPATION

The general approach to the management of a child with chronic constipation includes the following steps[39,53]:

- Provide parental counseling and education
- Determine whether a fecal impaction is present
- Disimpact the fecaloma if present
- Initiate oral medication

### Counseling and Education

Counseling and educating the family are the first steps in the management. The pathogenesis of constipation needs to be explained to the parents. If the patient has fecal soiling, the involuntary nature of overflow incontinence needs to be clarified to the parents. Parents are encouraged to maintain a consistent supportive attitude during the long period of treatment. Education of the child and parents, emotional support, and a commitment to continue to see the family until normal stooling is established are all important elements of the program.[51,53,54] The patient and the parents need to be aware that it may take 6 to 12 months or even years before a normal stooling pattern is achieved.

### Disimpaction

If the patient has fecal impaction, disimpaction is necessary before initiation of oral maintenance therapy. A fecal mass can be identified by physical examination in the lower abdomen, rectal examination, or radiographic methods. A typical symptom of fecal impaction is overflow incontinence. Disimpaction has been traditionally accomplished with bowel washouts, but oral medication is effective, too.[55,56]

Oral disimpaction can be accomplished by high doses of stimulant laxatives, docusate, mineral oil, and polyethylene glycol-electrolyte (PEG) solutions.[54,56] Osmotic laxatives such

as lactulose or sorbitol can be used in combination with other medication. Oral disimpaction is often associated with abdominal pain and colic, as well as an initial increase in fecal soiling.

Rectal washouts usually work faster than oral disimpaction. It is, however, invasive and painful, especially in patients who have associated anal pathology. Therefore rectal disimpaction is contraindicated in children with anal fissure. Saline, docusate, mineral oil, or phosphate enemas are recommended by different investigators.[53,57,58] When rectal disimpaction is used, it is essential that the number of enemas is kept minimal. Usually one to three washouts are required for complete disimpaction. In recalcitrant cases manual evacuation under general anesthesia may be considered.

### Maintenance Therapy

The goal of maintenance therapy is to produce one to two soft stools per day and prevent recurrent fecal impaction. This ensures that the vicious cycle of hard stools and painful defecation will be abolished. Treatment consists of dietary interventions, laxatives, and behavioral modification. Dietary changes are universally advised, particularly increased intake of fluids and fiber. The role of fiber may not be significant in children.[35] Too much milk is discouraged.[59]

There is no evidence that any particular drug treatment regimen is superior. Good compliance with the selected treatment is more essential. In the early phases of management after the disimpaction, more effective medication is often required. Stimulant laxatives (Senna, sodium picosulfate) should be used for short periods, as short as possible, and should be replaced by less harmful therapies. Osmotic laxatives (lactulose, docusate, PEG) can be safely used for months and years. A recent meta-analysis has shown that PEG is superior to lactulose for childhood chronic constipation.[60]

Having achieved regular pattern of bowel movements, the medication needs to be continued as long as needed. This usually means months and sometimes years. A good thumb rule is that the treatment continues as long as the patient has had symptoms before the management. The dosage of the medication needs to be tapered regularly; the goal is to use a minimum effective dose.

### Behavioral Therapy

Behavioral therapy varies with the age of the patient. In infants and toddlers, behavioral therapy has no role; it is important that too early and aggressive toilet training is discouraged. In young children younger than 2 to 3 years of age, the toilet should be avoided and diapers reinstituted as long as the child is ready to go back to potty or toilet.[53] Older children may benefit from regular toileting routines after a major meal during the day. Praise, rewards, and a diary may contribute to a successful outcome.[55]

### Long-Term Outcome

There are few studies of the long-term results of the management of chronic idiopathic constipation.[36,61] The reported final cure rates after 5 years of follow-up range between 50% and 70%. A recent longitudinal follow-up study showed that one third of children with chronic constipation continue to have severe complaints of constipation beyond puberty.[62]

### Surgical Options for Chronic Constipation

The majority of children with chronic constipation improve by appropriate medical therapy or with time. Most patients also comply even with aggressive medical therapy. However, a few children, despite optimal and maximal medical management, have persistent constipation, abdominal symptoms, and soiling throughout and beyond childhood. There are no controlled studies in children devoted to the surgery of pediatric idiopathic constipation.

For pediatric patients who are refractory to all medical therapy, there are some viable surgical options. It is essential that organic causes of constipation are ruled out. The MACE procedure[63] that has been originally used for neuropathic incontinence or incontinence following management of anorectal anomalies has been successfully used also for idiopathic constipation.[64,65] The MACE procedure can be easily reversed, which may make it an attractive alternative for enemas and laxatives, especially for pubertal and adolescent patients. Resection of the megarectum and megasigmoid has been performed for patients with functional constipation, but there is a complete lack of controlled studies and longer-term follow-up data. Moreover, high failure rates have been reported following colon resections.[66] Colostomy has been used in selected patients with significant patient and parent satisfaction.[66,67]

## Functional Fecal Soiling Without Constipation

There is a small subgroup of children with fecal soiling who are otherwise healthy without constipation or any other organic or neuropsychiatric underlying cause for the incontinence.[68–71] A typical age of presentation is between 4 and 8 years of age. The main symptom is involuntary passage of variable amounts of stool to the underwear one to several times a day. The patients rarely soil at school or during sport and social activities. Most have regular bowel actions. At least one third of these patients suffer from daytime or nighttime wetting.

The authors have encountered an increasing number of such patients during the past decade.[72] Most of these patients had had extensive but unsuccessful therapies to treat constipation. No signs of neuropsychiatric disorders or myelopathy in MRI were observed. Patients had normal barium enemas and spinal radiographs. All had developed normally and went to normal schools. The incidence of daytime or nighttime enuresis was 40%. The only measurable functional abnormality was an isolated impairment of rectal sensibility at anorectal manometry; sphincter performance was comparable with constipated control individuals. Treatment consisted of counseling, toilet training, and dietary modification. Some patients, especially those with accompanying enuresis, benefit from anticholinergic treatment with oral oxibutynin hydrochloride (5 to 15 mg/day). Most patients improved with decreased frequency of soiling. All the patients who have reached adolescence have experienced striking improvement of soiling. The most important issue with this subgroup of patients with encopresis is to keep in mind that childhood fecal soiling is not always related to constipation.

## Rectal Prolapse

Rectal prolapse is a relatively common, usually self-limiting condition in children. The peak incidence is between 1 and 3 years of age. Prolapse can be either partial or complete. In partial prolapse the rectal mucosa protrudes only about 1 to 3 cm from the anal verge with characteristic radiating folds from the center of the anal aperture. In complete prolapse, the full thickness of the rectum is involved; 5 cm or more of the rectum protrudes, and the prolapse is distinguished by the circular folds of the mucosa (Fig. 104-2). There is significant controversy as to whether rectal prolapse in children is partial or complete.

### PATHOGENESIS AND DIAGNOSIS

The vast majority of patients suffering from rectal prolapse do not have any predisposing factors. The children suffering from idiopathic rectal prolapse are usually otherwise healthy. The role of constipation as an etiologic factor is controversial; only 3% of patients suffering from severe chronic constipation have rectal prolapse.[30]

Several organic conditions predispose to rectal prolapse. Cystic fibrosis is associated with rectal prolapse.[73] More than a fifth of the patients with cystic fibrosis develop rectal prolapse.[74,75] The neuropathic causes of complete rectal prolapse excluding myelomeningocele are rare. Nevertheless, paralysis of the levator ani with raised intra-abdominal pressure leads to procidentia and prolapse. In ectopia vesicae there is wide separation of the symphysis pubis and the puborectalis muscle, and this wide hiatus predisposes to prolapse of the pelvic organs including the rectum. Besides severe malnutrition, connective tissue diseases (e.g., Ehler-Danlos) and behavioral disorders (e.g., Asperger) predispose to rectal prolapse.

Iatrogenic full-thickness rectal prolapse may occur following pull-through operations for high anorectal anomalies. Much more common is mucosal prolapse that is usually not circumferential.[76] Rectal prolapse and mucosal ectopia were much more common before the era of the PSARP procedure.[77] Rectal polyps may be a leading point for a prolapse.

FIGURE 104-2 Rectal prolapse in a 2-year-old boy.

The diagnosis of rectal prolapse is usually based on history. Most commonly a rosette of rectal mucosa is noted after defecation. The child complains that something comes out of the anus. Usually the prolapse reduces spontaneously but must be sometimes reduced manually. In mild forms the prolapse comes out occasionally following major straining or during diarrheal illness. The problem is more annoying and worrisome for the patient and parents if the prolapse occurs after every defecation.

Usually the prolapse cannot be provoked when the child is brought to consultation. Rectal examination is indicated to rule out rectal polyps and ulcers. If there is a history of rectal bleeding, colonoscopy may be necessary to look for higher polyps or other lead points. Dynamic defecography is warranted at least when a prolapse is associated with rectal ulcer, suggesting intussuscepting prolapse of the sigmoid colon or accompanying enterocele.

### TREATMENT

In acute prolapse, reduction may occur spontaneously on standing up. If not, the prolapse must be reduced as soon as possible. The parents often rush the child to a hospital when the prolapse appears for the first time. The tip of the herniated bowel can usually be gently pushed into the anus. If edema has formed, a gentle squeezing pressure may be required. Reduction technique must be taught to the parents.

There is spontaneous cure in most cases of recurrent prolapse.[78] In many cases the prolapse reduces spontaneously. In cases without spontaneous reduction the parents can reduce the prolapse gently if appropriately instructed. Accompanying constipation is treated with laxatives when present. Local transanal treatments such as injections of the prolapse, multiple linear thermocauterization to the mucosa, excision of redundant mucosa, or insertion of a subcutaneous suture around the anus are not tested in controlled trials.

Operation is indicated in rare cases with intractable prolapse and may be considered in patients who are not spontaneously cured in 12 to 18 months of follow-up. Patients older than 4 years of age require surgery much more often than younger children. There are several surgical methods that have been used with success for recurrent prolapse. We prefer laparoscopic suspension of the rectum to anterior sacrum with routine suture closure of the space between the rectum and the vagina or the urinary bladder in order to avoid development of enterocele.[79] An additional resection of the sigmoid colon may be performed in intussuscepting prolapse of the sigmoid colon and in recurrent cases. Laparoscopic approach has been successful in nearly 20 patients that have required surgery. The procedure is associated with minimal postoperative pain and short hospital stay. Patients benefit from laxative therapy during the early postoperative period. Posterior sagittal approach with muscle repair and suspension of the rectum to the sacrum,[80–83] posterior rectal plication,[84] and Ekehorn rectosacropexy[85] are also reported to be associated with a high cure rate.

Secondary operation is indicated for iatrogenic prolapse after a pull-through operation in symptomatic patients. Typical symptoms include bleeding and leak of mucus. In patients with mucosal prolapse treatment involves excision

of the mucosal ectopia and reconstruction of a skin-lined anal canal with a local skin flap. Patients with a complete prolapse require a repeat posterior reconstruction of the levator funnel and external sphincter complex, as well as rectal suspension.

# Anal Fissure

Anal fissure is a longitudinal tear or ulcer in the distal anal canal epithelium extending to the anal verge. Most acute fissures heal spontaneously within a few weeks, but a proportion become chronic. Anal fissure is the most common cause of hematochezia in childhood, and it is one of the most common lesions to consider in the differential diagnosis of anal pain. Anal fissures are common, although their exact incidence in children is unknown.

## PATHOGENESIS

Pathogenesis of idiopathic anal fissure is still incompletely understood, and it may differ in adults and children.[86] Anal fissures in childhood are often associated with secondary constipation due to painful passage of stools. The classic concept of mechanical tear caused by hard stools as a primary causative factor may be too simple and outdated. However, deliberate avoiding of defecation does cause rectal distension and leads to decreased rectal sensation, which in turn, results in infrequent, bulky, and hard stools that prevent healing of fissure. Fear of painful defecation may lead to fecal retention and gives rise to a vicious circle.

There is a widely accepted theory on the pathogenesis of anal fissure in adults.[86,87] According to this theory increased internal sphincter pressure and muscle spasm lead to impaired tissue perfusion and finally epithelial ulceration. Spasm of internal anal sphincter is so severe that the pain caused by fissure is thought to be due to ischemia. The most common site of idiopathic anal fissure is posterior midline, which is less vascularized than other areas of the anal canal. Anal canal resting pressure is increased in patients with anal fissure. Decrease of anal canal pressure after surgical or pharmacologic sphincter relaxation is accompanied with improved perfusion of anoderm and healing of chronic fissures. Currently, it is unknown whether this theory also applies to pediatric patients. In children a vast majority of idiopathic anal fissures heal without any specific therapy. This may be due to relatively better tissue perfusion of the anal canal, greater regenerative capacity in general, or different pathogenesis in children than in adults. An unhealed fissure may become inflamed due to bacterial infection and chemical and mechanical irritation. As a result of long-standing inflammation, chronic anal fissure may have hypertrophied anal papilla proximally and a sentinel skin tag distally. This kind of chronic anal fissure is only rarely seen in children and should raise the suspicion of underlying Crohn disease.[88]

## DIAGNOSIS

Anal fissure may occur in any age. Typical age of presentation is around 2 years. Most often anal fissures present with bright red rectal bleeding that may be associated with painful defecation. The child may cry with bowel movements and have stools streaked with bright-red blood. Anal fissure is often but not necessarily associated with constipation, which is caused by fear of painful defecation.

The diagnosis is made by direct inspection. The typical longitudinal tear distal to the dentate line can be visualized by retracting the perianal skin gently away. No further diagnostic modalities are necessary. The most common location of idiopathic anal fissure is posterior midline, but especially in infants it may be found anywhere in the anal circumference. In female infants a common site of anal fissure is the anterior midline. A sentinel pile or skin tag at the area of the fissure is associated with chronic or subchronic fissure. Atypical fissures may be multiple and often off the midline and are commonly large and irregular. Atypical appearance of fissure should initiate further investigations including biopsy, cultures, and colonoscopy to rule out Crohn disease, immunodeficiency states, tuberculosis, venereal infection, and malignancies.

## TREATMENT

Most idiopathic anal fissures in children heal without any specific treatment in a few months.[89,90] Only symptomatic fissures require treatment. If fissure is associated with constipation and/or painful defecation, stool softening with dietary modification and bulk laxatives is indicated. Lubricants ease painful passage of stools. The goal is to interrupt the vicious circle of painful defecation, fecal retention, hard stools, and prevention of healing of fissure. As expected, most fissures respond promptly to stools softening and heal in several weeks.[89] Hematochezia stops when fissure heals. Occasionally a child presents with typical history after the symptoms have disappeared and the fissure has healed. Initially, these patients may be treated expectantly unless no abnormal clinical signs are present and hematochezia has not recurred.

Botulinum toxin injection into sphincter muscles in order to overcome increased pressure is a novel treatment for chronic fissures. Quick and effective healing has also been reported in children.[91] We use botulinum toxin injections into the internal part of the sphincter complex with a dose of 15-25 U, depending on the patient's age, into each of the four quadrants. Usually healing occurs in several weeks and injections may be repeated in refractory cases. After encouraging initial results in adults, several recent randomized placebo-controlled trials have assessed efficiency of topical glyceryl trinitrate in anal fissure in children.[89,90,92,93] Two studies reported faster healing of fissures and relief of symptoms in children treated with glyceryl trinitrate,[90,93] whereas no benefit was found in one.[89] Few children experienced temporary incontinence, and none reported headache during glyceryl trinitrate treatment.[89,90,93] Taken together, topical glyceryl trinitrate for anal fissures is only marginally better than placebo.[92]

Surgical therapies reported for treatment of anal fissure in children include fissurectomy, anal dilatation under general anesthesia, and lateral internal sphincterotomy.[94,95] Lateral subcutaneous sphincterotomy also appears to be an effective procedure in children.[94] Fissure cure rates (80%) after fissurectomy combined with laxatives are comparable with simple laxative therapy.[89,95] Anal dilatation causes unpredictable degree of sphincter damage and should be avoided. In adult patients, lateral sphincterotomy is associated with an

incontinence rate of 10%.[96] Anal stretch has a significantly higher risk of minor incontinence than sphincterotomy.[96] Outcomes of different surgical procedures for fissures are poorly characterized in children. Thus lateral internal sphincterotomy should be reserved for those rare children whose anal fissure has progressed to a real chronic fissure after treatment with botulinum toxin has failed. In these cases a biopsy should be obtained to rule out possible Crohn disease.

## Perianal Streptococcal Dermatitis

Perianal streptococcal dermatitis is a common cause of anal complaints (e.g., pain, itching, anal discharge, constipation) in preschool-aged children. The clinical finding of sharply demarcated wet perianal erythema is usually characteristic (Fig. 104-3). A positive culture of group A or B β-hemolytic streptococci from a perianal swab confirms the diagnosis. The treatment includes oral antibiotics for 10 to 14 days with penicillin V or cephalosporin and topical antimicrobial therapy.[97]

## Perianal Abscess and Fistula in Ano

Perianal abscess is not uncommon in small infants. The vast majority of patients are male.[98] A congenital etiology has been suggested for infant anal fistulas.[99,100] A proposed relationship to androgens resulting in congenital deep, epithelialized crypts may explain the predominant occurrence in male infants.[100,101] A typical presentation is a perianal abscess in a child younger than 12 months (Fig. 104-4), in the majority before the age of 6 months. After initial incision the condition may progress to or recur as an anal fistula. The incidence of fistula formation in patients with perianal abscess may be as low as 10% to 20%.[102,103] The fistula may present alone without preceding perianal abscess. The fistula is typically subcutaneous and straight. It usually traverses from the affected crypt through the subcutaneous external sphincter to the perianal skin. The fistulas are usually distributed evenly around the anal circumference. Multiple lesions occur in 15% to 20% of cases (Fig. 104-5).[103,104]

The traditional management of perianal abscess is incision and drainage. This is associated with a significant recurrence rate.[104,105] However, at the end of the day most abscesses are cured by expectant treatment only.[104,105] Fistula-in-ano has been considered as an indication for surgical treatment. The traditional method has been identification of the affected anal crypt and fistulotomy by deroofing of the fistula tract. Recurrent fistulas occur in 10% to 20% of cases. Recent reports have advocated expectant treatment for asymptomatic

FIGURE 104-3 Perianal streptoccoccal dermatitis.

FIGURE 104-4 Typical perianal abscess in a male infant.

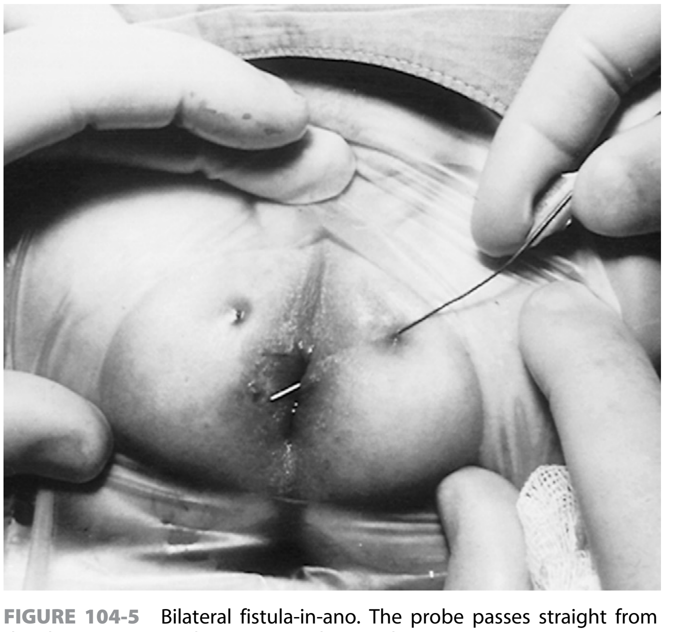

FIGURE 104-5 Bilateral fistula-in-ano. The probe passes straight from the skin opening to the corresponding anal crypt.

fistula-in-ano; most fistulas heal within 12 to 24 months without further sequelae.[104,105]

Fistulas in older children or adolescents are cryptoglandular or associated with inflammatory bowel disease, mainly Crohn disease. Crohn disease should be ruled out in all children who present outside the typical age groups, infants and adolescents. Treatment of adolescent fistula-in-ano should be along the same lines as in adults. The fistulous tract, once identified, is either incised and left open to granulate or excised with primary closure of the defect.

## Vascular Malformations

The classifications of intestinal vascular malformations have been confusing because different labels are laid on similar lesions without knowledge of their clinical and biologic properties. The classification of vascular malformations by Mulliken and Glowacki[106] is based on biologic properties of the lesion. The classification distinguishes between hemangiomas that are true neoplasms and usually regress spontaneously, and vascular malformations, which are nonproliferative lesions that do not regress. Intestinal bleeding from vascular malformations in children is rare. The most common sites are distal colon and rectum.[107] The vascular anomalies in the distal bowel are usually venous malformations and not hemangiomas as previously thought.[108] In the minority of cases the vascular lesion is part of a systemic disease such as Klippel-Trenaunay (congenital varicose veins, cutaneous hemangiomas, and ectatic hypertrophy of the lower limbs) and Osler-Rendu-Weber (multiple telangiectasia) syndromes.

A typical symptom of rectal vascular malformations is recurrent hematochezia that may sometimes be profuse. The patient may also present with hemorrhoids. The diagnosis of vascular anomalies may be difficult. In the distal bowel endoscopy may show findings that suggest localized inflammation. Dilated vessels are rarely visible. MRI and angiography are the best methods to diagnose and localize intestinal vascular lesions. Nonoperative methods may be used to control bleeding, but permanent cure is best achieved by complete resection of the lesion. Lesions that extend to the low rectum and anal canal are best treated by endorectal pull-through and colo-anal anastomosis.[109,110] This sphincter-saving operation eradicates bleeding episodes for long periods of time, if not permanently.

## Hemorrhoids

Hemorrhoids are uncommon in children unless in those with portal hypertension. One third of the children with portal hypertension have hemorrhoids. Hemorrhoids are more common in patients with extrahepatic portal hypertension than in those with intrahepatic disease.[111] Symptomatic hemorrhoids, however, are uncommon. Hemorrhoids in children may be associated with rectal vascular malformations.

Clinically detectable internal hemorrhoids with external extension occur also in otherwise healthy children but are rare (Fig. 104-6). We have seen approximately one to two healthy children with internal and external hemorrhoids per year during the past 15 years. Usually there are no symptoms, but the child or parents have noticed something to protrude

FIGURE 104-6 Hemorrhoids in a 5-year-old boy, without any underlying conditions. Note the typical adult type piles at 4, 7, and 11 o'clock.

from the anal opening. A more common finding, especially in constipated children, is a prominent venous plexus around the anal opening. This is a common source of rectal bleeding in constipated children. The venous sinuses of this venous plexus may rarely thrombose, causing similar symptoms as in adults with acute thrombosis of external hemorrhoids. Adult-type hemorrhoids begin to occur in adolescents and may be complicated by thrombosis of the external part of piles.

In otherwise healthy children hemorrhoids do not require surgical therapy. Major bleeding does not occur. Symptomatic patients with portal hypertension may require treatment. Banding or sclerotherapy controls the symptoms in most cases.[112]

## Solitary Rectal Ulcer

Solitary rectal ulcer syndrome (SRUS) is a chronic, benign disorder characterized by hematochezia, mucous discharge, tenesmus, and local perianal pain. It is rare in children but should be kept in mind in patients with local anal symptoms.[113,114]

In children the macroscopic finding at endoscopy is a thickened and edematous lesion that may have an ulcerative or polypoid appearance in the anterior rectal wall 2 to 5 cm above the anal verge. We have encountered 12 cases in the past 15 years. Some patients have a feeling of incomplete evacuation with frequent visits to the toilet associated with chronic straining at stool. Rectal or internal rectosigmoid prolapse has been reported to occur in a significant percentage of cases.[40] According to our experience, conservative management with stool softeners and local steroid suppositories is successful in most children. Open or laparoscopic rectopexy[113,115] has been suggested to correct the external or internal rectal prolapse that is often associated with SRUS; three of our patients have required rectopexy for recalcitrant symptoms.

## Infantile Proctocolitis

Apart from anal fissure, the most common cause of hematochezia in infants younger than 3 months of age is eosinophilic proctocolitis. The infantile proctocolitis typically presents at the age of 3 to 4 weeks with fresh blood streaks mixed in stools. The stools often contain mucus. Usually there are no other symptoms, and the growth and development of the infant is normal.[116] Colonoscopy shows colitis that is often patchy and rarely extends beyond the left colon. Histology reveals marked eosinophilic infiltrate. Some patients may also have an elevated eosinophilic count in peripheral blood. Allergic etiology has been suggested because of these findings but is found in a minority of cases.[117] The condition is self-limiting, and symptoms usually subside within a few weeks. Diet change has been also reported to be helpful in reversing the symptoms.[118]

## Proctalgia Fugax

Proctalgia fugax (PF) is a benign painful rectal condition that is defined as intermittent, recurring, and self-limiting pain in the anorectal region in the absence of organic pathology. There was also thought to be a male preponderance; however, more recently a female preponderance is reported.[119] The onset of symptoms is usually at school age or adolescence. The etiology of proctalgia fugax is unknown. Spasm of the anal sphincter complex is the most commonly suggested etiologic mechanism.

Rome III criteria define proctalgia fugax as recurrent episodes of pain that localize to the anus and lower rectum. The episode lasts from seconds to minutes, and there is no pain between episodes.[120] The condition is uncommon in children; the authors see approximately one to two new patients per year with proctalgia fugax. It is essential to rule out organic causes for anorectal pain before diagnosis of proctalgia fugax is made. Proctalgia fugax in children is a self-limiting condition that, however, may need treatment if episodes of pain are frequent and long lasting.

There no evidence-based management protocol for proctalgia fugax, but in most cases topical treatment with glyceryl nitrate cream or oral spasmolytics is helpful. Other options are oral clonidine or inhaled salbutamol. In recalcitrant cases local botulinum toxin injections may be helpful.[121]

## Sexual Abuse

Child sexual abuse is a common and worldwide problem. In Europe the incidence appears to be 6% to 36% of girls and 1% to 15% of boys younger than 16 years.[122] Sexual abuse rarely causes death, but its consequences can be serious and persist through adulthood. In child sexual abuse the significance of findings in the vagina and hymen are well recognized. In the context of anal abuse the findings are more controversial and difficult to verify.

Hobbs and Wynne[123] stated that "dilatation and reflex anal dilatation" are not seen in normal children and are signs of abuse. Reflex anal dilatation (even gross) was found on routine examination in 28 of 200 children (14%) examined consecutively in community health clinics, a pediatric outpatient clinic, a district hospital, and a rectal clinic.[124] Constipation or feces in the rectum, without associated sexual abuse, may often produce gaping of the anus on separation of the buttocks.[125] Hobbs and Wynne[126] also suggested that an anal fissure was a sign of abuse in 53% of 143 cases quoted. Pierce[127] found that the majority of children with strong or definite history of anal abuse had anal fissures or scars. However, an anal fissure is far too common a finding in routine clinical practice to be regarded as a cause for suspicion of sexual abuse.[128]

Obvious laceration, bruising around the anus or inner thighs, and scratches, especially with a suspicious or definitive history of abuse, are more conclusive. This sort of forensic evidence is rarely found in children because there is usually a significant time lapse between the abuse and medical examination.

If a child displays total passiveness and indifference to physical examination, or to inspection and examination of the anus, with no attempt to withdraw or tighten the striated muscle complex when a rectal examination is attempted, the clinician should be alert to the possibility of sexual abuse.

Perianal warts caused by the human papillomavirus should always raise the possibility of sexual interference because this is the most likely mode of transmission.[129,130] Although many studies suggest a high association with sexual abuse (60% to 90% of cases), recent studies have questioned this association, particularly in infants. Parents of children with condylomata often have warts on nongenital skin, and vertical transmission between mother and child has been well documented. The presence of condyloma acuminata in infants younger than 1 year of age may represent vertical transmission from the mother; older children must be treated with a high index of suspicion for child abuse.

CHAPTER 105

# The Jaundiced Infant: Biliary Atresia

Robert A. Cowles

## History

Biliary atresia was first described by John Thompson in 1892.[1] He detailed 49 clinical cases of congenital biliary obstruction and documented the autopsy findings in each case. In 1916 Holmes, a pediatrician and pathologist at Johns Hopkins University, reported his own case, reviewed previously reported cases, and concluded that successful surgical treatment for congenital atresia of the bile ducts was theoretically possible in at least 16% of cases.[2] Ladd was the first to report successful surgical correction of biliary atresia in cases where either the gallbladder or the common bile duct communicated with the liver.[3] This success led him to recommend a more aggressive surgical approach to cases of presumed biliary atresia. Despite this, a majority of infants do not have the favorable anatomy that was described by Holmes and Ladd and subsequent large series showed low success rates for surgery in cases of biliary atresia. From the late 1940s to the early 1960s several creative surgical approaches attempting to obtain bile drainage from the liver were used, but these were ultimately unsuccessful and subsequently abandoned.[4,5]

Diagnostic uncertainty made early surgery for biliary atresia an area of controversy during the 1960s. Thaler and Gallis felt that surgical manipulation was deleterious in cases of neonatal hepatitis and recommended a waiting period of 4 months before exploration for possible biliary atresia.[6,7] Other authors also reported that there was a possibility of spontaneous resolution of biliary atresia, further diminishing the potential merits of early operation. Finally, some believed that improved outcomes may be obtained after waiting for the course of the disease to progress with the hope that any ductal structures would enlarge, making repair more successful.[8–11] Outcomes for infants with "noncorrectable" biliary atresia remained dismal.

In the late 1950s Kasai and his colleagues in Japan noted that bile flow from the porta hepatis was possible after excision of the entire fibrotic extrahepatic biliary tree.[12–14] By surgically connecting the porta hepatis to the intestine (the duodenum in early cases), Kasai achieved the first long-term "cure" of a patient deemed to have the noncorrectable form of biliary atresia. Despite these encouraging initial results, Kasai's hepatic portoenterostomy did not gain immediate acceptance. Surgeons both in Japan and in the United States were initially skeptical of his results.[15,16] Over time, however, the outcomes associated with Kasai's hepatic portoenterostomy were confirmed[17,18] and in its most recent form, using a Roux-en-Y portoenterostomy, this procedure has become the standard operative treatment for biliary atresia.

Because many children develop progressive liver failure despite a technically well-executed hepatic portoenterostomy, salvage therapies are often necessary. Liver transplantation, popularized by Starzl in the early 1960s,[19] is the only readily available salvage treatment for children with biliary atresia and progressive liver dysfunction. In fact, biliary atresia is the most common diagnosis leading to liver transplantation in children.

## Incidence, Demographics, and Classification

Jaundice is a common finding in the newborn nursery and in young infants. In a majority of cases this hyperbilirubinemia is due to elevated unconjugated bilirubin and resolves spontaneously with no need for surgical consultation or intervention. It is important, however, to identify the rare infant who has persistent, pathologic jaundice beyond 2 weeks of life. These neonates should be presumed to have biliary obstruction due to biliary atresia or choledochal cyst or a cholestatic process due to a myriad of underlying causes, and a careful evaluation should be promptly undertaken.

Biliary atresia occurs in between 1 in 10,000 and 1 in 16,700 live births and this incidence has been consistent over time.[20–22] A slight predominance of females exists with a female-to-male ratio ranging between 1.4 to 1.7 to 1. No clear genetic factors have been associated with biliary atresia; however, the incidence of the disease appears to be higher in Asia than in Europe or North America.

Several systems have been proposed to classify the anatomy in cases of biliary atresia. The Japanese Association of Pediatric Surgeons proposed that cases should be classified according to the location of atresia. In their system, type I anatomy is

associated with atresia at the level of the common bile duct; in type II, atresia is at the level of the hepatic duct; and in type III, the most frequent type, atresia occurs at the porta hepatis.[22] The common anatomic variations are shown in Figure 105-1.

## Etiology

The exact etiology of biliary atresia is unknown and likely multifactorial. Theories implicating genetic, inflammatory, and infectious causes have been presented, but none has been proven. The higher incidence of biliary atresia in certain populations makes a genetic cause plausible. Moreover, the observation that up to 20% of biliary atresia cases are associated with other congenital malformations[22] (Table 105-1) implies a global developmental abnormality that may be under genetic control. Despite this, the occurrence of biliary atresia in twins is exceedingly rare, familial patterns have not been seen, and a clear genetic cause has not been found.

Theories suggesting an acquired, infectious etiology are supported by several findings. First, several viruses such as reovirus and rotavirus have been proposed as possible infectious agents responsible for the development of biliary atresia.[23,24] Animal models of perinatal viral infection produce biliary atresia,[25] although consistent viral isolation has not been possible in human cases.[26] In addition, given the high prevalence of these viruses, it would be expected that the incidence of biliary atresia would be higher if, in fact, viral infection was causative. Second, it appears that many cases of biliary atresia are acquired rather than congenital.[27] Up to 60% of infants who are found to have biliary atresia have been documented as having pigmented stools sometime during the postnatal period.[28] Third is the epidemiologic finding of seasonal clustering of biliary atresia cases during the winter months in some studies.[29]

Other proposed factors associated with biliary atresia include bile duct ischemia, abnormal bile acid metabolism, pancreaticobiliary maljunction, and the effect of certain environmental toxins.[30,31]

## Embryology

The biliary system originates from the hepatic diverticulum of the foregut at 4 weeks' gestation. This structure differentiates into cranial and caudal components, which give rise to the intrahepatic and extrahepatic bile ducts, respectively. It is during this period that the bile ducts undergo recanalization, eventually leading to an intact biliary tree. Errors in the recanalization process constituted early theories regarding the etiology of biliary atresia, but this is no longer believed to be correct.

## Pathology

The pathologist plays a central role in the diagnosis of biliary atresia and provides an important assessment of the structures present at the fibrous biliary remnant. Inflammation is invariably seen in liver biopsies and in resected specimens.[32–35] In the appropriate clinical scenario, a percutaneous liver biopsy can reliably aid in the diagnosis of biliary atresia. The finding of bile ductular proliferation in the liver biopsy is considered diagnostic for biliary atresia.[36,37] Associated findings often include bile stasis, periportal inflammation, identification of giant cells, and varying degrees of fibrosis.

Histologic evaluation of the fibrous remnant can reveal patency or partial patency of ductal structures or complete absence of these structures. This may depend on whether excision of the remnant occurred before or after inflammatory obliteration of the extrahepatic ducts. Identifiable

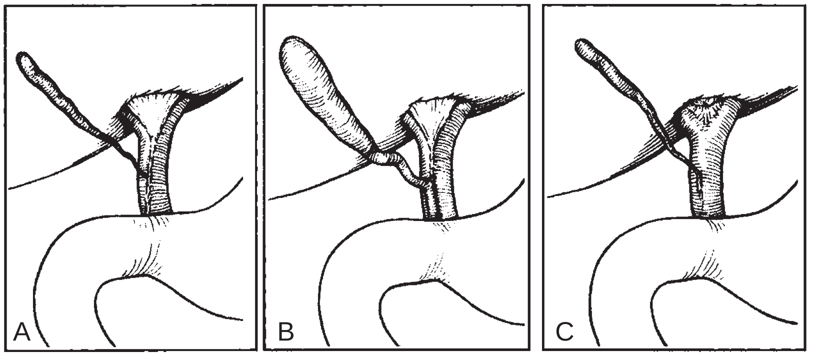

**FIGURE 105-1** Variants of ductal anatomy in biliary atresia. **A,** The most common pattern. Ducts are in continuity and obliterated from the porta hepatis to the common bile duct. **B,** The gallbladder, cystic duct, and distal common bile duct remain patent, but the hepatic ducts and porta are fibrotic. A cholangiogram in this case would show duodenal opacification, but no contrast would enter the intrahepatic ducts. **C,** Fibrous gallbladder with poor-quality tissue at the porta hepatis. (From Altman RP, Lilly JR, Greenfeld JR, et al: A multivariable risk factor analysis of the portoenterostomy [Kasai] procedure for biliary atresia: Twenty-five years of experience from two centers. Ann Surg 1997;226:348, discussion 353. Courtesy Lippincott & Wilkins.)

structures that can be found in the biliary remnant include bile ducts, collecting ductules, and biliary glands.[38] Of these, the ductules are ultimately responsible for bile drainage after the portoenterostomy procedure and, over time, these can form stable bile conduits (Fig. 105-2).

# Clinical Evaluation

## SIGNS AND SYMPTOMS

The combination of progressive jaundice, acholic stools, dark urine, and firm hepatomegaly in an infant should raise the suspicion for the presence of biliary atresia. Jaundice involves direct hyperbilirubinemia rather than the indirect hyperbilirubinemia seen in neonatal jaundice. In most cases, the perinatal course is unremarkable and meconium is described as normal. In more than 50% of cases, initial stools are considered pigmented.[28] Over time, stools take on a lighter color and become acholic due to biliary obstruction (Fig. 105-3). Eventually, signs of advanced liver disease such as palpable hepatomegaly and splenomegaly, ascites, failure to thrive, and malnutrition become present. If not treated, biliary atresia is fatal within the first 2 years of life with one study reporting a survival rate of less than 10% at 3 years.[20]

## DIAGNOSIS

Children with persistent jaundice, especially those with an elevated conjugated bilirubin, should be evaluated promptly to exclude the diagnosis of biliary atresia. No single test can reliably be used to differentiate biliary atresia from other causes of jaundice in the infant. For this reason, a combination of data obtained from a complete clinical assessment, blood tests, imaging studies, and pathologic evaluation is often used to arrive at a provisional diagnosis in almost all cases. The final diagnosis, however, is always confirmed at surgical exploration. The following evaluation is recommended as a useful guide.

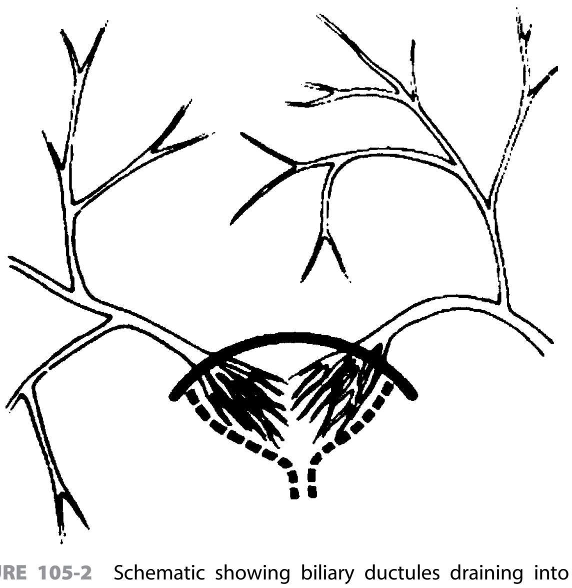

FIGURE 105-2 Schematic showing biliary ductules draining into the Roux limb as postulated to occur after successful hepatic portoenterostomy. (Courtesy M. Kasai, MD)

FIGURE 105-3 Gross appearance of acholic stool from an infant later confirmed to have biliary atresia.

## BLOOD TESTS

Standard serum “liver function tests” are uniformly obtained, but specificity is lacking. In biliary atresia both the direct and indirect bilirubin levels are elevated. The transaminases are also mildly to moderately increased. Alkaline phosphatase levels are often elevated in infants and children due to contribution from bone remodeling. For this reason, the gamma-glutamyl transpeptidase (GGTP) level can be used as a more specific indicator of hepatobiliary disease. Unless decompensated liver disease is present, tests of hepatic synthetic function such as the clotting cascade and serum albumin are normal.

In order to rule out conditions that can mimic biliary atresia, screening for perinatal infections due to members of the TORCH family (Toxoplasmosis, Other viruses, Rubella, Cytomegalovirus, and Herpes Simplex Virus) should be performed. In addition, screening for the presence of alpha-1 antitrypsin deficiency should occur.

## ULTRASOUND

Abdominal ultrasound is an easily obtained, simple, and noninvasive imaging study that can aid in the evaluation of infants suspected of having biliary atresia.[39,40] It should be obtained in the fasting state to allow for filling of the gallbladder, if patent, and the use of Doppler techniques can improve the accuracy of the study.[40] The echotexture of the liver, the presence of ascites, the patency of the hepatic vasculature, and the anatomy of the biliary structures can be assessed. Although the abdominal ultrasound does not secure a diagnosis in most cases, on occasion it can streamline the subsequent evaluation and management in specific situations. For example, the presence of a hilar cystic structure in the clinical setting of obstructive jaundice is sufficient information to proceed with surgical exploration with a presumptive diagnosis of cystic biliary atresia or choledochal cyst with obstruction.

In either scenario, relief of biliary obstruction should be provided as soon as feasible. Alternatively, an ultrasound appearance of dilated proximal bile ducts suggests the presence of inspissated bile syndrome, which may be treated by observation or, if needed, operative cholangiogram with or without biliary irrigation.

In almost all infants with biliary atresia, however, the ultrasound reveals that the gallbladder is either shrunken or normal appearing and the bile ducts are not easily delineated. In selected centers with extensive experience in the use of ultrasound in biliary atresia, an abnormal "cord" can be appreciated in the area of the portal plate.[41]

### HEPATOBILIARY SCINTIGRAPHY

Hepatobiliary scintigraphy relies on the use of isotopes of technetium 99m to assess excretion of bile from the liver into the small intestine and therefore biliary patency. The term "HIDA" (hydroxy iminodiacetic acid) scan is often used, but the technetium-labeled compound diisopropyl iminodiacetic acid (DISIDA) is more effective in the presence of significant cholestasis and therefore more commonly used. The usefulness of all hepatobiliary scintigraphy is diminished in the presence of severe jaundice, and this may cause errors in interpretation.

If time allows, all jaundiced infants undergoing hepatobiliary scintigraphy should be pretreated with phenobarbital (5 mg/kg/day) for 5 days before the study.[42] Presence of isotope in the intestine immediately confirms patency of the biliary system, and the diagnosis of biliary atresia can be excluded. Excretion of isotope may be delayed, however, in the presence of liver dysfunction. For this reason, a delayed assessment of isotope excretion at 24 hours is warranted. When no isotope is seen in the intestine after 24 hours, biliary obstruction is presumed and the diagnosis of biliary atresia must be further pursued.

## Liver Biopsy

A percutaneous liver biopsy can help differentiate biliary atresia from other cholestatic conditions with a high degree of reliability and should be considered the most accurate nonsurgical diagnostic test.[43,44] It is the most invasive of the diagnostic modalities but can be performed safely by an experienced pediatric hepatologist, or, if needed, by the surgeon. Typically, examination of several portal tracts by a well-trained pathologist will reveal important findings that can confirm or exclude biliary atresia. The presence of varying degrees of inflammation with ductular proliferation is considered compatible with the diagnosis of biliary atresia because these findings are not seen in other nonobstructive cholestatic syndromes. Further findings of bile stasis with plugging and giant cell transformation further support the diagnosis of biliary atresia. On the basis of the appearance of the liver biopsy, bile duct paucity syndromes can be readily differentiated from biliary atresia. In contrast, however, it can be difficult to differentiate between parenteral nutrition-associated cholestasis and biliary atresia on the basis of liver biopsy alone. This distinction should be made on the basis of the overall clinical assessment or, on rare occasions, at exploration when the diagnosis cannot be confirmed preoperatively.

## Other Tests

A combination of the previously described tests constitutes an adequate evaluation for biliary atresia, and operative therapy can be planned on the basis of these data. In some centers, however, other diagnostic modalities have been proposed. These adjunctive tests may be performed in certain circumstances but should not be considered part of the routine evaluation for biliary atresia.

Intubation of the duodenum via the nasoduodenal route with aspiration or prolonged collection of duodenal fluid can exclude biliary atresia if bile-stained fluid is obtained.[45] Although simple, this test is invasive, subjective, and similar in concept to the DISIDA scan, which is easily obtained in most centers.

Endoscopic retrograde cholangiopancreatography (ERCP) is a technique that is widely applied in the evaluation of biliary diseases in adults and older children. With improvements in endoscopic instrumentation, small side-viewing endoscopes that can be used in infants are available. Some authors have proposed ERCP as a useful adjunct in avoiding unnecessary exploration for presumed biliary atresia.[46] Because other less-invasive tests yield an accurate diagnosis in almost all cases, however, the practical use of ERCP is actually quite limited and is not currently recommended. Magnetic resonance imaging (MRI) techniques such as magnetic resonance cholangiopancreatography (MRCP) have superior accuracy in the diagnosis of biliary atresia.[47] MRI and MRCP, however, are expensive, sometimes require sedation, and have not been routinely used in most centers.

## Treatment

### PREOPERATIVE CARE

Infants with presumed biliary atresia should be prepared for exploration soon after diagnostic testing has been completed. Standard presurgical measures should be taken and, in general, children can be admitted on the day of surgery. A bowel preparation is not required, but a dose of broad-spectrum antibiotics should be administered before making the abdominal incision. Although most infants diagnosed with biliary atresia will have normal coagulation studies, poor absorption of the fat-soluble vitamin K can theoretically render them functionally vitamin K deficient. If possible, preoperative oral supplementation with fat-soluble vitamins (A, D, E, and K) or an intramuscular injection of vitamin K (1 mg) should be considered.

### SURGICAL TECHNIQUE

The Roux-en-Y hepatic portoenterostomy procedure (Kasai Procedure) is the standard initial operation for treatment of infants with biliary atresia. The operation involves excision of the entire extrahepatic biliary tree with transection of the fibrous portal plate near the hilum of the liver. Bilioenteric continuity is then reestablished with a Roux-en-Y limb.[13] The ultimate goal of the procedure is to allow drainage of bile

from the liver into the Roux limb via microscopic ductules in the portal plate. The conduct of the operation is described as follows.

The infant should be placed supine and on an operating table that will permit operative cholangiography, if deemed necessary. The exploration begins via a right upper abdominal incision. The left upper quadrant is examined, first searching for the spleen. Absence of the spleen or the finding of polysplenia can alert the surgeon to the presence of important associated anomalies such as malrotation, preduodenal portal vein, and interrupted inferior vena cava with azygous continuation. During evaluation of the left upper quadrant, adequate position of the tip of the nasogastric tube is also confirmed and the tube is secured by the anesthesiologist.

Next, the liver, biliary structures, and porta are inspected. The liver in biliary atresia can appear nodular and fibrotic with a greenish color. This finding is not common in neonatal hepatitis or bile duct paucity syndromes, where the liver is smooth and dark brown in color. Many infants with biliary atresia have a contracted, fibrotic gallbladder. If a rudimentary fibrous gallbladder is noted at initial exploration and if it clearly has no lumen, then the diagnosis of biliary atresia has been confirmed and the operation can proceed with dissection of the portal plate. If the gallbladder is normal-appearing or if it is felt to have a lumen, then additional intraoperative diagnostic maneuvers are warranted before dissecting the portal plate. In this situation, a purse-string suture can be placed in the fundus of the gallbladder and the fluid within the lumen of the gallbladder aspirated with an angiocath. If clear fluid (white bile) returns, then our approach has been to proceed with portal plate dissection without a cholangiogram. If, however, the aspirated fluid is darker in color or if there is any ongoing question regarding the diagnosis, then a cholangiogram should follow.

Although simple in concept, the cholangiogram can be difficult to perform and interpret successfully during this exploration. The following steps can be used to maximize the diagnostic yield of the intraoperative cholangiogram. First, a secure purse-string suture should be placed. A second purse-string suture can also be placed to prevent contrast leakage. Either an angiocath or a laparoscopic cholangiogram catheter can be placed into the lumen of the gallbladder before tying the purse-string suture(s). Diatrizoic acid (Hypaque or Gastrografin) is diluted 1:1 with normal saline and injected as the contrast agent via the cholangiogram catheter to assess for patency or obstruction of the biliary tree. Real-time, live fluoroscopy facilitates rapid intraoperative interpretation of the study. If contrast flows freely into the duodenum and into intrahepatic bile ducts, then patency of the biliary tree has been established and the diagnosis of biliary atresia excluded (Fig. 105-4). In this scenario, a wedge liver biopsy should be performed, the cholangiogram catheter removed, the cholecystotomy closed, and the operation concluded.

On occasion, contrast will flow freely into the gallbladder and down the distal common bile duct into the duodenum but not proximally into the intrahepatic bile ducts. This finding should be confirmed by occluding the distal common bile duct with an atraumatic "bulldog" clamp and reinjecting the cholangiogram catheter. This maneuver may encourage preferential filling of any patent proximal ducts that may have initially failed to opacify with contrast material when the distal resistance to flow was low. It is important to inject contrast gently because a speedy injection under pressure is likely to cause leakage of contrast around the purse-string suture, resulting in an obscured and confusing cholangiogram. Failure to delineate patent intrahepatic and extrahepatic biliary structures mandates that the surgeon proceed with portal dissection.

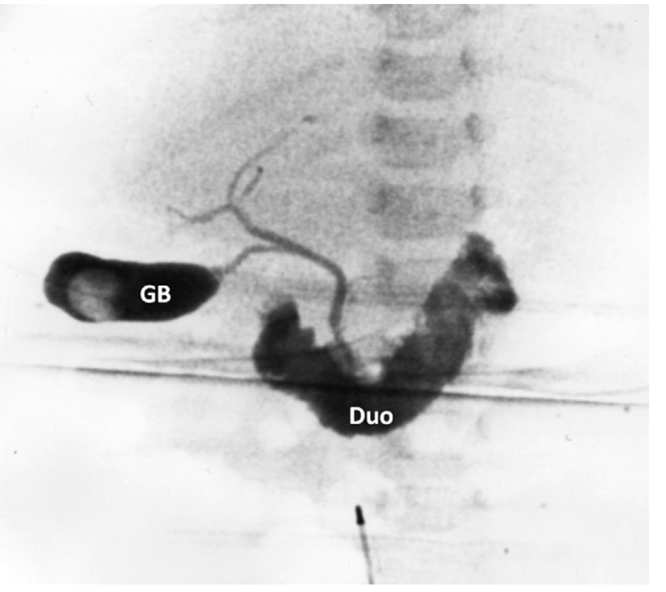

**FIGURE 105-4** Cholangiogram obtained during abdominal exploration for presumed biliary atresia. The gallbladder (*GB*) appeared normal, and an intraoperative cholangiogram revealed patency of the intrahepatic ducts to the duodenum (*Duo*). A liver biopsy was performed, and the procedure was concluded.

Regardless of the presence of a patent gallbladder or distal common bile duct, a direct Roux-en-Y hepatic portoenterostomy affords outcomes that are superior to other forms of reconstruction such as the portocholecystostomy.[48] Some surgeons gain exposure by dividing both triangular ligaments, thereby exteriorizing almost the entire liver.[49,50] This step is not necessary and likely disrupts lymphatics that may be responsible for the development of ascites. We have found that upward retraction of the liver to expose the porta affords excellent visualization of the critical structures and can be accomplished by assigning an assistant for retraction in the right upper surgical field or by carefully placing a fixed metal retractor with upward traction.

The peritoneum overlying the hepatoduodenal ligament is opened to allow identification of the structures in this area. The fibrous remnant of the distal common bile duct is often present here. It can be identified in the anterolateral aspect of the hepatoduodenal ligament, isolated and divided. Care should be taken to avoid injury to aberrant hepatic arteries that may be nearby. With traction on the cut end of the obliterated distal common bile duct, the fibrous biliary remnant can be dissected toward the porta. It is often necessary to dissect the right and left hepatic arteries away from the field in order to preserve them. During this dissection, the gallbladder remnant is also dissected away from the liver in continuity with the rest of the extrahepatic biliary remnant. As dissection continues proximally, the biliary remnant develops into a cone of fibrotic tissue that is located at the bifurcation of the main portal vein into its left and right branches. This constitutes the most important landmark during the dissection of the portal plate and should be the goal of every dissection.[51,52] In this

location it may be necessary to control several small portal vein branches to avoid inadvertent injury with subsequent bleeding. The absence of identifiable biliary remnant tissue or the finding of poor quality tissue at the expected location of the portal plate sometimes confuses the dissection. As stated earlier, the bifurcation of the portal vein should be used as a landmark and is especially important in such cases where the biliary remnants and portal plate are difficult to identify clearly.

Once the fibrous cone and portal plate region have been identified, the fibrous cone is placed on gentle traction and transected with sharp scissors or a knife. It is not beneficial to cut deeply toward the liver parenchyma because this may result in more scar formation and inhibition of bile drainage. Bleeding at the transected portal plate is controlled with pressure and placement of a surgical sponge in the area. Use of cautery on the portal plate is discouraged and should be minimized because this structure contains the fine ductules needed for success of the procedure. The resulting surgical specimen should be marked and submitted for routine pathologic evaluation. Careful measurement of the diameter of any biliary ductules by an experienced pathologist should be requested because this may provide important prognostic information. Although advocated by some,[53] we have not found frozen section to be helpful in guiding the level of transection.

With a completed portal plate dissection, the operation shifts to the construction of the Roux limb. The proximal jejunum is identified and transected about 10 centimeters distal to the ligament of Treitz. The distal end, destined for the right upper quadrant, is oversewn and the Roux limb is measured to 40 to 50 centimeters.[54] At this location, an end-to-side jejunojejunostomy is created with interrupted absorbable sutures. The oversewn end of the Roux limb is carefully brought into the right upper quadrant via a small defect created in the avascular portion of the transverse mesocolon.

The side of the Roux limb is opened, and the portoenterostomy is created. The posterior suture line is placed first using 6-0 absorbable suture with knots tied inside the lumen. Placement of these sutures must be exact with care taken to avoid injuring or impinging on the portal tissue. Once this posterior row is complete, the anterior sutures can be placed using similar care and precision. When complete, the entire surface of the portal plate must be contained within the jejunal lumen of the Roux limb. In this way, any bile drainage via biliary ductules at the portal plate will be contained within the Roux limb and proceed distally.

Before closure, it is advisable to close the mesenteric defect created by construction of the Roux limb and to anchor the Roux limb to the edges of the defect in the transverse mesocolon. These maneuvers are aimed at preventing internal herniation and at keeping the Roux limb in the right upper quadrant and without tension. A small closed suction drain is placed near the portoenteric anastomosis, and a wedge liver biopsy is routinely performed but likely not absolutely necessary. The abdomen is then closed using standard techniques. The completed operation is shown in (Fig. 105-5).

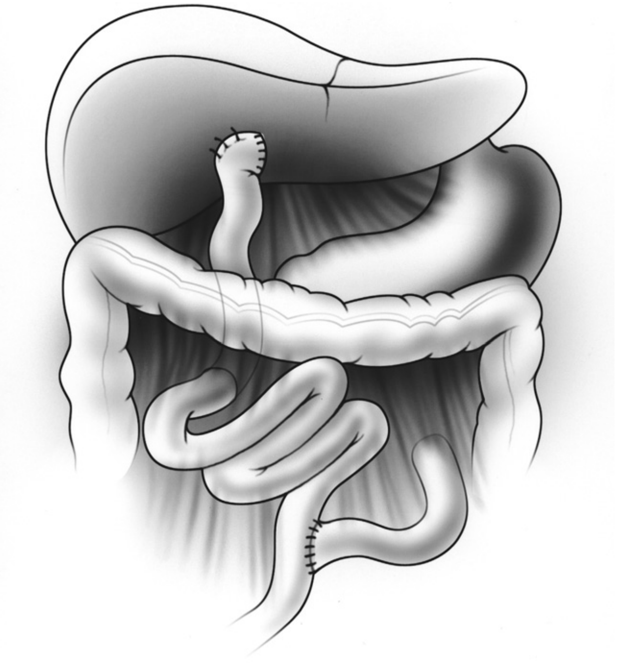

**FIGURE 105-5** Artist's rendition of the completed hepatic portoenterostomy procedure.

## SURGICAL CONTROVERSIES

Much of the controversy surrounding surgery for biliary atresia has subsided. Previously reported techniques with stomas to exteriorize the Roux Limb[28] or antireflux valves[28,55–57] have been subsequently abandoned either due to associated complications or lack of effectiveness.[58–60] Similarly, use of the appendix as a conduit between the liver and the small intestine has been proposed but its use has been limited with some reports suggesting an inferior surgical outcome.[61]

With the widespread application of minimally invasive techniques, even to the most complex operations, the laparoscopic Kasai procedure has been described and used at several centers worldwide.[62,63] Most reports, however, involve single cases or small series of carefully selected patients. A recent prospective trial confirmed the feasibility of the operation but revealed a significantly poorer outcome at 6 and 24 months, causing the trial to be stopped.[64] Outcomes of other series have been variable,[65] and therefore the laparoscopic Kasai procedure currently lacks support among general pediatric surgeons including those who specialize in minimally invasive pediatric surgery. Laparoscopic techniques may be used to perform the exploration and cholangiogram.

Some investigators have proposed that primary liver transplantation be considered the initial treatment for infants with biliary atresia, citing deleterious effects of the Kasai procedure on subsequent liver transplantation, if needed. This approach, however, would subject a percentage of children to the dangers of transplantation and its associated short- and long-term complications who would have been cured by the Kasai procedure. For this reason, primary liver transplantation has been reserved for selected cases such as delayed diagnosis with severe liver failure where a Kasai procedure would be risky and have a high failure rate.[66–68] For all other children with compensated liver function and a timely diagnosis, the Kasai procedure and liver transplant are considered by most to be sequential, complementary procedures.[69]

### POSTOPERATIVE CARE

Drainage of gastric secretions with a nasogastric tube should continue for the first 48 hours, and the tube can usually be removed at this point. By the second or third postoperative day, infants often have already passed gas and stool and an oral diet can be started. Intravenous antibiotics are administered until the child begins feeding, and this is subsequently converted to long-term oral antibiotics that are continued at discharge. The closed suction drain is removed before discharge, typically on the fifth postoperative day. Antibiotics, a choleretic agent, fat-soluble vitamin supplements, and an oral steroid taper have been the routine for our group (Table 105-2), although the support for the use of steroids is not universal as discussed in the next section.

### STEROID CONTROVERSY

Steroids are known to have antiinflammatory and immunosuppressive effects. Their use in patients with biliary atresia with its significant inflammatory component is therefore logical. In addition, steroids have been postulated to have a choleretic effect, making them even more attractive in this patient population. Despite this, definitive evidence for the beneficial effects of adjunctive steroids in biliary atresia has been elusive. First, attempts to prove the choleretic action of steroids were not successful.[70] Second, many studies commenting on the efficacy of steroids are retrospective and contain confounding factors that make it impossible to comment on the isolated effects of steroid treatment. Finally, studies often appear underpowered to allow definitive conclusions.[71,72] For these reasons, it is not surprising that one study found that perioperative steroids were used in less than 50% of patients in the United States between 2003 and 2008.[73]

The paucity of data regarding the utility of steroids may be changing, however. A recent randomized, double-blind, placebo-controlled trial of corticosteroids after hepatic portoenterostomy revealed that steroids resulted in accelerated clearance of jaundice but did not result in improved survival of the native liver.[74] A current study by the biliary atresia research consortium in the United States is also attempting to address this question systematically. The results are pending.

Adverse sequelae of steroid use are not commonly reported. Fluid retention and appetite suppression are minor side effects, but major steroid-related complications such as infection and wound breakdown have not been problematic. Given that the evidence supporting steroid use is currently stronger than the evidence against it, our group has incorporated a protocol for postoperative steroid administration (see Table 105-2).

**TABLE 105-2**
**Postoperative Medical Regimen After Hepatic Portoenterostomy**

| Vitamins ADEK drops—1 mL/day |
| Prednisone—2 mg/kg/day and taper over 6 weeks |

## Outcomes

Over the past 50 years, the hepatic portoenterostomy procedure has dramatically improved the outlook for infants diagnosed with biliary atresia. Before the introduction of the hepatic portoenterostomy, few surgical options were available for treating infants with biliary atresia. A review of 89 patients who were explored for biliary atresia before the advent of formal surgical correction revealed a "cure" rate of 1.1% (1 of 89) and a known mortality of 94% (84 of 89).[75] The current 30-day mortality is low, ranging between 0% and 5%, reflecting the safety of the hepatic portoenterostomy.[61,69]

An important initial observation is the color of the stool after hepatic portoenterostomy. Pigmented stools either immediately or within the first 10 to 14 days after surgery suggest successful bile flow from the liver to the intestinal tract. This occurs in two thirds of patients, on average.[59,61,69] Of these patients who have documented bile flow, half will continue to drain bile well, with efficient clearance of jaundice and normal development. This is considered a "cure," and liver transplantation is not necessary.

In the remaining patients who initially had good bile drainage, ongoing inflammation and scarring of the liver will lead to progressive liver failure. Jaundice, which may have initially cleared completely or partially, returns. Signs of portal hypertension and failure to thrive eventually appear, and liver transplantation is therefore required. In this patient population that had initial successful palliation, liver transplantation occurs at a mean age of 5.4 years.[69]

The remaining patients (15% to 30%) who continue to have acholic stools after hepatic portoenterostomy never experience clinically relevant bile drainage. Jaundice continues to worsen, and the liver fails within months. In these infants an evaluation for liver transplantation, either cadaveric or living related, should commence before the arrival of true end-stage liver disease.

The 10-year survival after hepatic portoenterostomy has improved over time. Initial improvements were likely due to refinement of the portoenterostomy procedure, while more recent gains have been made in the technique of liver transplantation and in immunosuppressive strategies and medications. A biliary atresia registry report from the United States in 1990 found 5- and 10-year survival rates of 48% and 30%, respectively,[20] while a report from our center in 1997 found a 20-year survival rate of 49%.[69] A recent multicenter study in the United States reported a 2-year overall survival rate of 91% with a 56% native liver survival and 40% liver transplant rate.[76] Studies from other countries including Japan quote similar statistics.[21,22,56,61,77]

Long-term patient outcomes beyond liver function are available. Abnormalities in menstruation and pubertal disorders occur and are closely related to liver function. These findings suggest that hepatic function is deteriorating and transplantation will eventually be necessary. When transplantation occurs, menstrual abnormalities have been shown to improve.[78] Pregnancy can be challenging for patients who have been treated with hepatic portoenterostomy for biliary atresia. Progression of liver disease with development of portal hypertension has been documented during gestation.[78] Newborns can be small but are generally healthy. The postpartum period has also been documented as complicated.[79]

These data suggest that great care should be taken in counseling former biliary atresia patients regarding pregnancy, and careful monitoring is indicated when pregnancy is being considered.

Psychosocial outcomes have been reported in long-term survivors of the hepatic portoenterostomy.[78] This study of 44 patients with long-term follow-up revealed that almost all patients (93%) are functioning well in society with high levels of employment and education. Psychologic morbidity was present, however, in 18% of this population.

### OUTCOME VARIABLES

A variety of factors appear to play a role in the outcome after hepatic portoenterostomy for biliary atresia. Age at operation, operative technique, severity of liver disease, gross and microscopic aspects of the biliary tree and portal plate, and the presence of comorbid conditions are a few of the many variables that can affect outcome.

Strong evidence suggests that age at operation is an important factor in outcome, and this is supported by multiple reports.[69,80–84] The exact cutoff, however, where outcome from surgery becomes predictably poor, is unknown. This may be due to the existence of several distinct pathologic forms of biliary atresia. In fact, recent studies suggest that age at surgery may be a factor only in certain subsets of children such as those with cystic biliary atresia or those with biliary atresia splenic malformation as compared with those who present with isolated biliary atresia.[85] In our series, infants operated on at 0 to 49 days had equivalent outcomes when compared with those who underwent operation at 50 to 70 days of age. Those explored at 71 days or older had a statistically higher rate of failure when compared with both of the younger groups.[69] In the Japanese experience, the better outcomes were seen until the age of 90 days with subsequent worsening outcome after 90 days.[22] Therefore it is the goal at most centers to accurately obtain a provisional diagnosis of biliary atresia and successfully operate before 70 to 90 days of life. It is important to note, however, that hepatic portoenterostomy is not contraindicated after 90 days of age. A study of older children ($\geq$100 days) revealed acceptable survival rates, supporting the use of the procedure, if possible, even in older infants.[86]

The gross appearance of the biliary tree appears to influence outcome. Patients with a patent gallbladder had better outcomes when compared with those with complete fibrosis or complete absence of the fibrous cone of the portal plate.[16]

The size of ductules that are present at the level of the portal plate seems to be related to prognosis. It is logical that larger ductules allow for more efficient drainage of bile and therefore would result in an overall better outcome. Our series found that bile drainage was universal in patients with ductules greater than 150 micrometers, occurred in 86% of those with ductules less than 150 micrometers, but was only seen in 12% of those with no identifiable ductules.[69] Other studies have supported these findings.[34,38,87–90]

The experience of the surgeon and the center has been suggested as a factor in outcome of hepatic portoenterostomy. Our study revealed inferior outcomes in patients who had surgery in the 1970s, possibly reflecting a learning curve regarding surgery and the care of these patients.[69] Recent studies in the United Kingdom[91] and in France[92] also suggest that experienced centers and centralization of care for patients with biliary atresia produce superior outcomes. These national health policies, however, have not been implemented in many countries and long-term outcome differences are pending.

## Complications

### NUTRITIONAL COMPLICATIONS

Nutrition with a well-functioning hepatic portoenterostomy follows a normal course. Specialty formulas and vitamin supplements, if used, can often be discontinued after several months without harm. In the face of ongoing or progressive liver dysfunction, however, weight gain can be affected and metabolic complications may occur.[93] Nutritional parameters, vitamin levels, and growth should be monitored over the long term. In fact, some authors suggest that growth failure is an important marker for liver disease and an indication for liver transplantation in biliary atresia.[94]

### CHOLANGITIS

Cholangitis is the most common complication of the hepatic portoenterostomy and occurs in 33% to 60% of patients.[54,77,95] Cholangitis occurs most frequently during the first several years after initial surgery. Because cholangitis causes liver injury and promotes accelerated development of cirrhosis, prevention and active treatment are important adjuncts during the postoperative period.

The exact cause of cholangitis is unknown, although reflux of intestinal contents via the Roux limb, portal venous infection, impaired lymphatic drainage at the porta, and bacterial translocation have been proposed. Intrahepatic biliary stasis due to the fibrotic ductal obstruction is also felt to play a role in the pathogenesis of cholangitis. The offending organisms have been identified as enteric gram-negative and anaerobic bacteria, further supporting an enteric source for the condition.[96]

The clinical signs of cholangitis include fever, diminished bile flow, jaundice, and sometimes abdominal pain. Blood testing will reveal leukocytosis, elevated serum bilirubin, elevated hepatic enzymes (transaminases, alkaline phosphatase, and GGTP), and inflammatory parameters such as C-reactive protein.

Treatment of cholangitis is aimed at the presumed infection and the ongoing inflammation. The mainstay of treatment includes intravenous fluids, broad-spectrum intravenous antibiotics including coverage of anaerobes, and choleretic agents. Steroids are indicated for their ability to decrease inflammation and edema of the periductular areas.[97]

Prevention of cholangitis is an important goal. An adequately constructed Roux limb is a surgical maneuver that aids in prevention of cholangitis. Similarly, postoperative use of oral antibiotics is generally felt to be efficacious as a preventative measure. Studies have shown that use of trimethoprim-sulfamethoxazole or neomycin appeared to delay the onset and reduce the number of episodes of cholangitis compared with historic controls.[98] The use of steroid pulses during the postoperative period has also decreased the frequency of this complication.[99]

A surgical approach to revise a failing hepatic portoenterostomy with recurrent jaundice or unrelenting cholangitis

has been attempted.[48,100] Hasegawa reported the results of attempted revision of the hepatic portoenterostomy in 25 patients who did not drain effectively after the initial operation.[101] Only five patients had improvement in jaundice, a similar result to a series from the United States in which two of seven children were helped by a re-do portoenterostomy.[48] A similarly low success rate has been shown for surgical revision of the hepatic portoenterostomy in children who develop severe, intractable cholangitis.[22,102] Given these discouraging outcomes, the possibility that repeated operations can negatively affect the eventual success of liver transplantation, and in an era where liver transplantation has improved dramatically, operative approaches to rescue a failed or failing portoenterostomy are not recommended.

## PORTAL HYPERTENSION

Portal hypertension occurs in 34% to 76% of children and young adults after hepatic portoenterostomy and can occur despite a seemingly excellent result from the point of view of bile drainage.[103,104] Ongoing intrahepatic inflammation, often manifested as recurrent cholangitis, is likely responsible even when jaundice clears.

The most common finding in patients with portal hypertension is ascites, occurring in more than 60%. Esophageal varices, the most feared sequela of elevated portal pressure, occur in nearly half of patients who are followed for more than 3 years. Surveillance endoscopy therefore is indicated, especially in cases where progressive liver dysfunction is suspected. No clear recommendations are available for the frequency of surveillance endoscopy; however, yearly or semiannual examinations have been recommended. When varices are identified endoscopically, prophylactic sclerotherapy has shown benefit in randomized trials.[105]

Bleeding from esophageal varices can be massive and life threatening. Treatment consists of endoscopic sclerotherapy, often requiring multiple sessions.[77] Other interventions that can aid in treatment include use of octreotide or beta-adrenergic blockers or variceal ligation.[106–108] Although concerning, variceal bleeding should not prompt urgent consideration of liver transplantation and does not signify the arrival of end-stage liver disease.[77]

Portal hypertension–associated hypersplenism occurs in 16% to 35% of patients after portoenterostomy, and the associated thrombocytopenia can complicate episodes of gastrointestinal bleeding from varices or other causes.[109] Although splenectomy, portosystemic shunting, and splenic embolization have been described,[110] evaluation for liver transplantation is the most prudent option in patients who develop this serious secondary complication of portal hypertension.

## LIVER TRANSPLANTATION

Liver transplantation is covered in a separate section of this textbook. Nevertheless, it is mentioned here because liver failure due to biliary atresia represents the most common indication for liver transplantation in the pediatric age group. The general indications for liver transplantation in biliary atresia include (1) failure of initial portoenterostomy with no bile drainage and progressive liver disease; (2) episodic or inefficient bile drainage with slow deterioration of liver function and development of growth failure; and (3) development of one or more complications of chronic liver disease such as cholangitis or portal hypertension that cannot be easily managed despite an apparently functional portoenterostomy.

Thankfully, death on the transplant waiting list is uncommon. Improvements in allocation of organs using the pediatric end-stage liver disease system, based on several markers of severity of disease, result in transplantation in the most severely affected first. In addition, two techniques have resulted in an increase in the number of available organs. First was the technique of splitting or rescuing the size of organs for use in children,[111] and the second is the development of living-related liver transplantation.[112] These techniques have been applied in liver transplantation programs worldwide with excellent success.[113–115]

With continual improvement in the outcomes of pediatric liver transplantation, some have questioned whether primary liver transplantation without an initial attempt at hepatic portoenterostomy is indicated.[68,116,117] At this juncture, however, most believe that a well-executed hepatic portoenterostomy is the best initial surgical treatment for biliary atresia. This opinion is based on several important observations: (1) Nearly half of infants who undergo hepatic portoenterostomy obtain bile drainage and maintain either excellent or adequate liver function after surgery. Even in those who eventually progress to end-stage liver disease, transplantation is delayed by having undergone hepatic portoenterostomy first; (2) The improved but still insufficient supply of donor organs would make primary liver transplantation logistically challenging; and (3) A subset of children who would have been "cured" by the hepatic portoenterostomy would be unnecessarily exposed to the morbidity (surgical, infectious, and oncologic) and mortality of liver transplantation. At this point, therefore, liver transplantation remains the most important rescue therapy for children with biliary atresia after portoenterostomy with 5-year survival rates expected to exceed 90%.[118,119]

CHAPTER 106

# Choledochal Cyst

Kelly D. Gonzales and Hanmin Lee

Choledochal cyst is a congenital anomaly involving cystic dilation of various ducts of the biliary tree. They are relatively rare in the Western world but more common in Asia. Several hypotheses exist as to the etiology of choledochal cysts including pancreaticobiliary maljunction. Three patterns of presentation have emerged since Alonso-Lei and colleagues published their landmark paper describing their classification of ductal dilation. The first is a cystic mass in the abdomen identified prenatally, the second is jaundice presenting in infancy, and the third is ascending cholangitis, obstructive jaundice, or pancreatitis presenting later in childhood or in adulthood. Regardless of the time of presentation, surgical intervention is indicated to mitigate potential damage to the liver, prevent jaundice and pancreatitis, and prevent cancer.

## Epidemiology and Etiology

The incidence of choledochal cyst ranges from 1 in 100,000 to 150,000 live births in Western populations with the incidence in the United States reportedly as high as 1 in 13,500. Choledochal cysts are significantly more common in Asia, with rates as high as 1 in 1000 in Japan. There is a well-documented female dominance (3 to 4:1) that contributes to the belief that choledochal cyst is sex-linked.[1–3] Familial cases have been recognized, but no genetic basis has been evident. The majority (≈60%) of choledochal cysts are diagnosed in the first decade of life. Roughly 20% remain undiagnosed until later in childhood or adulthood, and the remaining 20% to 25% of cases are diagnosed prenatally. Prenatal diagnosis of choledochal cysts is increasing in frequency,[2] as is the number of cases diagnosed in adulthood in the United States and Europe, perhaps due to higher index of suspicion or improved imaging techniques.

The etiology of choledochal cyst remains unknown but is commonly accepted to be congenital in nature. Distal obstruction, weakness of the duct wall, or a combination of the two are the predominant hypotheses.[4–6] The etiologic basis for choledochal cyst is likely multifactorial. In 1852 Douglas reported that there is potential congenital weakness of the common bile duct in the common fusiform type.[5] In 1936 Yotsuyanagi reported that the defect is due to failed formation in the early embryologic development of the biliary system from an overproduction of epithelial cells, leading to a dilated common bile duct.[7] This hypothesis is now largely regarded as unlikely, however.

In 1916 Kozumi and Kodama recognized an anomalous junction between the bile and pancreatic ducts during an autopsy case with choledochal cyst.[8] In 1969 Babbitt described the "long common channel" theory, also known as *pancreaticobiliary maljunction* (PBM), which is commonly seen in association with choledochal cyst.[9,10] PBM is a rare congenital anomaly described as a proximal insertion of the pancreatic duct into the common bile duct as a result of incomplete migration of the choledochopancreatic junction into the duodenal wall, creating a "long common channel." In 1984 Todani and colleagues were able to show PBM through analysis of endoscopic retrograde cholangiopancreatography (ERCP).[11] In fetal development, PBM creates a nidus for reflux of pancreatic enzymes into the common duct that causes damage to the ductal wall and leads to cyst formation. Due to the reflux, PBM is also commonly associated with carcinoma of the bile duct and gallbladder. Distal obstruction at the level of the duodenum is an additional factor leading to damage of the ductal wall and causing formation of a saccular dilation.[11–15] Investigators have proposed various mechanisms related to distal ductal stenosis such as an abnormal ductal insertion into the duodenum, distal common bile duct stenosis, persistent epithelial web, valve dysfunction, or neuromuscular irregularity of the sphincter.[13] PBM has a reported 3% incidence.[16] PBM is commonly associated with choledochal cysts and carcinoma of the biliary duct and gallbladder. The majority of choledochal cysts are associated with PBM; however, PBM can be seen without an associated choledochal cyst in 20% to 30% of cases. Carcinoma of the gallbladder and, less frequently, the bile duct remains an association with PBM even without ductal dilation.[16]

Other types of choledochal cysts, specifically choledochocele and Caroli disease, have different proposed etiologies. Choledochocele has two main variations as described by Manning and colleagues.[17] In the most common variation, the common bile duct and pancreatic duct enter the duodenum separately. In the second variation, a common bile duct diverticulum arises at the level of the ampulla of Vater with the pancreatic duct entering the distal common bile duct in its normal anatomic variation. The formation of the diverticulum is thought to be due to either an obstruction of the ampulla and a low insertion or a congenital duodenal duplication. Caroli disease is believed to arise from an arrest in the twelfth

week of gestation in the ductal plate at the level of the large ducts of the hilum. This is distinct from Caroli syndrome, in which there is arrest of the small ductules of the periphery.[18,19] Caroli disease has been associated with polycystic kidney disease.[1,20–22] Overall, the etiologic background of choledochal cyst is congenital in nature, resulting from reflux of pancreatic enzymes causing damage to the bile duct wall and complete or partial distal obstruction of the bile duct.

## Embryology

In normal development the fourth week of gestation marks the formation of a hepatic diverticulum extending from the ventral aspect of the foregut. Thus the biliary structures are endodermal in nature. The diverticulum progresses to cranial and caudal buds. The liver and extrahepatic biliary tree form from the cranial bud and the caudal bud becomes the superior and inferior buds. The gallbladder and cystic duct are derived from the superior bud, and the inferior bud gives rise to the right and left ventral pancreas. There is some controversy regarding whether there is a solid phase to the biliary tree early in gestation and eventual recanalization or whether the biliary tree has a continuous lumen.[23] At the sixth week, the ventral pancreatic bud and common bile duct rotate around the duodenum clockwise by 180 degrees. The common bile duct at this point enters the duodenum at the left posterior surface. In the seventh week the main pancreatic duct (Wirsung duct) and common bile duct junction ends in the developing duodenum as closed cavities through elongation to form the ampulla of Vater. The junction retracts in the eighth week of gestation to reside in the submucosa of the duodenal wall. A concentric ring of mesenchyme forms around the junction of the pancreatic and biliary ducts, beginning the formation of the sphincter of Oddi. In the twelfth week of gestation, the main pancreatic and common bile ducts are obliquely arranged in the duodenum. PBM is believed to arise from a misarrangement of the pancreatic and common bile duct and not due to the pancreaticobiliary system or termination of the junction migration as once thought.[24]

## Anatomic Classification

The original anatomic classification of choledochal cysts included types I, II, and III.[4] After review of cholangiograms, Todani and colleagues broadened the classification into five types with some subtypes (Fig. 106-1).[25,26] Type I is by far the most common, accounting for 90% to 95% of cases,[4] and constitutes the cystic/saccular or fusiform dilation of the common bile duct.[27] Type I is divided into three subtypes (types Ia, Ib, and Ic). Type Ia consists of cystic dilation of the entire common bile duct. Type Ib is cystic dilation of a segment of the common bile duct, and type Ic is fusiform dilation of the common bile duct. Type II is a diverticulum of the common bile duct with no dilation of the common bile, extrahepatic, or intrahepatic ducts. Type III, also referred to as a *choledochocele* (Fig. 106-2), usually has a normal common bile duct and main pancreatic duct with cystic dilation of the distal common bile duct that is either intraduodenal or intrapancreatic in location. The ducts may either enter the choledochocele separately or in union at the wall of the duodenum, but are usually stenotic at their openings due to chronic inflammation. Type IV is composed of multiple cysts located intrahepatically, extrahepatically, or in both locations. Type V comprises single or multiple intrahepatic cysts without extrahepatic duct dilation. Type V cysts in conjunction with hepatic fibrosis are commonly referred to as Caroli disease.

## Pathology

The gross pathology of choledochal cysts is largely described in the anatomic classification section earlier. As described, choledochal cysts can occur in the intrahepatic ducts, the common bile duct, intraduodenally, or in a combination of

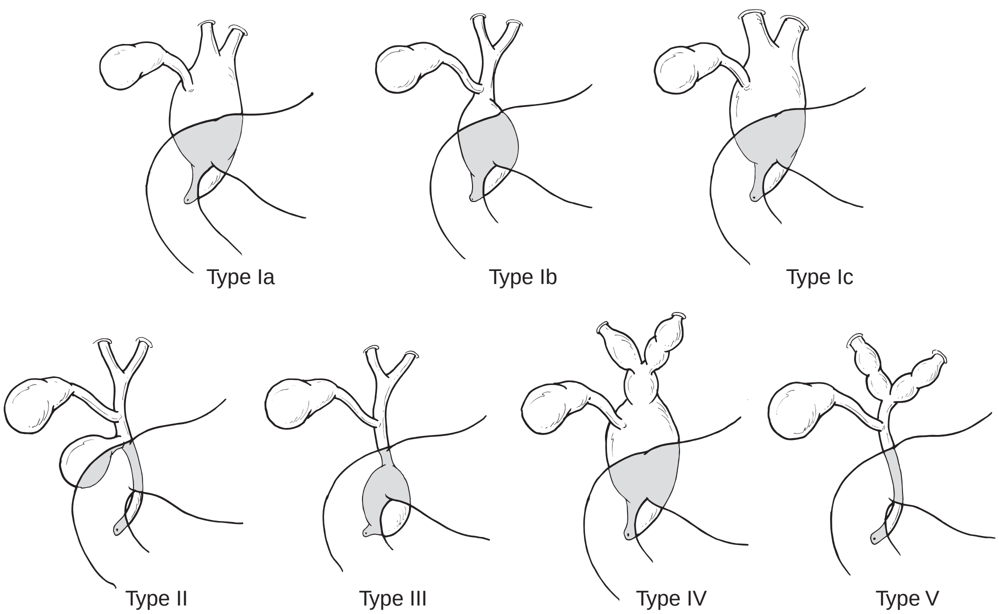

**FIGURE 106-1** Classification of the five major choledochal cyst forms and some subtypes.

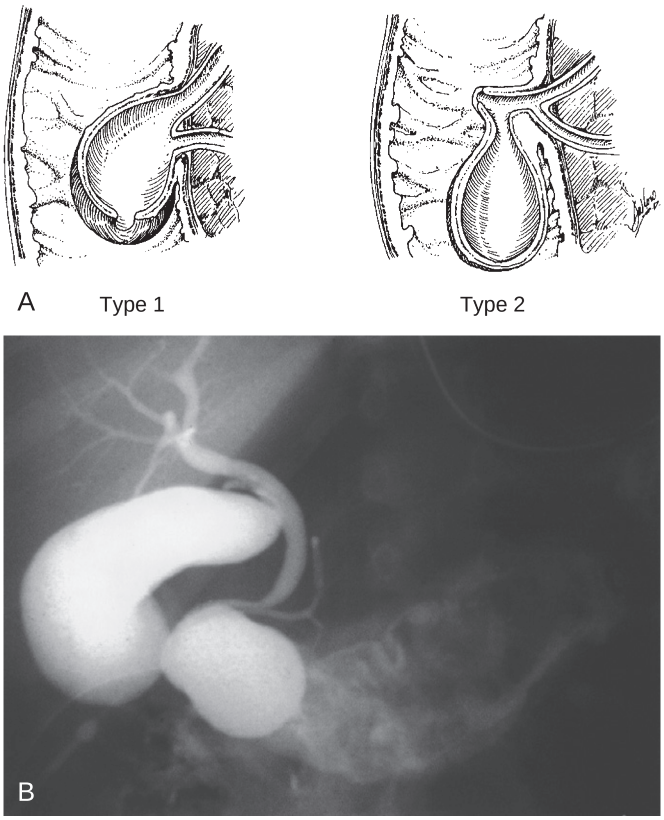

FIGURE 106-2 Two types of choledochoceles. (**A** from O'Neill JA: Choledochal cyst. Curr Probl Surg 1992;29:374. Used with permission.)

locations. The dilation is primarily fusiform. Pancreaticobiliary maljunction is common, as is stricture of the common bile duct. Sludge, cholelithiasis, or choledocholithiasis is commonly found with choledochal cysts.

The histopathology depends on patient age and severity of symptoms. The extrahepatic ducts are thickened with dense connective tissue intermixed with smooth muscle strands. Inflammatory reaction is usually present but may be minimal in the infantile stage. Generally, the inflammatory reaction increases with age and may lead to ulceration in the mucosa and submucosa. The inflammation can extend through the cyst leading to possible adherence to adjacent structures. The most marked inflammation is noted in the intrahepatic cysts. The lining of the cyst is not composed of typical biliary mucosa but rather is relatively acellular and may lack a typical mucosal lining. In the wall of the cyst, mucin-secreting cells are seen in intramural glands. A gastrointestinal mucosa-type composition of immunoreactive gastrin- and somatostatin-containing cells may also be found in the cyst wall due to repeated destruction and regrowth causing epithelial metaplasia. Small areas of columnar epithelium and bile ducts can be noted in the cystic wall of young patients.[28] The degree of epithelial metaplasia generally increases with age, as does the risk for adenocarcinoma.[1,29–31] These histologic changes are commonly seen in pancreaticobiliary maljunction as well. As mentioned, the distal common bile duct has various degrees of stricture, with a high-grade stricture commonly seen in the infantile stage. Older patients have stenosis of the distal common bile duct but not complete obstruction.

The histologic changes of choledochocele differ from those of the other forms of choledochal cysts that were described earlier. As these ducts are primarily intraduodenal, the cystic lining takes on a duodenal lining rather than biliary. The common bile duct, although normal on gross pathology, reveals inflammatory change on histologic examination. Sludge and stones may also be identified in the common bile duct extending into the extrahepatic and intrahepatic ducts, especially in older patients.

Liver pathology in a newborn is usually normal or reveals mild proliferation of intrahepatic ducts. Mild periportal fibrosis is often noted on liver histology of older patients. Congenital hepatic fibrosis has also been described in some patients.[32]

Chronic inflammation is the likely cause of carcinoma in the choledochal cyst wall found in older patients. PBM with or without the presence of choledochal cysts increases the risk factor for carcinoma of the biliary tract.[28,33,34] Adenosquamous carcinoma is the most common type of carcinoma found in the wall, although small-cell carcinoma has also been reported. The choledochal cyst wall is the primary location of carcinomas, but the gallbladder and pancreatic head are other common sites. The location of carcinoma in the head of the pancreas is usually associated with the presence of PBM.[2,10,35]

## Prenatal Diagnosis

Choledochal cysts are being diagnosed with increasing frequency on prenatal anatomic ultrasounds in the second and third trimesters.[36–42] The typical finding on high-resolution ultrasound is that of a cyst in the porta hepatis. The differential diagnosis includes hepatic cysts, duodenal atresia, mesenteric or omental cysts, intestinal duplication, gallbladder duplication, and ovarian cysts.[43] Because choledochal cysts are rare anomalies, prenatal diagnosis can be challenging.[44] Having a skilled and experienced sonologist performing the prenatal ultrasound has, in our experience, been critical in increasing both the sensitivity and specificity of prenatal ultrasound for choledochal cysts.

Fetal magnetic resonance imaging (MRI) has also been performed to aid in the diagnosis.[45] Our group has not found that MRI adds significantly to the information found on ultrasound, but as both imaging techniques evolve, they may increase diagnostic yield in a complementary fashion.

As discussed in further detail later in this chapter, choledochal cysts historically presented in two broad categories: (1) the infantile form indicated by obstructive jaundice and (2) the adult form generally presenting with obstructive jaundice, pancreatitis, or ascending cholangitis.[46] Prenatally diagnosed choledochal cysts could fall into either of these categories. The true natural history of choledochal cysts diagnosed prenatally is impossible to accurately delineate due to widespread support for early surgical management to avoid the high risk of potential complications from untreated choledochal cysts. Clearly, those with an infantile form need surgical excision and reconstruction within the first several weeks of life. Many of these neonates may have choledochal cysts in conjunction with complete or nearly complete biliary obstruction. Some categorize these patients as having biliary atresia in association with choledochal cyst, whereas others may term

these patients as having what was historically called *surgically correctable biliary atresia*. Some overlap between the two diseases is likely.

In those patients with prenatally diagnosed choledochal cysts that are asymptomatic, opinions differ in management. Some have advocated for repair within the first several months of life to avoid potential complications of cholangitis and hepatopathy.[39,47] These papers compare infants diagnosed prenatally who underwent surgery within the first 6 months of life to children diagnosed later who underwent surgery at an average age of 4 to 6 years. In one series, children in the older group had greater hepatic fibrosis, as well as a higher incidence of preoperative clinical manifestations of choledochal cysts. However, no long-term follow-up was conducted to provide data on long-term liver function and quality of life in order to compare these two different cohorts. In our center, our general recommendation has been to perform laparoscopic operation for asymptomatic choledochal cysts diagnosed prenatally within the first year of life.

# Clinical Presentation

Patients with choledochal cysts can manifest clinical symptoms at any time during their life, with 80% of patients being symptomatic before the age of 10 years.[48] Abdominal pain, jaundice, and a palpable right upper quadrant abdominal mass is the classic triad described for patients with choledochal cyst. The triad is only reported in about 20% of patients diagnosed. Two of the three symptoms are seen in two thirds of patients at the time of diagnosis.[48] Some have applied a classification according to age at presentation. The infantile form occurs before 12 months of age, and these patients tend to present with obstructive jaundice, acholic stools, and hepatomegaly similar to biliary atresia.[49] The adult form occurs anytime after 12 months of age and usually has a greater number of symptoms including fever, nausea, vomiting, and jaundice.[4] As previously mentioned, choledochal cysts diagnosed prenatally may fall into either category.

Signs of hepatic fibrosis may be present in the infantile form, and these patients benefit the most from early treatment. Delayed treatment of asymptomatic infants is advocated by some; however, the risk of progressive hepatic fibrosis exists. In the infantile form, patients with the fusiform type of choledochal cyst tend to present with transient jaundice. Perforation of the choledochal cyst is rare (1% to 12%) and thought to be due to a fragile cystic wall from inflammation, increased ductal pressure, or increased intra-abdominal pressure. The site of rupture is at the low-flow region of the junction of the cystic and common bile ducts. These patients present with abdominal pain, sepsis, and peritonitis.[50]

The adult form usually presents after 2 years of age. These patients tend to have a fusiform dilation of the common bile duct without complete obstruction of the distal common bile duct and present with intermittent symptoms from a mucous plug or biliary sludge. Patients with the adult form are more likely to present with the classic triad of abdominal pain, jaundice, and a palpable right upper quadrant abdominal mass compared with the infantile form.

Symptoms arise from biliary obstruction leading to ascending cholangitis and complications of pancreatitis.[3,27,46,48,51,52] Bile stasis, sludge, stone formation, inflammation, and recurrent superinfection have all been identified as complications leading to intermittent jaundice and abdominal pain in the right upper quadrant. Mucous or protein plugging is likely due to chronic inflammation leading to formation of albumin-rich exudates or dysplastic epithelium with hypersecretion of mucin.[53] Persistent bacterial colonization of intrahepatic ducts in type IV and V cysts is exacerbated by bile stasis, sludge, and stone formation and is one theory for recurrent cholangitis. Secondary biliary cirrhosis is noted in 40% to 50% of patients due to obstruction and inflammation and leads to portal hypertension in some patients.[48] In cases of choledochal cyst not diagnosed until adulthood, patients may present with cholelithiasis and symptoms mimicking biliary colic or cholecystitis. If imaging has been inadequate, the diagnosis of choledochal cyst may only be made intraoperatively by visual inspection or cholangiography. In some, cholecystectomy may be performed without diagnosis of the choledochal cyst. Pain similar to recurrent pancreatitis has been described by some patients, which has led to a misdiagnosis of abnormal amylase clearance; however, after further work-up, an elevated serum amylase is noted.[54,55] However, these patients may truly be having pancreatitis as a result of mucous plugging in the PBM.

# Diagnosis

## LABORATORY STUDIES

Laboratory data are usually obtained in patients with choledochal cysts in the diagnostic workup but are reserved primarily for evaluating the clinical condition of the patient and not diagnosis. Serum markers of obstructive jaundice (e.g., conjugated hyperbilirubinemia and increased serum alkaline phosphatase) are usually present. An elevated conjugated bilirubin is typical in the infantile form but may or may not be present in the adult form due to intermittent or incomplete biliary obstruction. In chronic cases an abnormal coagulation profile may be evident due to hepatic injury.

## IMAGING STUDIES

Diagnosis of choledochal cysts is made by imaging studies. An abdominal ultrasound is the first imaging modality used because it is noninvasive, inexpensive, and provides excellent detail of the portal structures. Choledochal cyst on ultrasound is commonly identified as a cystic mass that is not part of the gallbladder in the right upper quadrant and is usually in the porta hepatis. The cyst needs to be in continuity with the biliary tree to be diagnosed as a choledochal cyst because other cystic abnormalities such as pancreatic pseudocyst, biliary cystadenomas, or echinococcal cysts can exist in this area.[18] The diagnosis of choledochal cyst on ultrasound carries a 71% to 97% sensitivity.[56] Ultrasonography is an excellent screening tool and is used by some as the only imaging study in infants.

In the event that choledochal cyst is suspected on ultrasound, a technectium-99 HIDA scan may provide more definitive data. Photopenia is initially evident at the cyst followed by filling and delayed emptying. The HIDA scan has varying sensitivities, with 100% for type I cysts and 67% for type IV.[56]

A HIDA scan has decreased sensitivity for intrahepatic cysts. A HIDA scan may also be helpful for distinguishing between choledochal cyst and biliary atresia. Biliary atresia on a HIDA scan is characterized by lack of contrast emptying into the duodenum, whereas a choledochal cyst will have contrast entering the duodenum. A HIDA scan may also be useful in the diagnosis of cystic rupture, in which case contrast would empty into the peritoneal cavity.[48]

An abdominal computed tomography (CT) scan may be another useful modality. A CT can show the intrahepatic ducts, distal common bile ducts, and the pancreatic duct, features that are not reliably identified on ultrasound, making CT scan highly useful in identifying type IV and type V cysts. The full anatomy of the biliary tree can be delineated using CT cholangiography, a valuable modality in preoperative planning. The sensitivity of CT cholangiography is 93% for biliary tree visualization and diagnosing lithiasis, 90% for diagnosing choledochal cysts, and only 64% for characterizing the pancreatic duct.[57] The risk of using CT or CT cholangiography is contrast toxicity that can cause nephrotoxicity or hepatotoxicity and radiation exposure.

Invasive imaging studies also play a role in diagnosis and evaluation of the biliary anatomy. These modalities include cholangiography through endoscopic retrograde cholangiopancreatography (ERCP), percutaneous transhepatic cholangiography (PTC), and intraoperative cholangiogram. Cholangiography will delineate the anatomy and locate abnormalities such as PBM and filling defects caused by stones, stenosis, or carcinomas.[58,59] The risk of cholangitis and pancreatitis after invasive cholangiography is higher than in the general population, with reported incidences as high as 87.5%[48] due to the frequency of PBM, dilated ducts, and dysfunctional sphincters in patients with choledochal cyst. Due to recurrent inflammation and scarring, ERCP can be challenging with respect to cannulization of the ampulla. A high volume of dye load is often required for adequate visualization, especially in the setting of large cysts.[48]

Magnetic resonance cholangiopancreatography (MRCP) is now considered the gold standard for imaging choledochal cyst, especially given the complications and concerns with invasive cholangiography (Fig. 106-3). The diagnostic sensitivity of MRCP is 90% to 100%.[60] Administration of secretin increases pancreatic secretion and dilates the pancreatic duct. Thus some centers administer secretin before MRCP to increase diagnostic yield.[61] As the technology for MRCP has improved, smaller ductal structures are being visualized with finer detail. This has allowed for increased diagnosis of PBM and pancreatic divisum and usually gives accurate information as to the location of insertion of the pancreatic duct. The type and extent of the choledochal cyst are well visualized, and images can be reconstructed in three dimensions (Fig. 106-4). MRCP avoids radiation associated with CT scan and ERCP and avoids the potential post-ERCP complications of cholangitis and pancreatitis.

Choledochoceles (type III cysts) can be diagnosed with various imaging modalities such as upper gastrointestinal series (UGIS), endoscopy, ERCP, MRCP, and CT cholangiography. On UGIS for choledochoceles, a filling defect is noted at the level of the cyst entering the duodenum. The papilla will have a smooth bulging on endoscopy and ERCP. The advantage of ERCP over MRCP and CT cholangiography for choledochoceles is the ability to perform a therapeutic procedure such as a sphincterotomy. Endoscopic ultrasound is also well-suited to diagnosing choledochoceles because this modality can reach close to the cyst for appropriate visualization. The best imaging techniques for Caroli disease (type V cysts) are ultrasound, CT, and MRI.[48] The "central dot sign" has been described for Caroli disease but is not pathognomic.[62] On HIDA scan a beaded appearance due to intraductal bridging may be indicative of Caroli disease.

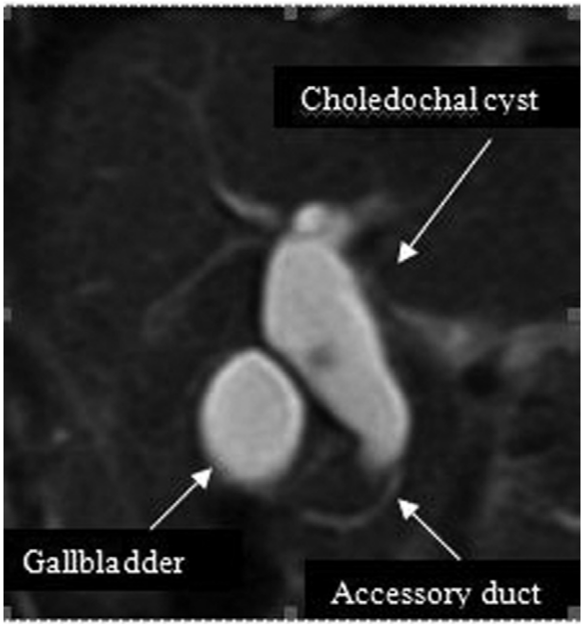

**FIGURE 106-3** A magnetic resonance cholangiopancreatography of a patient with type I choledochal cyst and an accessory pancreatic duct entering the duodenum.

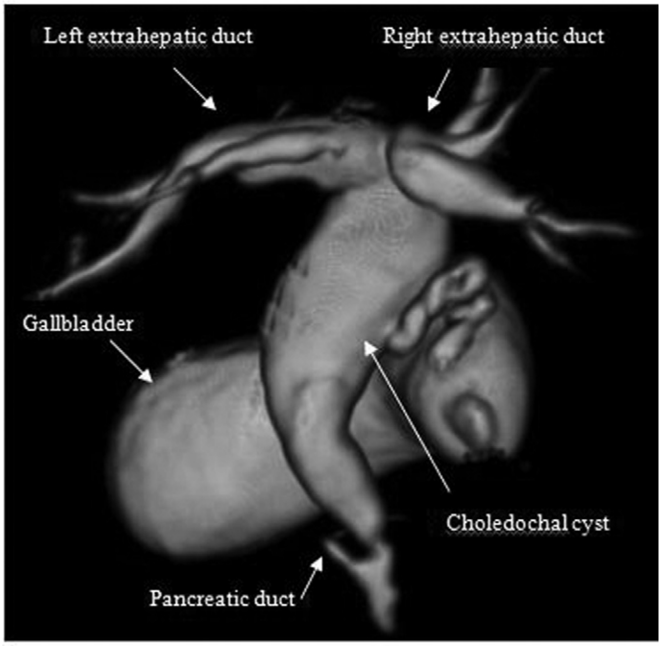

**FIGURE 106-4** Three-dimensional reconstruction of a magnetic resonance cholangiopancreatography image of a choledochal cyst with mild dilation (6 mm) of the right and left extrahepatic ducts. Pancreatic duct is seen entering the normal caliber distal common bile duct.

Our preference for imaging for all types of choledochal cysts is ultrasound followed by MRCP. If the MRCP does not give sufficient anatomic detail to guide therapy, we perform either an ERCP before operation or an intraoperative cholangiogram at the time of cyst resection.

## Surgical Management

The management of types I and IV choledochal cysts has evolved from either internal or external drainage to cyst excision and hepaticojejunostomy to a Roux-en-Y limb (Fig. 106-5). Due to the relatively complex nature of cyst excision, early attempts at treatment focused on external drainage to avoid complications of biliary tract obstruction. However, an external biliary fistula proved to have high morbidity and mortality.[4] As surgical techniques advanced, subsequent attempts focused on cyst duodenostomy or cyst jejunostomy to a Roux-en-Y limb to internalize biliary drainage.[15,27,63,64] However, complications of cholangitis and progressive liver damage and the high risk of cancer in the choledochal cyst led to the current surgical strategy of cyst excision with Roux-en-Y jejunostomy as advocated by Kasai and colleagues[65] and Ishida and colleagues.[66–68] This operative approach eliminates the potentially premalignant epithelial cyst lining and also separates the pancreatic drainage from the biliary drainage. This strategy is summarized in Figure 106-6. This technique is essentially identical to our laparoscopic technique for treatment for type I and type IV cysts and is described in detail later in the laparoscopic section. Some surgeons prefer cyst resection with hepaticoduodenostomy, which yields similar outcomes to that of drainage with a Roux-en-Y limb.[69]

In previous series of choledochal cysts, diagnosis was often delayed, leading to patient presentation with repeated episodes of cholangitis. Delayed diagnosis led to inflammation of the cyst and adherence to the periportal structures, particularly the portal vein. In patients such as these, for whom excision of the full thickness of the cyst may carry an unacceptably high complication rate, the technique described by Lilly can be performed[70,71]: The cyst can be incised anteriorly away from the hepatic artery and portal vein, allowing the inner epithelial lining of the entire choledochal cyst to be excised while avoiding the difficult and potentially dangerous plane of dissection between the outer cyst wall and the portal vein. This removes the potentially premalignant aspects of the cyst while minimizing potential operative complications.

Type II choledochal cysts are rare but appear to have a low malignant potential. This type requires simple cyst resection and is easily amenable to a laparoscopic approach because complicated dissection and reconstruction are not required. In fact, the first laparoscopic treatment for a choledochal cyst in the pediatric population was reported in a child with a type II cyst.[72]

Type III choledochal cysts, or choledochoceles, are intraduodenal or intrapancreatic dilations of the distal common bile duct, as outlined previously. Management has traditionally been operative marsupialization of the cyst, usually through a transduodenal approach.[73] Increasingly, however, choledochoceles are being treated by sphincterotomy or cyst marsupialization during an ERCP.[74–76] The incidence of cancer is unclear due to the rarity of this type of cyst but is likely significantly elevated.[77] It is unclear to what extent drainage with either an operative approach or via ERCP minimizes the malignant potential for choledochoceles.

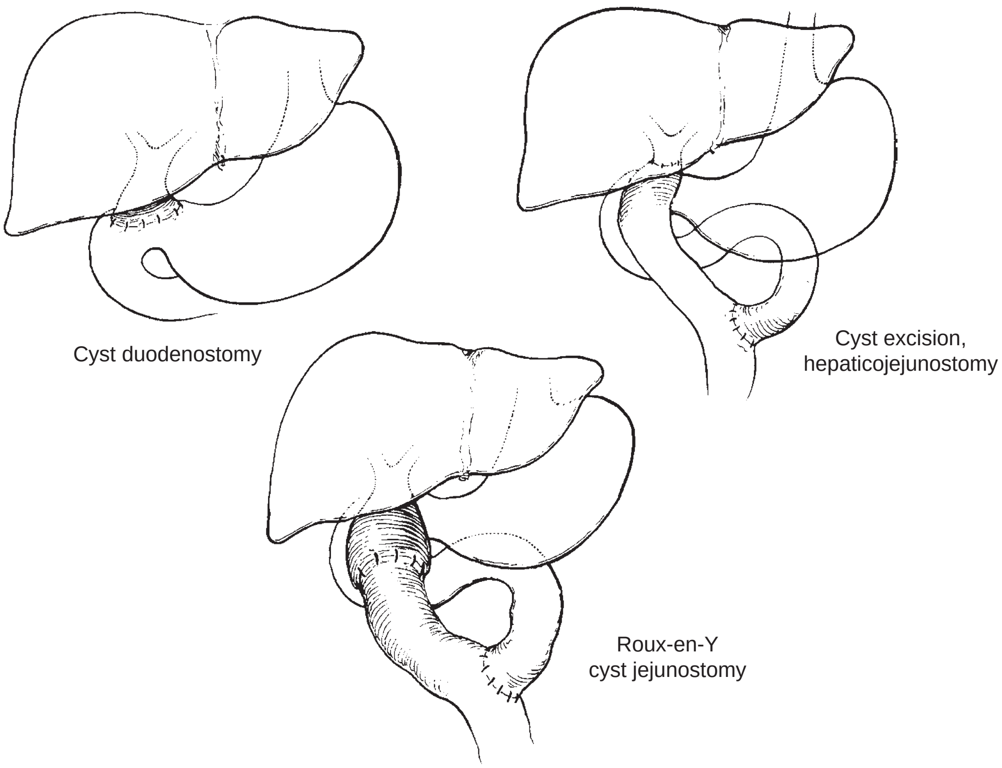

**FIGURE 106-5** Surgical operative management of choledochal cyst and the types of anastomoses that can be created.

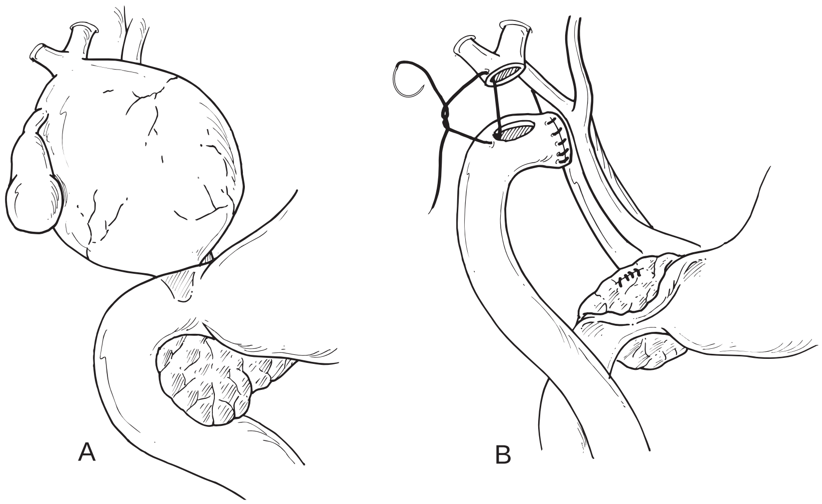

**FIGURE 106-6** Diagram reveals preoperative anatomy **(A)** and postoperative anatomy **(B)** after cyst excision and Roux-en-Y reconstruction.

For patients with type IV disease, most surgeons recommend cyst resection to the hepatic ducts, leaving in place the dilated intrahepatic ducts because they may decrease in size without distal obstruction. However, careful long-term follow-up is required to monitor the relative size of the intrahepatic ducts and for the possibility of symptomatic lithiasis and cholangitis. Surgical treatment of type V (Caroli disease) is challenging. Segmental resections can be performed if the disease is localized to a portion of the liver. Liver transplantation has also been performed.[78,79]

We and others have reported laparoscopic excision of choledochal cysts with either Roux-en-Y reconstruction or hepatico-duodenostomy.[80–83] The largest series, from Tang and colleagues,[83] was a retrospective review of 62 children undergoing laparoscopic resection of choledochal cysts. They reported outcomes comparable with those of published open series with a low rate of complications including only one case of a biliary leak. Long-term outcome for laparoscopic surgery for choledochal cyst in the pediatric population has not been well-reported, and data are similarly scarce for outcomes of open surgery. A recent series from the long-term follow-up data reported by Ono and colleagues is discussed in "Outcome and Complications" later and provides the best overall long-term data from open cases.[84]

Techniques for laparoscopic repair including ours are all similar. This next section describes in detail our technique for laparoscopic excision of type I choledochal cysts with Roux-en-Y reconstruction, as previously reported.[81]

Detailed preoperative workup including an MRCP is essential in determining the type of cyst and the insertion of the pancreatic duct(s) for safe resection. Particularly in instances in which the pancreatic duct inserts near the distal extent of the choledochal cyst, care must be taken to avoid the pancreatic duct in the distal dissection. Intraoperative cholangiography may also be performed by placing a catheter in the gallbladder if MRCP is inadequate or not available. The placement of four ports for the procedure is illustrated in Figure 106-7. A 5-mm port is placed through the umbilicus for the camera. Typically, we prefer a 4-mm or 5-mm 30-degree endoscope due to the improved optics as compared with smaller endoscopes. A 3-mm port is placed in the right abdomen between the midaxillary line and the midclavicular line just inferior to the level of the umbilicus. This is the

**FIGURE 106-7** Port placements for laparoscopic choledochal cyst excision and Roux-en-Y hepaticojejunostomy.

left-handed working port for the primary surgeon. A 5-mm port is placed in the left midclavicular line just superior to the level of the umbilicus for the right-handed working port for the primary surgeon. The fourth port is located in the left anterior axillary line just below the costal margin. This port is used by the assistant to retract the gallbladder and liver superiorly. The location of this port, although it may seem counterintuitive, has proven to be the optimal location for retraction and affords adequate distance from the other instruments. Placing two ports in the right abdomen, as one would typically do for a cholecystectomy, results in inadequate distance between instruments placed through these ports. After laparoscopically confirming the diagnosis of a choledochal cyst, a cholangiogram is performed, if necessary, by placing an angiocatheter into the gallbladder and installing water soluble contrast (Fig. 106-8).

The gallbladder is then divided at the cystic duct junction with clips or ties (Fig. 106-9). This allows the assistant to retract the gallbladder superiorly through the left subcostal port and expose the porta hepatis. If the cyst is large enough that the hepatic hilum is obscured, it may need to be decompressed. Next, the hepatic duct is divided just superior to the

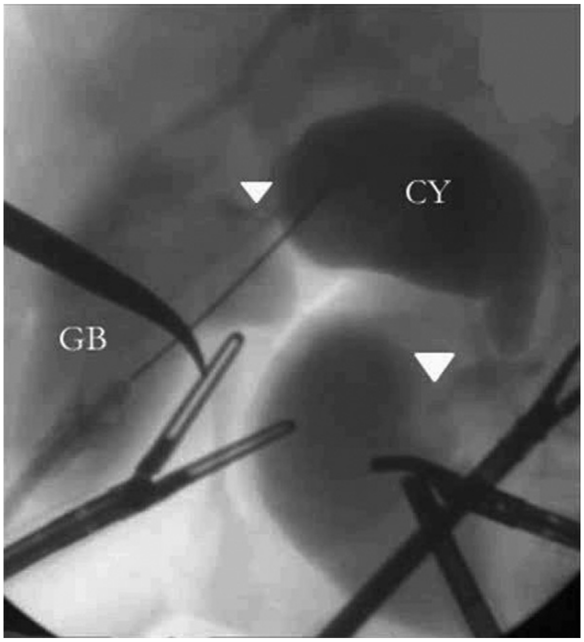

**FIGURE 106-8** Intraoperative cholangiogram during laparoscopic cyst excision and Roux-en-Y hepaticojejunostomy revealing the gallbladder (*GB*) and the choledochal cyst (*CY*).

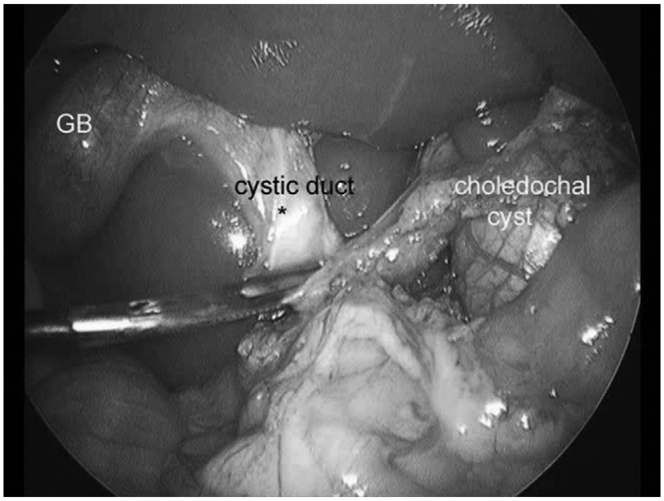

**FIGURE 106-9** Intraoperative laparoscopic view of the gallbladder (*GB*) and cystic duct in relation to the choledochal cyst.

most cephalic extent of the choledochal cyst. Care should be taken to identify the right and left branches. In some instances, separate anastomoses may be required from the right and left ducts to the Roux-en-Y limb. Dividing the hepatic duct early in the operation allows the surgeon to manipulate both the superior and right lateral aspects of the choledochal cyst to aid in the dissection. The cyst is then carefully dissected away from the hepatic artery and the portal vein. At this point, the cyst is attached only to the distal common bile duct within the pancreas. Dissection continues distally, dissecting closely on the cyst wall to avoid damage to the duodenum or pancreas until the cyst begins tapering in size to become a normal-sized common bile duct. Again, the MRCP can be valuable in guiding the distal dissection with respect to the location of the pancreatic duct insertion. The common bile duct is excised, and the distal common bile duct is ligated with a tie or occluded with a clip. If the cyst is not leaking bile, we prefer to place the cyst on the lateral aspect of the liver and remove it subsequently along with the gallbladder.

We then begin the creation of the Roux-en-Y limb. The ligament of Treitz is identified by elevating the transverse colon. The area of the jejunum that will be divided for the Roux-en-Y limb is identified approximately 15 cm from the ligament. We prefer to mark this area by placing vessel loops of different colors separated by 1 to 2 cm. Marking the jejunum in this manner allows easy identification of the proximal and distal aspects of the jejunum when the bowel is exteriorized. Next, the umbilical incision is extended to approximately 1.5 cm and the marked jejunum is exteriorized. A 30- to 40-cm Roux-en-Y limb is then created in the standard fashion, the bowel is then returned intracorporeally, and the umbilical port is replaced. The Roux-en-Y limb is brought to the porta hepatic in a retrocolic fashion, and then an end-to-side anastomosis is performed from the hepatic duct to the Roux-en-Y limb. We use fine absorbable monofilament suture material. We have found that using a continuous suture on the posterior aspect of the anastomosis and interrupted sutures on the anterior and lateral aspects is simplest. All knots are tied on the outside of the anastomosis to prevent the potential for a focus of formation or collection of biliary sludge on the knots. Finally, a cholecystectomy is performed and the gallbladder and the choledochal cyst are removed through the umbilical port site.

## Outcome and Complications

In past operative treatment of cystenterostomy, there was a high rate of complications such as anastomotic stricture, recurrent ascending cholangitis, bowel obstruction, portal hypertension, and malignancy. However, the advancement of surgical treatment to include cyst excision resulted in minimal morbidity and mortality and reduced the number of late complications. The most common late complication continues to be anastomotic stricture. Early diagnosis and cyst excision results in low complication rates in most experienced centers. The type of internal drainage after cyst excision has not been shown to affect postoperative complications. The technique of Roux-en-Y hepaticojejunostomy is favored by most, although comparable results can be achieved by hepaticoduodenostomy. Either procedure can be performed laparoscopically as well.

Although late complications are reduced with current surgical management, studies suggest that long-term follow-up to 17 years or beyond is indicated due to the potential for problems such as anastomotic stricture, cholangitis, intrahepatic stone formation, and malignancy.[85] This is particularly important for patients with type IV disease because malignancy can occur in incompletely resected cystic hepatic ducts or recurrent cysts.[85] The risk of malignancy is greatly reduced after cyst excision but is still elevated as compared with the general population. Intrahepatic stone formation in the intraoperative setting has been evaluated and reported in the literature and seen in patients who showed no stone formation in the preoperative course. Stone formation has been reported to occur

anywhere from 3 to 22 years postoperatively.[86] However, if the duct is patent and there is no stenosis of the hepaticojejunostomy, stones are likely to pass spontaneously. Intrahepatic stones usually present in cases of stenosis that initially cause bile stasis and lead to stone formation.[85] Todani and colleagues[87] reported a 25-year review with the identification of biliary complications primarily associated with either anastomotic stricture or primary ductal stricture and recommended a wide hepatic hilum anastomosis to prevent biliary complications.

The long-term complication of malignancy can be avoided with cyst excision. In addition, any cause of chronic inflammation and stasis, as seen with PBM, has to be treated appropriately.[34] The incidence of malignancy of the gallbladder and bile ducts remains high in patients with PBM compared with the general population and occurs at a younger age. Further studies reviewing the genetic changes of PBM have revealed KRAS gene mutations early in epithelial hyperplasia and metaplasia. In the late progression of adenocarcinoma of the biliary tract, inactivation of DPC4 gene occurs.[28,44,88]

# Conclusion

The management of choledochal cysts is performed predominantly by pediatric surgeons. Generally considered a congenital abnormality, most cases are diagnosed in infancy with many now being diagnosed prenatally, though presentation may be delayed until adulthood. Because of the high risk of serious sequelae including malignancy, early surgical excision is warranted even in asymptomatic patients. Adequate imaging with MRCP helps map the extent of the dilated biliary tree, as well as the insertion of the pancreatic duct(s), ensuring safe resection. Increasingly, surgery is being performed with minimally invasive techniques with good outcomes. Because of the rare nature of this disease, extensive knowledge of the different variants and experience with advanced biliary tract surgery is critical in attaining good outcomes.

CHAPTER 107

# Gallbladder Disease and Hepatic Infections

George W. Holcomb III and Walter S. Andrews

## Gallbladder Disease

Cholelithiasis and biliary dyskinesia are being increasingly diagnosed in children. Whether their incidence is actually escalating or the diagnostic accuracy is improving because of the increasing use of ultrasonography (US) and cholescintigraphy remains unclear. Moreover, hemolytic disease is no longer a prerequisite for the development of gallstones.[1–3]

### NONHEMOLYTIC CHOLELITHIASIS

Several factors are known to cause cholelithiasis in children. By far, the most commonly reported condition associated with the development of nonhemolytic cholelithiasis, particularly in neonates and infants, is the use of total parenteral nutrition (TPN).[4–6] Up to 43% of children receiving long-term TPN develop gallstones.[7] The mechanism of gallstone formation related to TPN remains unclear but may be associated with changes in bile composition caused by the amino acid infusion. Also, the lack of enteral feeding leads to ineffective gallbladder contraction and results in reduced enterohepatic circulation of bile. The administration of fat is believed to ameliorate the deleterious effects of the amino acids in the TPN.

Because many infants receive TPN and only a few develop gallstones, other factors are probably necessary for the development of cholelithiasis in this patient population. Septicemia, dehydration, chronic furosemide therapy, cystic fibrosis, short-bowel syndrome, and ileal resection for necrotizing enterocolitis also may be important contributing factors.[6,8–10] The cause of gallstone formation is probably multifactorial. Stasis, sepsis, a lack of enteral feedings, and some alteration of the enterohepatic pathway for the recirculation of bile are all important for stone development. Moreover, neonates and, particularly, premature infants are susceptible to the cholestatic effects of TPN because of the immaturity of their enterohepatic circulation of bile salts. Finally, the composition of gallstones in children may be different than that found in adults. Whereas stones in adults are primarily cholesterol in composition, calcium carbonate and black pigment stones are often found in pediatric patients, especially those younger than 10 years of age.[11–13]

Causes associated with gallstones in older children include the use of oral contraceptives, cystic fibrosis, pregnancy, obesity, and ileal resection.[14–17] Cholelithiasis has also been reported in children undergoing cardiac transplantation who are receiving cyclosporine and in patients who have previously required extracorporeal membrane oxygenation as a newborn.[18–21]

### HEMOLYTIC CHOLELITHIASIS

Although the incidence of nonhemolytic cholelithiasis is increasing at many centers, hemolytic cholelithiasis (usually secondary to sickle cell disease [SCD]) remains the most common cause of gallstones in children at many academic institutions, especially in urban areas where an active sickle cell program exists. The prevalence of pigment gallstones associated with sickle cell disease appears to be age dependent. Fifty percent of patients with sickle cell anemia develop gallstones by 20 years of age.[22–24] Interestingly, in one study, patients with sickle cell disease and gallstones had rates of bilirubin production, bilirubin clearance, and plasma levels of unconjugated bilirubin similar to patients with sickle cell hemoglobin and no gallstones.[25] Thus the researchers suggested that excessive unconjugated hyperbilirubinemia alone is not sufficient to produce pigment gallstones. In that study, enlarged fasting and postprandial gallbladder volumes were found in patients who developed stones. It was hypothesized that stasis occurs as a result of incomplete emptying and leads to sludge and later to gallstone formation. In addition, genotyping may become a screening tool for predicting SCD children who are most likely to develop gallbladder disease.[26] Because gallbladder sludge is frequently documented in patients with sickle cell anemia, elective cholecystectomy has been recommended when evidence suggests the presence of sludge, with or without stones.[27] In one study of 35 patients with sickle cell disease and biliary sludge, 23 (65.7%) went on to develop gallstones.[28]

### COMPLICATIONS

Patients with SCD represent the largest group of patients at risk for postoperative complications after cholecystectomy. In a report of 364 cases from a national sickle cell disease

study group, the total complication rate was 39%, with sickle cell events representing 19%; intraoperative or recovery room problems, 11%; transfusion complications, 10%; postoperative surgical events, 4%; and death, 1%.[29] The open operation was performed in 58% of the patients, and the laparoscopic route was used in 42%. The complication rates were similar between the two groups. From that study, it was believed that the incidence of sickle cell events may be higher in patients who were not preoperatively transfused. Moreover, the laparoscopic approach is now recommended for this patient population.[30]

The acute chest syndrome can be seen in up to 20% of sickle cell patients undergoing abdominal operation. The laparoscopic approach did not decrease the incidence of this complication.[31] Meticulous attention to perioperative management, transfusion guidelines, and pulmonary care may reduce the incidence of the acute chest syndrome.

Two other hemolytic conditions commonly associated with gallstones are hereditary spherocytosis and thalassemia. The incidence of cholelithiasis in patients with hereditary spherocytosis ranges from 43% to 63% and is slightly more common in girls than boys.[32,33] Because of this association, US is recommended before elective splenectomy to determine whether concomitant cholecystectomy should be performed at the time of the splenectomy. Previously, patients with thalassemia major comprised a group of children at risk for cholelithiasis.[34] However, the incidence of cholelithiasis has markedly decreased in this patient population. This reduction has been attributed to a hypertransfusion regimen that blocks the bone marrow so that the fragile cells of thalassemia major are not produced.[35] Currently, patients with this disorder are rarely seen with cholelithiasis.

## CLINICAL PRESENTATION

Gallbladder disease in infants usually occurs during a systemic illness or following TPN use. Some infants will also have undergone ileal resection because of acquired diseases such as necrotizing enterocolitis or congenital anomalies. Jaundice may occur before gallstones are detected with US. Most of these stones are composed of calcium bilirubinate.

Gallstones that develop between 2 and 12 years of age are primarily composed of mixtures of calcium bilirubinate, with varying amounts of calcium carbonate and cholesterol. Opaque gallstones are sometimes detected on plain radiographs (Fig. 107-1), but the diagnosis is usually determined with US. Unfortunately, the diagnosis may be delayed in this young age group despite abdominal pain, nausea, emesis, and, occasionally, fever. Abdominal pain may vary from the typical right upper abdominal location to vague and poorly localized pain, especially in younger children. Older patients are usually more specific in localizing their pain to the right subcostal region.

The symptoms and physical findings in teenagers are similar to those found in adults. The pain is usually described as right subcostal with some radiation to the subscapular area. Nausea and vomiting commonly occur, and intolerance to fatty foods is often mentioned.

The primary reason for elective cholecystectomy in patients with cholelithiasis is to prevent associated complications. Four major complications can occur: cholecystitis, jaundice, cholangitis, and biliary pancreatitis. The incidence of acute cholecystitis seems to be increasing. In one report of 100 patients undergoing laparoscopic cholecystectomy, 22% presented initially with complications related to gallstones.[19] Seven presented with acute cholecystitis, six presented with jaundice and pain, five developed gallstone pancreatitis, and four had acute biliary colic without evidence of cholecystitis. Others have also reported a large number of patients presenting with symptomatic choledochal obstruction.[36,37] In such patients, management should be initially directed at trying to reduce the inflammation in the region, followed by laparoscopic cholecystectomy several days later.

## ACALCULOUS CONDITIONS

Hydrops of the gallbladder, acalculous cholecystitis, biliary dyskinesia, and gallbladder polyps are being seen more frequently. Hydrops is characterized by massive distention of the gallbladder in the absence of stones, infection, or congenital anomalies. It has been most frequently reported in association with Kawasaki disease and is usually due to a transient obstruction of the cystic duct or to increased mucus secretion by the gallbladder resulting in poor emptying.[38–42] With additional gallbladder distention, further angulation of the cystic duct may increase the obstruction.[43] Conservative treatment is initially recommended in this setting. Appropriate antibiotics for septic patients and early initiation of enteral feedings to stimulate gallbladder emptying often lead to resolution of this condition. If serial US examinations show progressive gallbladder distention with increasing pain, or if the gallbladder appears gangrenous, cholecystectomy is recommended.

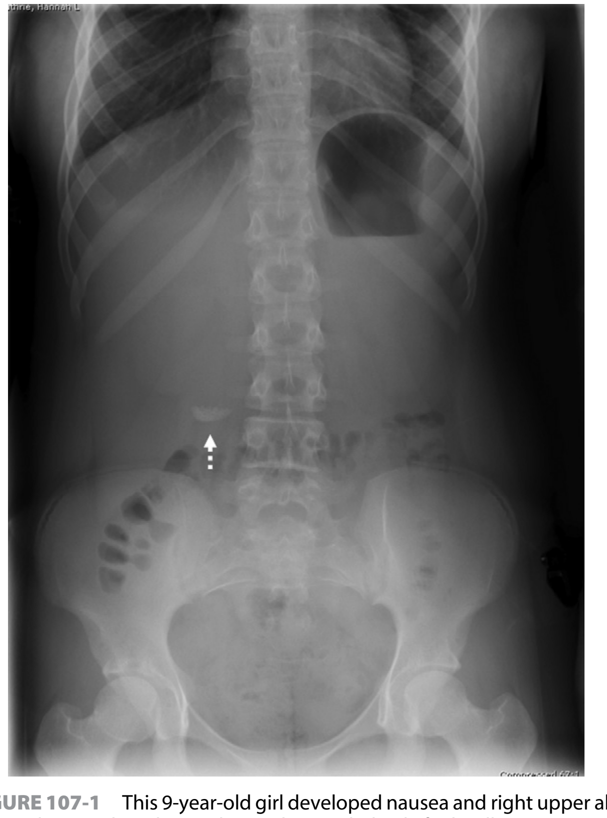

FIGURE 107-1 This 9-year-old girl developed nausea and right upper abdominal pain. This plain radiograph revealed calcified gallstones (*arrow*) that had settled in the dependent portion of the gallbladder on this upright abdominal film.

Acalculous cholecystitis commonly occurs in association with severe illness such as sepsis, burns, or trauma that results in dehydration, hypotension, and ileus. In this setting, TPN is often administered and, if prolonged, may be followed by decreased gallbladder contractility with progressive distention, stasis, and possible infection. In a small report of 12 patients, the investigators used daily US criteria for clues to indicate the need for cholecystectomy. In the three patients who underwent operation, there was progressively increasing gallbladder wall thickness and distention along with pericholecystic fluid. In the other patients, the daily US examinations found progressive improvement from the previous day's findings. These patients all recovered uneventfully.[44]

Biliary dyskinesia is now a common diagnosis in children.[45–56] In some centers, it has become the most common reason for cholecystectomy.[57–59] This disorder is characterized by poor gallbladder contractility and the presence of cholesterol crystals within the bile. It should be considered when patients present with typical biliary pain but no evidence of gallstones on US. Gallbladder contractility can be assessed with radionuclide scanning during cholecystokinin (CCK) injection. Recently, Lipomul has been shown to provide similar findings.[49] Most surgeons use a gallbladder ejection fraction of less than 35% as an indicator for cholecystectomy in a patient with symptoms.[53,59–62] Laparoscopic cholecystectomy has been shown to be an effective treatment for this disorder, with expected resolution of symptoms in more than 80% of the patients using this benchmark.* Chronic cholecystitis is often documented on histologic examination of the gallbladder specimen.[63] A few centers use a lower benchmark for operation. In a review of 51 patients who underwent laparoscopic cholecystectomy for symptoms consistent with biliary dyskinesia, it was found that nausea, pain, and a decreased gallbladder ejection fraction of less than 15% most reliably (93% PPV, 81% NPV) predicted which children will benefit from cholecystectomy for this condition. In that report, children with an ejection fraction greater than 15% did not have predictable resolution of symptoms.[46]

In a recent report from our institution, we have found that children with biliary dyskinesia have a marked increased number of mucosal mast cells in the gallbladder mucosa compared with patients with stone disease.[64] In a follow-up study, a moderate to high degree of mast cell activation was also found in children with both biliary dyskinesia and gallstones.[65] These findings provide biologic credibility for cholecystectomy in both patient groups.

Gallbladder polyps are being described more frequently in children.[66,67] Cholecystectomy is advisable if there are biliary symptoms or if the polyp is greater than or equal to 1 cm.[68,69]

Several unusual conditions merit attention. First, partial external biliary diversion interposing a jejunal loop between the gallbladder and abdominal wall has been described to treat the intractable pruritus in patients with progressive familial intrahepatic cholestasis.[70] We have used this technique as well with resolution of the pruritus. Thus in these children, cholecystectomy should be avoided. Second, ventriculo-gallbladder shunts have been performed in patients with a scarred peritoneal cavity from multiple previous operations or severe peritonitis.[71] We have performed one ventriculo-gallbladder shunt with a good result.

## RADIOGRAPHIC EVALUATION

Although a plain abdominal radiograph is often the initial imaging study used to evaluate abdominal pain in children, it is rarely helpful with gallbladder disease unless the gallstones are calcified (see Fig. 107-1). The incidence of radiopaque stones has been reported to be as high as 50% in patients with hemolytic disorders compared with approximately 15% in adolescents with cholesterol stones.[72] Oral cholecystography is rarely used today because of the superior accuracy of US. Real-time US has an accuracy of approximately 96% for gallbladder disease and is effective in determining hepatic and common bile duct involvement, the presence of thickening of the gallbladder wall, and any abnormalities in the liver or head of the pancreas.[73] The most useful procedure for diagnosing acute cholecystitis is cholescintigraphy that uses technetium-99m-labeled iminodiacetic acid analogues. With this study, the gallbladder is not visualized in patients with acute cholecystitis. In critically ill patients, especially infants who are fasting, have severe associated illnesses, or are receiving TPN, there may be a false-positive result. Intravenous morphine may be useful in this setting because it causes spasm at the sphincter of Oddi, resulting in increased bile duct pressure. The latter, in turn, enhances visualization of the gallbladder and helps reduce the rate of false-positive studies.[74] Cholecystokinin-assisted or Lipomul-challenged cholescintigraphy is an accurate predictor of biliary dyskinesia and also suggests the likelihood of symptomatic relief with cholecystectomy.[45,46,48,49,75,76]

## NONSURGICAL TREATMENT

Nonsurgical treatment for gallstones in children or adults is of historical interest only. Previously, attempts at oral dissolution therapy or extracorporeal shockwave lithotripsy were attempted in adults with minimal success.[43,77,78] In one adult study evaluating lithotripsy, the duration of treatment, the high cost, and the 50% risk of recurrent gallstones within 5 years were significant disadvantages.[77] In these studies, children were not included for a variety of reasons including the fact that pigmented stones would not be amenable to these therapies. Currently, observation is not recommended for children older than age 2 or 3 years with gallstones. In some reports, gallstones that developed in infants secondary to prolonged TPN have been found to resolve spontaneously.[79–82] Thus a 6- to 12-month period of observation in this age group is not unreasonable after cessation of the TPN and initiation of enteral alimentation.

In a study of 55 patients with biliary dyskinesia comparing observation versus laparoscopic cholecystectomy, there was no difference (74% vs. 75%) in resolution of pain at 2 years between groups.[83] However, of those patients whose symptoms improved, those who underwent laparoscopic cholecystectomy had a much quicker resolution of pain compared with those who were observed.

## SURGICAL TREATMENT

Surgical treatment for symptomatic cholelithiasis consists of either cholecystectomy or cholecystolithotomy. In a preliminary report, one group reserved laparoscopic cholecystolithotomy for symptomatic cholelithiasis in patients before the onset of puberty.[84] However, long-term outcome data from

this approach are lacking. In another report of 10 patients undergoing cholecystolithotomy over 25 years with a mean follow-up of 5 years, 30% of the patients undergoing cholecystolithotomy were reported as having recurrent right upper abdominal pain and recurrent stones.[85] Because of the high recurrence rate, these authors believe that cholecystectomy is preferred in children.

The laparoscopic approach has become the standard method for cholecystectomy in children over the past 20 years. The major advantages of this approach include decreased discomfort and reduced length of hospitalization, an improved cosmetic result, and a faster return to routine activities such as work, school, play, or participation in athletic activities. These advantages result from less muscle disruption from the small incisions and reduced trauma to the tissue, leading to less discomfort and ileus than with the open approach. In most reports, children without complications undergoing laparoscopic cholecystectomy are ready for discharge on either the first or the second postoperative day.[19,53,75,86–88] However, there are recent reports of laparoscopic cholecystectomy being performed in children as an outpatient procedure.[59,89] Patients with sickle cell disease require special preoperative care to prevent postoperative complications. Several authors have reported favorable results with cholecystectomy in this patient population and have emphasized the need for preoperative transfusion.[29,31,90–92] From recent reports, the laparoscopic approach does not appear to be more hazardous for these patients and may be preferred.[19,29–31,91]

Several special circumstances merit attention. The first is the child with hereditary spherocytosis who is undergoing splenectomy. In these patients, a gallbladder US is recommended before the splenectomy. If gallstones are present, then cholecystectomy should be performed at the time of the splenectomy, regardless of whether the laparoscopic or open approach is used. Whether splenectomy protects these patients from the future development of cholelithiasis is unclear. However, in a study of 17 patients undergoing splenectomy alone in which cholelithiasis was not seen at the time of the splenectomy, none of the patients subsequently developed symptoms of cholelithiasis with a mean follow-up of 15 years.[93] Thus prophylactic cholecystectomy at the time of splenectomy is probably not indicated in patients with hereditary spherocytosis who do not have gallstones.

The second situation is that of the patient who presents with known or suspected choledocholithiasis in addition to cholelithiasis. A number of management strategies for such patients are available.[94–97] Options include preoperative endoscopic retrograde cholangiopancreatography (ERCP) with sphincterotomy and stone extraction, laparoscopic or open common duct exploration at the time of laparoscopic cholecystectomy, or postoperative endoscopic sphincterotomy with stone extraction, which is the approach commonly used in adults. This decision analysis appears to be related to two factors: the surgeon's experience with laparoscopic common duct exploration and the availability of ERCP and sphincterotomy in children and adolescents at the treating institution. For those pediatric surgeons who are facile with laparoscopic common duct exploration, this may be an attractive approach with postoperative endoscopic sphincterotomy reserved for the unsuccessful cases. However, for most pediatric surgeons, this is probably not the best option because postoperative endoscopic sphincterotomy is a rarely performed procedure in many pediatric surgical centers. Thus in this setting, it would appear best to perform preoperative ERCP with sphincterotomy and stone extraction if stones are found. If successful, the surgeon can then proceed with uncomplicated laparoscopic cholecystectomy in the next few days. However, if the endoscopic sphincterotomy and stone extraction are not successful, then the surgeon will know at the time of the operative procedure whether a laparoscopic or open common duct exploration is necessary (Fig. 107-2). Both approaches have been used at our institution.

A final preoperative concern is whether to perform an intraoperative cholangiogram. In the early to mid-1990s, when there was not much experience with laparoscopic cholecystectomy in children, it was suggested that most, if not all, children undergo a cholangiogram for surgeon-training purposes and to ensure that the correct anatomy has been visualized. A third reason was to evaluate for the presence of common duct stones, although this is often suspected preoperatively either from symptoms, US, or laboratory studies. As pediatric surgeons have gained more familiarity with the technique of laparoscopic cholecystectomy, routine intraoperative cholangiography for surgeon-training purposes does not appear necessary once the surgeon has become familiar with the technique. Thus in our minds, intraoperative cholangiography is useful primarily to ensure that the correct anatomy is visualized and to evaluate for choledocholithiasis. We often obtain a US evaluation a few days before the laparoscopic

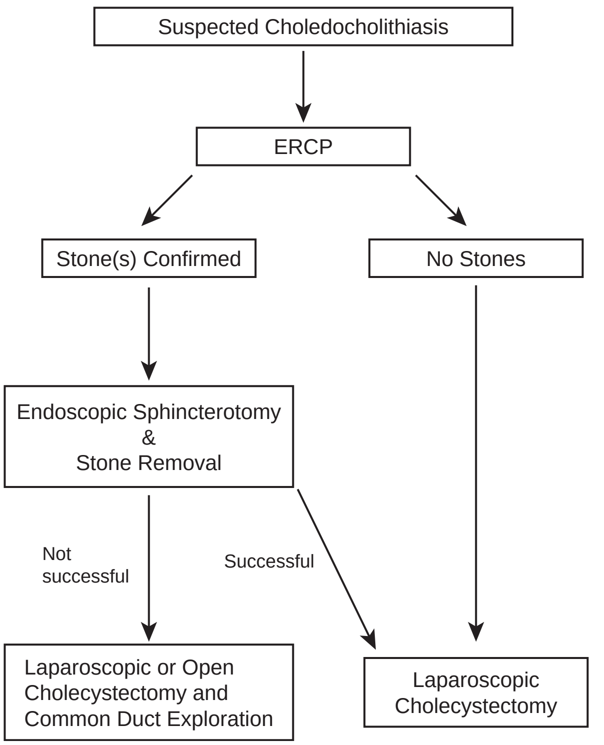

FIGURE 107-2 This algorithm depicts the authors' preferred strategy for managing patients with suspected choledocholithiasis. Preoperative endoscopic retrograde cholangiopancreatography (ERCP) is favored with stone extraction and sphincterotomy, if necessary, before the laparoscopic cholecystectomy. If the ERCP does not show evidence of choledocholithiasis, then laparoscopic cholecystectomy is performed. The reason this approach is favored is that, at the time of the laparoscopic cholecystectomy, the surgeon knows whether a laparoscopic or open choledochal exploration is necessary.

**TABLE 107-1**

**Financial Analysis of Preoperative Ultrasonography Versus Intraoperative Cholangiography for Detection of Choledocholithiasis at Children's Mercy Hospital, Kansas City, MO**

| *Immediate Preoperative Evaluation with Ultrasound* | *Charges* | *Intraoperative Cholangiography* | *Charges* |
|---|---|---|---|
| Ultrasound study (including radiologist's fee) | $307.67 | 15 minutes operating room time | $734.25 |
| | | C-arm with radiologist's fee | $365.41 |
| | | Sterile drape for C-arm | $20.00 |
| | | Cholangiocatheter | $83.50 |
| | | Contrast agent for cholangiogram | $40.00 |
| Total | $307.67 | Total | $1,243.16 |

cholecystectomy to confirm the presence of gallstones and to evaluate for common duct obstruction. This approach reduces the operative time and is cost effective (Table 107-1). Thus at the time of the operation, the primary need for cholangiography is to ensure the anatomic roadmap. If the anatomy appears clear at the time of the laparoscopic operation and there is no suspicion of common duct stones, routine cholangiography is not performed. If cholangiography is necessary, we still prefer the Kumar clamp technique, although a number of other techniques in which a catheter is introduced into the cystic duct through a transcystic incision are certainly appropriate.[1,98] Fluoroscopy is also useful because it is more time efficient than static radiography and allows dynamic assessment of the biliary tree (Fig. 107-3).

Another modification in the authors' technique over the past several years merits mention. For many laparoscopic operations including cholecystectomy, we have adopted a "stab incision" technique for instruments that are not continually exteriorized and reinserted into the abdominal cavity during the operation. In a study of 511 patients undergoing a variety of laparoscopic procedures in which only one or two Step (Covidien, Norwalk, Conn.) cannulas were used, a reduction of $187,180 was noted in the patient charges.[99] If the Ethicon (Ethicon Endosurgery, Cincinnati) disposable cannulas were used, patient savings of about $123,000 would have been realized. For cholecystectomy, the instruments placed through the two right-sided incisions are not routinely changed. Thus these two sites are optimal for the stab incision technique (Fig. 107-4). The telescope is introduced through the umbilical cannula, and the main working port is in the upper abdomen, so two Step cannulas are still used in these sites.

## LAPAROSCOPIC CHOLECYSTECTOMY

### Four-Port Technique

The patient is placed supine on the operating table with two video monitors situated at the head of the table. After induction of anesthesia, an orogastric tube is inserted for gastric decompression and the urinary bladder is evacuated using a Credé maneuver. A two-cannula and two "stab-incision" technique is used, but the location of the incisions and the cannulas depends on the patient's age and size (Fig.107-5). For infants and small children, the right lower abdominal incision can be positioned in the inguinal crease region and the epigastric cannula should be situated more on the patient's left to allow adequate working space between the instruments.

A 10-mm incision is made in the umbilicus, through which a 10-mm cannula is inserted into the abdominal cavity and abdominal insufflation is initiated. After creation of an adequate

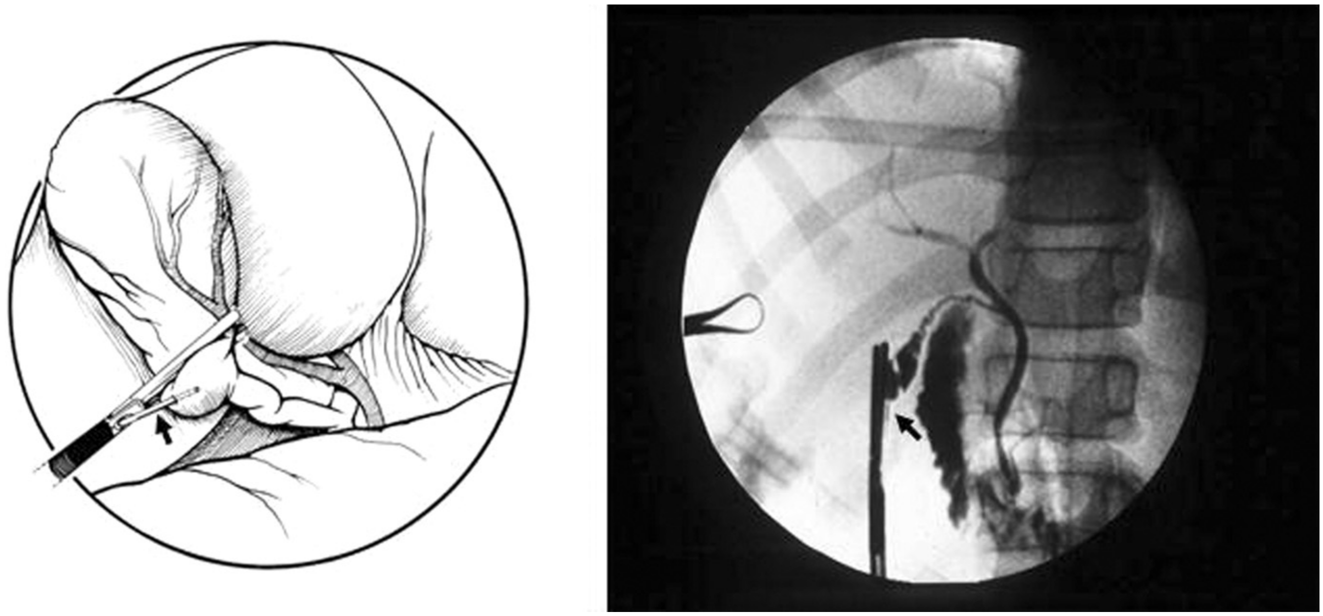

**FIGURE 107-3** The Kumar clamp technique for cholangiography in infants and small children is depicted. Note the clamp across the infundibulum and the sclerotherapy needle (*arrow*), which exits the side arm of the clamp and is introduced into the proximal infundibulum. The advantage of this technique is that lateral incision and cannulation of the small cystic duct are not necessary.

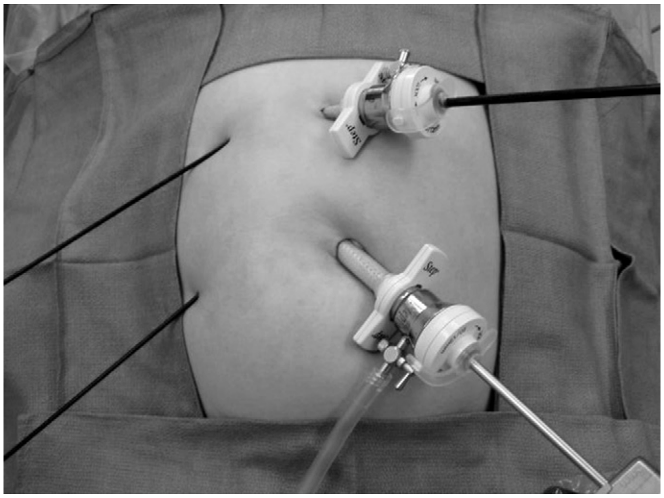

FIGURE 107-4 This operative photograph depicts the stab incision technique in a 5-year-old undergoing laparoscopic cholecystectomy. On the patient's right side, the two 3-mm instruments were introduced through the stab incision technique without the use of cannulas. A 5-mm cannula has been placed in the epigastric region, and a 10-mm cannula is introduced into the umbilicus. This is the site of extraction of the gallbladder. One advantage of the stab incision technique is cost savings because two additional cannulas are not necessary.

pneumoperitoneum, a 5- or 10-mm 45-degree telescope is inserted through the umbilical cannula and connected to the camera. The image is then displayed on the video monitors. The right lower abdominal stab incision is created with a No. 11 blade, and a locking, grasping forceps is introduced for retraction of the gallbladder superiorly over the liver by the assistant. Usually this is a 5-mm instrument, but a 3-mm instrument can be used in small children. Through the right upper abdominal stab incision, a nonlocking, grasping forceps is inserted for lateral retraction of the infundibulum of the gallbladder by the operating surgeon. The epigastric port is usually 5 mm in diameter and is the main working site. Occasionally, in larger adolescents, a 10-mm port may be necessary if a 10-mm endoscopic clip is required to completely occlude the cystic duct. Once the location of the cannulas is individualized according to the patient's size, the remaining principles of the procedure are similar to those used in adults.

For improved exposure, the patient and table are usually rotated into reverse Trendelenburg and left-dependent positions, which helps the adjacent viscera fall away from the surgical area. In addition, lateral retraction of the infundibulum is important because the cystic duct is then positioned at more of a 90-degree orientation to the common duct rather than an oblique or even parallel orientation, which occurs without such lateral retraction (Fig. 107-6). This parallel orientation may lead to misidentification of the cystic and common bile ducts resulting in injury to the common duct.

The initial surgical maneuver is to expose the cystic duct and identify the cystic artery. Adhesions between the duodenum and stomach often require lysis for access to the infundibulum and triangle of Calot. Once the cystic duct is identified, two options are available. One is to proceed with cholangiography as previously discussed. If the anatomy is clear and there is no evidence of choledochal obstruction on a preoperative US, we proceed with ligation and division of the cystic duct. Usually 5-mm clips are adequate, although a 10-mm clip may be required in larger patients. Two clips are placed on the cystic duct approximately 5 mm from its insertion into the common bile duct (Fig. 107-7). Another one or two clips are placed on the cystic duct near the infundibulum to prevent spillage of stones from the gallbladder. The cystic duct is then divided, and the cystic artery is similarly ligated and transected. Once these two structures are divided, the gallbladder is detached in a retrograde manner using one of several instruments: the hook cautery, spatula cautery, or endoscopic scissors attached to the cautery.

Before the gallbladder is completely separated from the liver bed, the triangle of Calot should be carefully inspected to ensure that all clips are secure and that there is no evidence of bleeding. After complete detachment of the gallbladder, the telescope is rotated from the umbilical port to the epigastric port. If the epigastric port is 5 mm, then a 5-mm telescope is used to visualize the gallbladder and a locking, grasping instrument is introduced through the umbilical cannula to secure the gallbladder. The gallbladder is then extracted through the umbilical port. In older patients, the gallbladder may be too large for removal without further incising the umbilical fascia. This opening should be enlarged in patients with large gallbladders to prevent rupture with spillage of stones and bile during removal of the gallbladder. These gallstones, if spilled, should be removed because complications from retained stones have been reported in adults.[15,100,101] After the gallbladder is extracted, the area of dissection is again

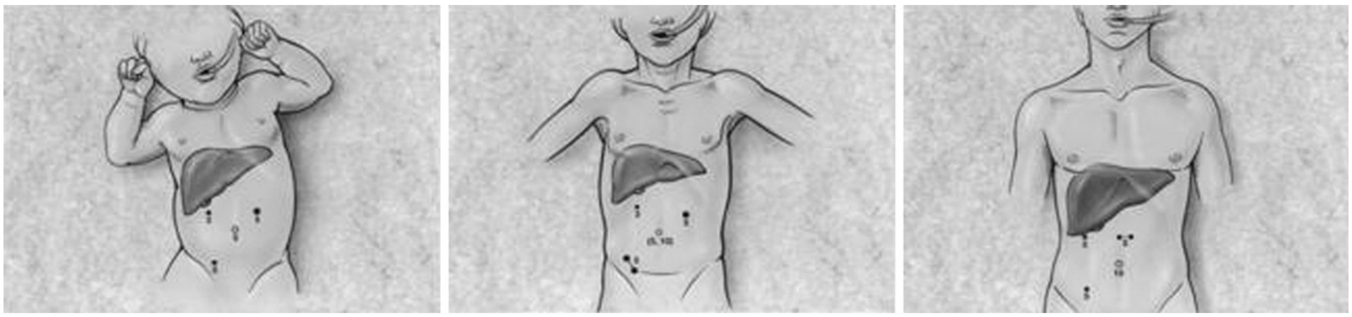

FIGURE 107-5 Placement of the cannulas and instruments in patients undergoing laparoscopic cholecystectomy depends on the patient's age and size. In an infant, 3- and 5-mm ports/instruments can be used. Also, the ports/instruments should be separated as much as possible to create an adequate working space for the operation (*left*). In a prepubertal child the port/instruments should be widely spaced as well. A 3-mm instrument can often be used in the surgeon's left hand. In younger patients in this age range, a 5-mm umbilical cannula may be possible. However, for most patients, a 10-mm umbilical cannula is necessary to extract the gallbladder through this incision (*middle*). In a teenager, the port placement more closely resembles that seen in adults (*right*).

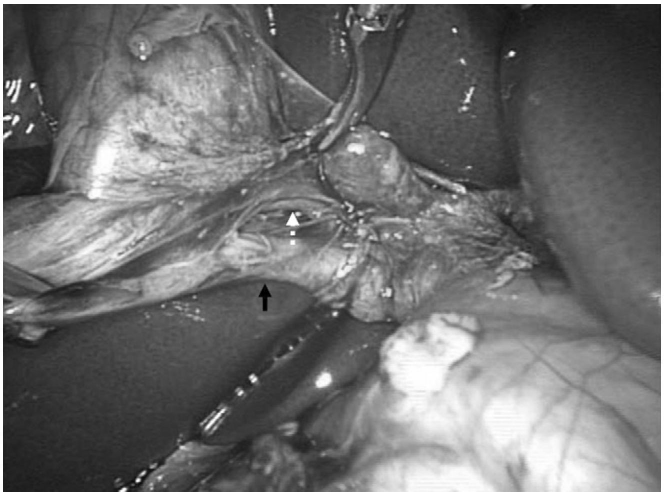

**FIGURE 107-6** During the initial stages of the laparoscopic cholecystectomy, it is vitally important to retract the infundibulum directly lateral so as to create a 90-degree angle between the cystic duct (*solid arrow*) and common duct. Note the cystic artery (*dotted arrow*) cephalad to the cystic duct.

carefully inspected to ensure adequate hemostasis. All irrigant is evacuated, and bupivacaine is injected into the incisions for postoperative analgesia. In smaller patients, the fascia surrounding the 5-mm cannula sites should be closed. In larger patients, fascial closure for the 5-mm ports or stab incisions is usually unnecessary, but the fascia surrounding the 10-mm cannula sites should be approximated carefully to prevent herniation. For the stab incisions, skin closure is usually all that is necessary. The patients are usually hospitalized after the procedure and discharged the next morning.

### Single-Site Umbilical Laparoscopic Cholecystectomy

Single-site umbilical laparoscopic surgery (SSULS) is being used more and more frequently for common surgical procedures such as cholecystectomy and appendectomy. It has also been used for splenectomy, pyloromyotomy, and ileocecectomy for Crohn disease. When compared with traditional three- and four-port/incision laparoscopic surgery, the only advantage of SSULS appears to be cosmesis. SSULS has become an attractive alternative between traditional laparoscopic surgery and natural orifice transluminal endoscopic surgery (NOTES) because there are a number of real and potential complications with access to the abdominal cavity with NOTES. Similar to SSULS, the only advantage of NOTES over traditional laparoscopic procedures is cosmesis.

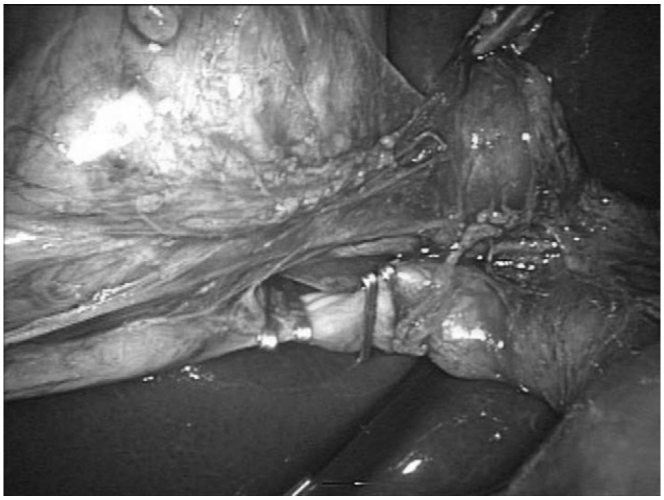

**FIGURE 107-7** After identification and isolation of the cystic duct, the duct is doubly ligated with two clips proximal and two clips distal. The duct will be divided between the two middle endoscopic clips.

For single-site laparoscopic cholecystectomy, an umbilical incision of approximately 2 cm is necessary. For this particular indication, our group uses either the SILS port (Covidien, Norwalk, Conn.) or the Tri-Port (Olympus America, Center Valley, Pa.). The SILS port is a foam port with three channels through which the telescope and instruments are introduced. A fourth instrument is then introduced along the side of the foam port for retraction of the gallbladder (Fig. 107-8, *A*). There is also a channel for insufflation. The TriStar port is designed for three instruments, but a fourth 3-mm instrument can be introduced through one of the insufflation portals (Fig. 107-8, *B*). As with other SSULS procedures, it is helpful to have a long telescope so that the telescope/camera holder can stand away from the operating surgeon. Once the telescope and instruments are introduced, the operation proceeds

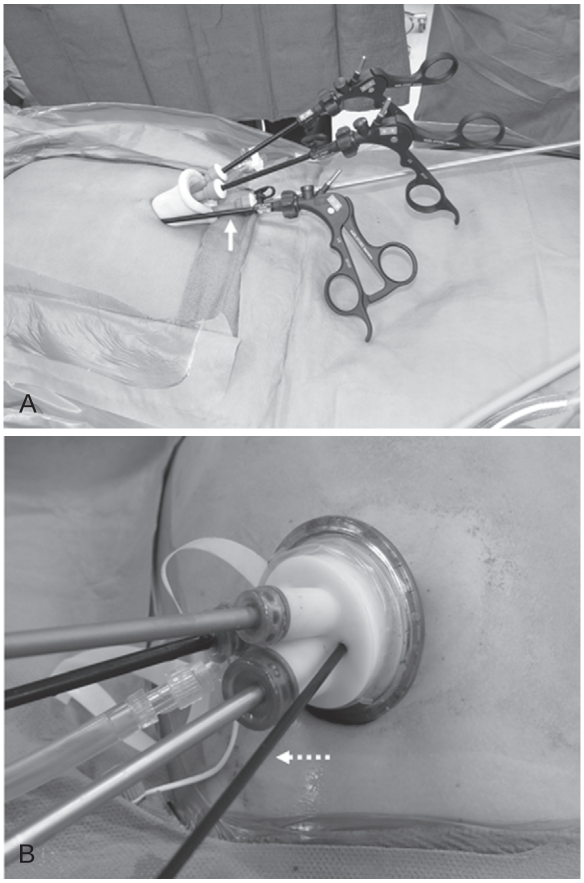

**FIGURE 107-8** For single-site laparoscopic cholecystectomy, an umbilical incision of approximately 2 cm is necessary. Our group uses both the Covidien SILS port (**A**) and the Olympus Tri-Port (**B**). The SILS port is a foam port with three channels through which the telescope and instruments are inserted. A fourth instrument (*arrow*) is then introduced along the side of the SILS port for retraction of the gallbladder over the liver. The Tri-Port is designed for single-site umbilical surgery as well. We insert a fourth 3-mm instrument through one of the insufflation ports (*dotted arrow*), if necessary.

exactly like a traditional four-port laparoscopic cholecystectomy. The instrument used to grasp the dome of the gallbladder is introduced at approximately 9 o'clock in the SILS or TriStar port, and another instrument is used to retract the infundibulum. With the SILS port, this instrument is introduced along the side of the port in the umbilical incision. The telescope should be angled at 30 to 45 degrees. As with traditional laparoscopic cholecystectomy, it is important to retract the infundibulum of the gallbladder laterally to create a right-angle orientation of the cystic and common bile ducts. Following identification and dissection of the cystic duct and cystic artery, the duct is ligated with endoscopic clips (Fig. 107-9, *A*). In a similar fashion, the cystic artery is divided as well (Fig. 107-9, *B*). After division of the cystic duct and cystic artery, the gallbladder is dissected free from its liver attachment using electrocautery. A number of instruments can

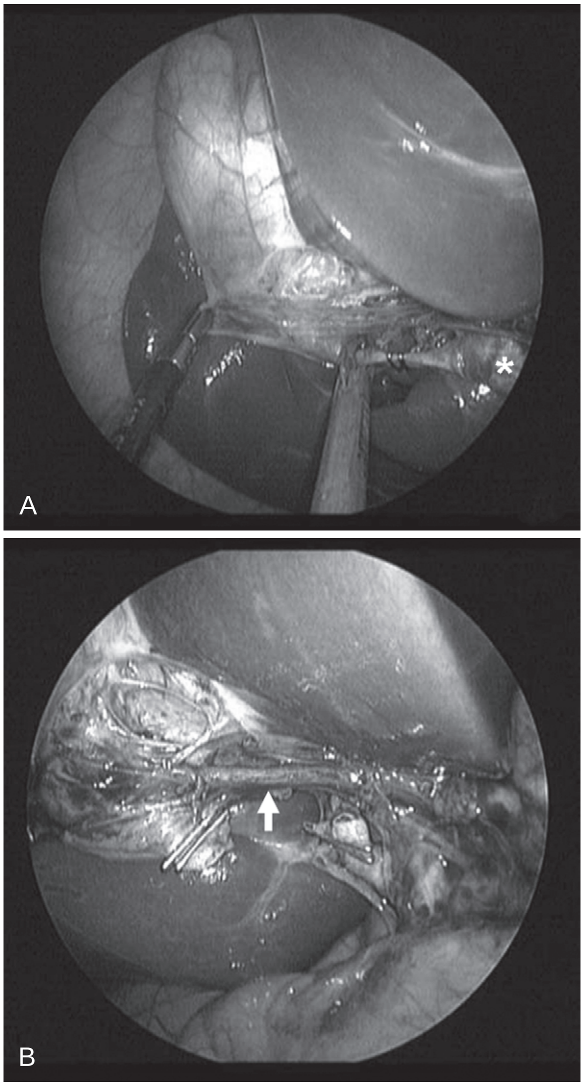

**FIGURE 107-9** Once the telescope and instruments are introduced, the operation proceeds exactly like the traditional four-port laparoscopic cholecystectomy. It is important to retract the infundibulum of the gallbladder laterally to create a right-angle orientation of the cystic and common bile ducts. In the top photograph (**A**), the endoscopic clips are being applied to the cystic duct. Note the right-angle orientation of the cystic and common bile ducts (*asterisk*). Following ligation and division of the cystic duct (**B**), the cystic artery (*arrow*) is well visualized and will be similarly ligated and divided.

**FIGURE 107-10** This teenager underwent a single-site umbilical laparoscopic cholecystectomy and was discharged the following day. She has achieved a nice cosmetic appearance at 1 month postoperatively. (She removed her belly-button ring for this photograph.)

be used for this purpose including the hook cautery, spatula cautery, or a Maryland dissector attached to cautery. After complete mobilization of the gallbladder, it is then grasped with an instrument placed through one of the channels in the umbilical port and exteriorized through the umbilical incision along with the port. Before extracting the gallbladder, it is helpful to assess for bleeding and to irrigate/suction because it would be necessary to reintroduce the umbilical port to recreate the pneumoperitoneum to perform these functions after removing the gallbladder.

The umbilical fascia is then closed with 0 absorbable suture in an interrupted or continuous fashion. We prefer to close the skin with interrupted 5-0 plain sutures, which is our usual practice for umbilical skin closure for traditional laparoscopic surgery. A nice cosmetic result is achieved using this SSULS approach for cholecystectomy (Fig. 107-10).

## CHILDREN'S MERCY HOSPITAL EXPERIENCE

Despite the widespread use of laparoscopic cholecystectomy in children, there are surprisingly few reports in the literature describing a series as large as 100 patients.[19,37,53,58,61,94] In a 1999 review of 100 patients undergoing laparoscopic cholecystectomy at Vanderbilt University Medical Center, one of the authors (GWH) described 78 children who underwent an elective operation and 22 who required an urgent operation for acute complications of cholelithiasis.[19] In that series, 19 patients had hemolytic disease and two patients had biliary dyskinesia. The six patients who presented with jaundice underwent ERCP before the laparoscopic cholecystectomy. Stones were extracted in two patients, and the other studies were normal. In that report, two patients required laparoscopic choledochal exploration. The operating time and postoperative hospitalization were significantly longer for the complicated group when compared with the elective patients. No significant complications occurred such as the need for reoperation, injury to the choledochus or other viscera, bile leak, or retained choledocholithiasis.

Recently, our group reported a 6-year experience with traditional four-port laparoscopic cholecystectomy at Children's Mercy Hospital (Table 107-2).[53] Between September 2000 and June 2006, 224 patients underwent laparoscopic

**TABLE 107-2**
**Patients Undergoing Laparoscopic Cholecystectomy at Children's Mercy Hospital (September 2000 to June 2006)**

| *Symptomatic gallstones (Hemolytic Disease)* | *166 (29)* | *Mean Age (Yr)* | *12.9 (0-21)* |
|---|---|---|---|
| Biliary dyskinesia | 35 | Mean weight (Kg) | 58.3 (3-121) |
| Gallstone pancreatitis | 7 | Mean operating time (min) | 77 (30-285) |
| Concomitant splenectomy | 6 | Major complications | 1 |
| Calculous cholecystitis | 5 | | |
| Miscellaneous | 5 | | |
| | 224 | | |

From St. Peter SD, Keckler SJ, Nair A, et al: Laparoscopic cholecystectomy in the pediatric population. J Laparoendosc Adv Surg Tech A 2008;18:127-130.

cholecystectomy.[53] The mean age was 12.9 years (range 0 to 21 years) with a mean weight of 58.3 kg (range 3 to 121 kg). One hundred and sixty-six children had symptomatic gallstones, 35 children had biliary dyskinesia, seven patients presented with gallstone pancreatitis, six patients were undergoing splenectomy and found to have gallstones, five patients had calculous cholecystitis, and one patient each had choledocholithiasis, gallbladder polyp, acalculous cholecystitis, and congenital cystic duct obstruction. In this series there were only 29 patients with hemolytic disease. Eighteen patients had sickle cell disease, and 11 had hereditary spherocytosis. The mean operative time (excluding patients undergoing a concomitant operation) was 77 minutes (range 30 to 285 minutes).

Due to preoperative concerns about choledocholithiasis, a preoperative ERCP was performed in 17 patients. Stones were retrieved endoscopically in eight of these patients. Additionally, an operative cholangiogram was performed in 38 patients and common duct stones (CBD) were identified in 9 patients. CBD stones were cleared intraoperatively in five patients, while the other four patients required postoperative endoscopy and sphincterotomy to retrieve the stones. Because of a postoperative rise in direct bilirubin, two patients who did not have an intraoperative cholangiogram underwent a postoperative ERCP. The ERCP was normal in both cases.

There were no conversions, ductal injuries, bile leaks, or mortality. However, one sickle cell patient developed a postoperative hemorrhage, which required laparotomy for control. Interestingly, biliary dyskinesia was diagnosed in only 10% of the first 30 patients in this series but was diagnosed in 40% of the last 30 patients studied. The mean ejection fraction in these patients was 21%. All of these patients had improvement in their symptoms following the laparoscopic cholecystectomy.

Over the past 10 years, laparoscopic cholecystectomy has become the accepted standard for removal of the gallbladder in children and adolescents. Reported complications have been rare. There are no reports of choledochal injury in children, although some have undoubtedly occurred. As additional experience is gained, pediatric surgeons may use intraoperative US rather than cholangiography to assess the correct anatomy and the presence of choledocholithiasis.

SSULS is also being used for gallbladder removal at our institution. A prospective, randomized trial is under way at our hospital comparing single-site umbilical laparoscopic cholecystectomy with traditional four-port laparoscopic cholecystectomy. Operative time is the primary outcome variable. Using an alpha of 0.05 and a power of 0.80, a total of 60 patients will be enrolled. To date, 42 patients have participated in this trial.

# Hepatic Infections

Various hepatic infections occur in infancy and childhood (Table 105-3). The focus in this section of the chapter is on hepatic infections that often require surgical consultation for either diagnosis or treatment. This group includes hepatic abscess and nonviral causes of liver infection. In most pediatric series, more than half of liver abscesses are found in patients younger than 5 years of age and more than 25% occur during the first year of life.[102–104]

## PATHOPHYSIOLOGY

Bacteria and other organisms may enter the liver through various routes, the most common being the biliary tract, the portal vein, and the hepatic artery. Also, organisms may directly invade the liver during penetrating trauma. In one report, a liver abscess occurred in 4 of 16 patients with unruptured post-traumatic intrahepatic hematomas.[105]

The clinical signs and symptoms of liver abscess are usually nonspecific. The most common signs and symptoms are fever, abdominal pain, and hepatomegaly. Abnormalities in leukocyte count, liver enzyme levels, or bilirubin levels vary in degree. Symptoms may last from days to months. The diagnosis of an hepatic abscess with imaging techniques has improved markedly with the availability of US and computed tomography (CT) (Figs. 107-11 and 107-12).[102,103]

## PYOGENIC LIVER ABSCESS

Pyogenic liver abscess (PLA) is uncommon in children, with a reported incidence varying from 3 to 25 per 100,000 pediatric hospital admissions.[106] Its incidence has decreased since the introduction of antibiotics. In contrast to adults, in whom

**FIGURE 107-11** Computed tomography scan demonstrating several hepatic abscesses (defects) in a child with staphylococcal infection related to chronic granulomatous disease.

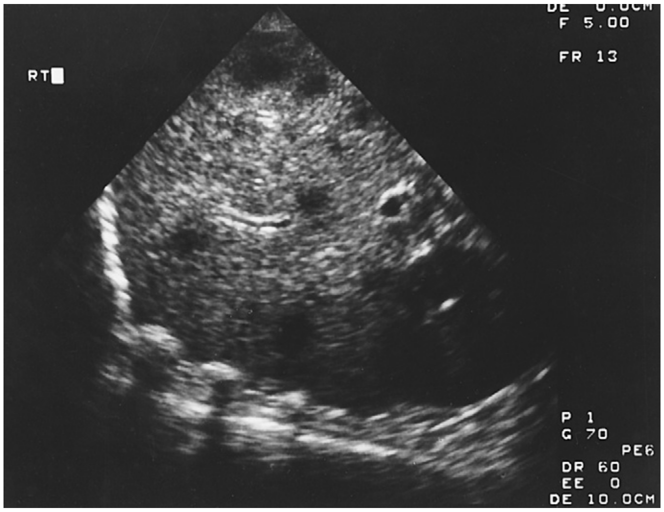

**FIGURE 107-12** Sonogram demonstrating several hepatic abscesses (echolucent areas) in the same patient as in Figure 107-13.

biliary tract disease is the primary cause of hepatic abscess, pyogenic liver abscess in children can be caused by a number of different conditions. Historically, the most frequent cause of hepatic abscess in children was perforated appendicitis. The development of hepatic infection in this setting was presumed to be due to pylephlebitis of the mesenteric and portal veins with ascending migration of bacteria into the liver. An intra-abdominal source of bacteria is still a common etiology of PLA, but liver abscesses are also seen in children with chronic malnutrition, granulocyte dysfunction, sickle cell disease, and with congenital or acquired immunosuppression.

Chronic granulomatous disease of childhood is one of the more common immunodeficiencies. Also, acquired impairment in host resistance, such as that caused by chemotherapy or transplantation immunosuppression, can predispose patients to hepatic abscess formation. In immunocompetent children, causes for PLA include an intestinal source (i.e., appendicitis, Crohn disease), chronic cholangitis with intrahepatic abscess formation in patients with biliary atresia or choledochal cysts, umbilical vein catheterization (neonates), and systemic bacteremia of any cause.[107] Abdominal trauma, either penetrating or blunt, with liver injury is also associated with an increased incidence of hepatic abscess.[108,109] Abscesses in such cases are presumed to be secondary to bacterial seeding of the devitalized liver parenchyma and are often associated with a hematoma. It must be remembered, however, that liver abscesses do occur in otherwise normal children without any obvious predisposing conditions.[110,111] In 20% of these patients, the infectious source of the hepatic abscess is never found.[112]

The diagnosis of a PLA is often dependent on its being considered as part of the differential diagnosis. The low incidence of liver abscess in childhood leads to a low index of suspicion and sometimes delays the diagnosis for weeks to months. The overall mean age of presentation for PLA is reported to be 7.5 years with children from developing countries presenting at younger ages and children from developed countries presenting at older ages.[113] The classic signs and symptoms of fever, abdominal pain, jaundice, and liver enlargement occur infrequently, which is why the diagnosis is often missed. These symptoms can develop slowly and, if associated with weight loss, can lead initially to the suspicion of cancer. Usually the presenting symptoms are nonspecific, with the major symptom being abdominal pain.[106,110] The duration of symptoms is highly variable, but usually patients present between 1 week and 1 month after they become ill. Most patients are febrile, but an enlarged liver is rarely found on physical examination. Right upper quadrant tenderness is only found in about 40% of patients.[107] Hematologic studies are usually not helpful because only mild leukocytosis is seen. Elevated liver function studies are found in only one half of the patients. Inflammatory markers, however, are frequently elevated in patients with a PLA.[113]

When the bacteriology of pyogenic abscesses is examined in children, *Staphylococcus aureus* is the primary infecting agent in 37% to 50% of the children.[106,110,112,114] Most hepatic abscesses, however, tend to be polymicrobial with gram-positive cocci and gram-negative rods including *Escherichia coli, Klebsiella, Enterobacter,* and *Pseudomonas.* Recently, anaerobes have also been cultured from these abscesses in at least 20% of the cases.[114–116] Blood cultures are positive in about 50% of patients. However, blood cultures often grow fewer bacterial types than are subsequently recovered from direct cultures of the abscess. As a cautionary note, in a third of the blood cultures, the organisms that were recovered from the blood were not subsequently recovered from the cultures of the liver abscess. Unfortunately, whereas Gram stains of a direct aspirate from a liver abscess are highly accurate for gram-positive cocci, they have only a 50% sensitivity for gram-negative organisms.[117] Fungal abscesses have been found with an increasing incidence in children who become febrile and neutropenic while being treated for acute leukemia.[118] One prospective series reported a 29% incidence of fungal hepatic and/or splenic abscesses in this population.[119] A specific ultrasonographic appearance for hepatic and splenic candidiasis has been described.[120]

Neonates comprise another special subpopulation of patients. In the perinatal period, direct transplacental bacterial seeding of the liver can occur. This seeding may be associated with premature rupture of membranes. Omphalitis, with or without catheterization of the umbilical vein, has been rarely associated with bacterial hepatitis or abscess. Most of the time these abscesses are miliary. There is a disproportionately high representation of gram-negative organisms in the neonatal hepatic abscess. Because they are usually miliary, they are not amenable to percutaneous drainage. Therefore high-dose, long-term antibiotic treatment is necessary.

In those neonates who presented with a solitary hepatic abscess, the offending organism is usually *S. aureus.* These patients present with an enlarging right upper quadrant mass that is often confused with a tumor. Treatment of these solitary abscesses has often been resection because of the difficulty in distinguishing between an abscess and a solid tumor.[121]

## RADIOLOGIC EVALUATION

The radiologic studies that are most helpful in the diagnosis of PLA are abdominal US and CT. US is usually preferred as the initial screening tool because of the lack of need for sedation and the absence of ionizing radiation. CT, however, is more sensitive and can discover lesions that are missed by US. In addition, CT is usually the preferred radiologic modality for localization of the abscess for percutaneous drainage.[106]

On radiologic evaluation, PLAs can present as either a solitary lesion or as multiple lesions. There is also a predisposition for the lesions to be in the right lobe of the liver.[122]

## TREATMENT

The initial treatment of a PLA should be with broad-spectrum antibiotics with coverage for gram-positive, gram-negative, and anaerobic organisms. As part of the gram-negative spectrum, *Pseudomonas* coverage must be included. The preferred therapeutic and diagnostic intervention is percutaneous drainage/aspiration of the abscess under either CT or US guidance. After the abscess has been drained and specific bacteria have been recovered, antibiotic therapy can then be tailored to cover these organisms. The recommended duration of intravenous antibiotic therapy is 4 to 6 weeks, followed by oral antibiotics for an additional 4 to 8 weeks.[104] The complication rate of percutaneous drainage has been reported to be about 4%, with a failure rate of 15%.[123] However, if the patient does not respond to percutaneous drainage or if percutaneous drainage is not possible, then an operative approach is warranted.[110,124] One study reported the laparoscopic approach for drainage of a pyogenic liver abscess.[125] With an aggressive approach to treatment of pyogenic liver abscess, the mortality of this condition has dropped from 36% in the 1970s to 15% in the late 1980s and 10% now.

One complication of PLA that has been reported in the adult population is endophthalmitis. In one series, there was a 3.5% incidence of this complication, which can lead to a variety of devastating visual problems, ranging from decreased visual acuity to complete blindness.[126] The best results for recovery were associated with initiation of treatment within 24 hours of any visual symptoms. Therefore a child who appears to be having any visual difficulties with a pyogenic abscess should undergo an ophthalmologic evaluation.

## CAT-SCRATCH DISEASE

Cat-scratch disease is a subacute illness preceded by exposure to an infected cat. It is characterized by regional lymphadenitis but may involve other organ systems including the liver, brain, and bone. This disorder was first described as oculoglandular syndrome in 1889, and the association with a scratch by a cat was reported in 1950 by Debre.[127] Since then, various infectious organisms have been postulated as the etiologic agent. Cat-scratch disease is now known to be caused by *Bartonella henselae* and is seen throughout North America with most cases occurring in late summer to fall. The disease primarily affects children and adolescents (75% to 80% of cases). A primary lesion develops at the site of inoculation in most cases, usually within 1 to 2 weeks of inoculation. This lesion is typically a single papule 2 to 5 mm in diameter. Regional lymphadenopathy develops approximately 3 weeks later and frequently involves axillary, inguinal, and cervical nodes. The primary skin lesion has often resolved by the time the adenopathy occurs. Other associated symptoms are fever, anorexia, malaise, fatigue, and headache. Traditionally the diagnosis has been confirmed by acute/convalescent IgG titers. Recently, polymerase chain reaction (PCR) of tissue, lymph node, or peripheral blood has been found to be both sensitive and specific for *B. henselae,* as well as having a rapid turn-around time.[128]

It is estimated that 5% to 10% of patients present with significant systemic symptoms or atypical manifestations of the disease. In these patients, the typical regional adenopathy may be absent.[129] Patients who are immunosuppressed are also at risk for cat-scratch disease. There have been several recent reports documenting cat-scratch disease causing liver masses in patients after liver transplantation.[130–132]

Liver involvement is the third most common clinical manifestation of cat-scratch disease after fever and lymphadenopathy.[133] It is usually diagnosed by abdominal CT, which is performed as part of the evaluation for fever of unknown origin. This test typically shows multiple lesions in both lobes of the liver and, sometimes, associated splenic involvement.[127,134] The diagnosis is confirmed by liver biopsy, either open or guided by laparoscopy. The histologic features consist of a granulomatous reaction with necrosis. Cultures of the lesions are usually negative for bacteria and fungi. Treatment of cat-scratch disease remains controversial because most untreated cases resolve without sequelae. Patients with marked symptoms or visceral involvement are usually treated with antibiotics (e.g., gentamicin, ciprofloxacin, rifampin, or azithromycin).[135] Currently azithromycin is the agent of choice for uncomplicated disease. For hepatic involvement, a multidrug regimen (gentamicin and rifampin) has been used for 2 to 3 weeks.[136]

## PERIHEPATITIS

In the pediatric population, bacterial liver infection with either *Neisseria gonorrhoeae* or *Chlamydia trachomatis* tends to occur most frequently in teenage girls. The initial pelvic infection travels cephalad in the abdomen, resulting in the perihepatitis. If the perihepatitis is untreated, then the classic "violin string" adhesions develop between the liver and the peritoneal cavity that are associated with the Fitz-Hugh-Curtis syndrome.

In addition to the typical symptoms of pelvic inflammatory disease including dysmenorrhea, vaginal discharge, and lower abdominal pain, these patients also present with severe pleuritic right upper abdominal pain that often radiates to the right shoulder. It is not unusual for the patient to complain of left upper quadrant pain as well. In these patients, the liver is often tender to palpation and a rub may be audible near the costal margin. Pelvic findings of acute salpingitis are usually present. Laboratory findings include leukocytosis, elevated aminotransferase levels, and occasional hyperbilirubinemia.

Perihepatitis can mimic a variety of other conditions in the upper abdomen including cholelithiasis, hepatitis, a perforated peptic ulcer, appendicitis, or pancreatitis. In female adolescents with a history of pelvic inflammatory disease, perihepatitis must be part of the differential diagnosis when these patients present with right upper quadrant pain. Recently, dynamic abdominal CT scanning including the arterial phase has been reported as an important tool in the diagnosis of this syndrome.[137] If the arterial phase of the scan shows hepatic capsular enhancement (secondary to increased blood flow in the inflamed hepatic capsule), then the diagnosis of Fitz-Hugh-Curtis syndrome can be made without further invasive studies.

In patients in whom the diagnosis is uncertain or in patients who have persistent symptoms, diagnostic laparoscopy can allow direct visualization of the perihepatic space.

If found, the classic adhesions can be lysed, which often results in a significant improvement in pain.[138]

Recent reports have implicated *C. trachomatis,* in addition to *N. gonorrhoeae,* as a cause of this syndrome.[137,139] Therefore a treatment regimen that is effective against both chlamydial infection and gonococcus is necessary. This would include tetracycline or doxycycline or erythromycin for patients in whom tetracycline is contraindicated.[140]

## AMEBIC ABSCESS

The incidence of amebic liver abscess in the United States seems to have gradually increased. Hepatic involvement by *Entamoeba histolytica* is primarily a disease of adults but does occur in younger patients, most commonly in early childhood.[141] Poor sanitation and crowded conditions help foster the development and spread of amebiasis. In patients with amebic colitis, trophozoites from colon ulcers travel through the portal vein to the liver, where they initiate a necrotizing process with subsequent abscess formation. In the adult population, liver involvement with an amebic abscess occurs in 10% to 50% of adults with a 90% male predominance. In children, however, liver involvement occurs in only 1% to 7% of the patients with an equal distribution between males and females.[142–144] Corticosteroids and immunosuppression seems to predispose patients to amebic abscess formation.

More than 80% of amebic liver abscesses occur in the right lobe of the liver. Symptoms include fever, chills, nausea, weight loss, and abdominal distention. On physical examination, the children tend to have hepatomegaly, but abdominal pain and liver tenderness are relatively infrequent. Breath sounds are often decreased in the lower right chest, and right-sided pleural effusions are common. Clinical jaundice is uncommon. A history of exposure or travel to endemic areas (Mexico, South America, or Southeast Asia) is often a better indicator of amebiasis than are the imaging studies.[145] In the United States the typical patient is a child of immigrants who come from an area that is endemic for amebiasis but are not necessarily living in poverty.[146]

Laboratory findings include leukocytosis without eosinophilia, mild anemia, and normal or mildly abnormal liver function studies. Abdominal US and CT are useful for defining the location and number of lesions. The characteristic US appearance is a hypoechoic, thin-walled abscess that sometimes contains air. CT shows a nonspecific picture of a well-circumscribed, low-density lesion that is usually solitary and has predominance for the right lobe of the liver. Also, with modern imaging techniques, it is now clear that multiple amebic abscesses can be found within the liver.[147]

The diagnosis of an amebic liver abscess relies on the identification of a space-occupying lesion in the liver and the presence of positive amebic serology. Amebic serology (indirect hemoglobin assay or agar gel immunodiffusion precipitant) has been found to be highly sensitive (>94%) and highly specific (>95%) for the diagnosis of amebic liver abscess.[148] PCR analysis for *E. histolytica* and *E. dispar* has become available and may prove to be more sensitive and specific than the previous assays.[149] If it is not possible to distinguish clinically between a pyogenic versus an amebic liver abscess, if the abscess does not respond to appropriate medical treatment, or if serologic tests for ameba are inconclusive, then aspiration of the abscess is indicated for culture.

The current treatment for an amebic abscess is oral metronidazole (30 to 50 mg/kg/day divided 3 times a day for 7 to 10 days). Most patients will respond to this therapy with resolution of their fever and abdominal pain. Currently there is no indication for aspiration of an uncomplicated amebic abscess because the majority of these will resolve with medical management alone.[147,150–152] If the patient does not respond to medical management within 4 days, if the liver abscess is greater than 5 cm in diameter, if it is located in the left lobe of the liver, or if it is believed to be in danger of rupture, then aspiration and percutaneous drainage is advisable. In addition, percutaneous catheter drainage is also indicated in patients who have had rupture of an amebic abscess into the right pleural space. Total resolution of the abscess may take months to years and can be followed by US.

The most common complication of an amebic liver abscess is erosion through the diaphragm and rupture into the right chest. The rupture rate of a right lobe amebic liver abscess is relatively low, but the rupture rate of a left lobe abscess has been reported to be as high as 22%.[153] Intraperitoneal rupture of an amebic abscess carries a 20% to 75% mortality, and the patients who are at the highest risk are those who present with acute peritonitis.[154,155] Intraperitoneal rupture results in a clinical picture of peritonitis and shock. If this develops, fluid resuscitation, antibiotics, antiamebic drugs, and surgical exploration are necessary. Erosion into the pericardial sac is less frequent but may cause cardiac tamponade. Erosion into intra-abdominal organs including the stomach has also been reported.[146,156]

There have been attempts at developing a vaccine for *E. histolytica* in an attempt to eradicate amebiasis. However, unfortunately in some cases, a natural infection with *E. histolytica* does not seem to result in long-term immunity. In fact, recurrent amebic liver abscesses are a well-known problem in areas where *E. histolytica* is endemic.[157–159]

## ECHINOCOCCAL CYST

Hydatid disease is generally caused by infection with the larval stage of the dog tapeworm *Echinococcus granulosis.* The ingested ova burrow through the intestinal mucosa and travel to the liver through the mesenteric veins. A few ova may bypass the liver and be trapped in the lung. The reported peak incidence of echinococcal infection in children is between 5 and 15 years of age.[160,161] The liver is involved in about 60% of the cases, the lung in about 20%, and other organs (kidney, brain, bone, or muscle) in about 20% of the cases. A solitary cyst will develop in one organ about 80% of the time.[162] The host organ separates itself from the parasite by forming a pericyst, which is a capsule of native connective tissue. For most surgical procedures, the pericyst is left behind and the intraluminal contents of the cyst are removed.

The usual presenting symptoms include right upper quadrant pain, a mass, and right pleuritic type chest pain in about one half of the patients. Interestingly, about a fourth of the patients are asymptomatic at presentation. Untreated cysts tend to grow until they reach the surface of the liver, where they can then spontaneously rupture, resulting in dissemination of the parasite into the peritoneal cavity and possible anaphylaxis.[163] In one fourth of the cases, the cyst can become secondarily infected with bacteria.[147] Echinococcal liver abscess is best diagnosed by serologic testing. The indirect hemagglutination

assay is the most specific test, but it lacks sensitivity for echinococcal disease. Results are considered positive for tissue invasion at a titer of 1:512, suspicious at a titer of 1:128, and negative at a titer of 1:32. Additional tests include an enzyme-linked immunosorbent assay (ELISA), which has been reported to be positive in 96% of patients, or a compliment fixation test, which has an 89% positivity rate.[162] Sunita and colleagues have also reported excellent results using urine and saliva for ELISA antibody testing. The combination of two positive serologic tests provides a laboratory diagnosis in more than 94% of patients with echinococcal disease.[163a]

Diagnostic aspiration is indicated if there is concern that the cyst could be a pyogenic or amebic abscess, but it is not indicated for echinococcal disease. Abdominal US or CT is the diagnostic imaging modality of choice.[164] A plain film of the abdomen or abdominal CT may show calcification of the rim of an echinococcal cyst or daughter cysts that is not found in amebic liver abscess (Fig. 107-13).

The definitive treatment of hepatic hydatid disease is surgical. Medical treatment of hydatid cyst includes the second-generation anthelmintic albendazole. Albendazole has been shown to be most effective in decreasing recurrent disease when it is given both preoperatively and postoperatively.[161,166,167]

Successful operative management starts with isolation of the liver from the rest of the abdomen, usually with sponges soaked in hypertonic saline or a povidone-iodine (Betadine) solution to prevent spillage of the cyst material. The cyst fluid is then aspirated. The cyst is then opened 2 to 3 cm and the remaining contents including the laminated membrane are removed. The cavity is then flushed with 20% saline; however, the effectiveness of this step has been questioned.[168] The cavity then needs to be obliterated using one of several different techniques: closed suction drainage (cystostomy with drainage), obliteration with absorbable sutures (cystostomy with capitonnage), placement of an omental flap over the residual cavity (cystostomy with omentoplasty), or total excision of the entire cyst (cystectomy).[167,168] When cystostomy is performed, the cyst wall needs to be carefully inspected for any open biliary radicals. If found, they are individually sutured closed.[161] Recurrence rates after surgical excision of hepatic hydatid cysts have been reported to range from 1.1% to 9.6%.[169] When surgery and albendazole treatment are combined, the hepatic recurrence rate can be lowered to 2%.[161,165–168]

CHAPTER 108

# Portal Hypertension

Riccardo Superina

*A man who thinks that a science can perform what is outside its province, or that nature can accomplish unnatural things, is guilty of ignorance more akin to madness than to lack of learning. Our practice is limited by the instruments made available by Nature or by Art. When a man is attacked by a disease more powerful than the instruments of medicine, it must not be expected that medicine should prove victorious.*

**—Hippocrates**

The treatment of portal hypertension in children is always evolving as the nature of underlying disorders is better understood. Treatment is often successful, Hippocrates notwithstanding, and the strategy usually involves medical, surgical, or combined therapy. This improved outlook is a departure from past years because of the improved understanding of the underlying pathophysiology. More effective imaging techniques and a wider array of options in pharmacologic management have resulted in opportunities to apply both established and newer surgical techniques precisely and deliberately to address underlying disease processes that cause portal hypertension.

## Historical Background

The Italian physician and pathologist Guido Banti first described the relationship among splenic enlargement, anemia, and cirrhosis of the liver. The first splenectomy done for hypersplenism was done in Florence in 1903 on his advice. The constellation of symptoms later became known as *Banti syndrome*.[1]

Earlier, Nikolai Eck, a German anatomist, had produced a connection between the portal vein and the inferior vena cava in a dog.[2] Later studies described the association between the direct communication of portal and systemic venous blood and the onset of encephalopathy associated with hyperammonemia and protein ingestion.[3–5]

The first applications of portosystemic shunting in patients were reported in the 1950s and 1960s. More selective shunting procedures were devised when it was discovered that diversion of mesenteric blood flow into the systemic circulation could precipitate severe encephalopathy. Nonshunt procedures aimed at interrupting the blood flow to gastric and esophageal varices were also described.

Finally, with the advent of liver transplantation, portal hypertension caused by advanced liver disease was treated by replacement of the diseased organ, rather than palliative procedures that produced significant morbidity and often hastened the demise of the patient.

## Embryology and Anatomy

The portal vein develops through a complex system involving the formation and involution of primitive vessels, followed by circulatory changes at birth that affect the flow of blood in the mature portal circulation (Fig. 108-1).

The left and right omphalomesenteric veins drain the developing gut as it is formed from the yolk sac during the fourth to sixth weeks of embryonic life. At the same time, the umbilical veins transport blood from the placenta to the embryo. Blood from both the umbilical and the omphalomesenteric veins drains through the nascent hepatic sinusoids in the developing liver and into the hepatic veins back to the developing heart. Some of the blood from the umbilical veins bypasses the liver and drains into the sinus venosus through the ductus venosus. Although the omphalomesenteric veins communicate by a series of intermediary vessels early in embryonic life, the right one involutes and disappears by the sixth week of gestation. The left one develops into the permanent portal vein, which drains the mesenteric venous bed through the superior mesenteric vein and its branches. The right umbilical vein also involutes, and the left remains patent until shortly after birth, when it thromboses and becomes the ligamentum teres.

The portal vein is formed by the confluence of the splenic and superior mesenteric veins posterior to the head of the pancreas. The coronary vein draining the gastric venous bed inserts into the portal vein at or just distal to the splenomesenteric confluence, and the inferior mesenteric vein drains into the splenic vein anywhere along its length, also behind the pancreas.

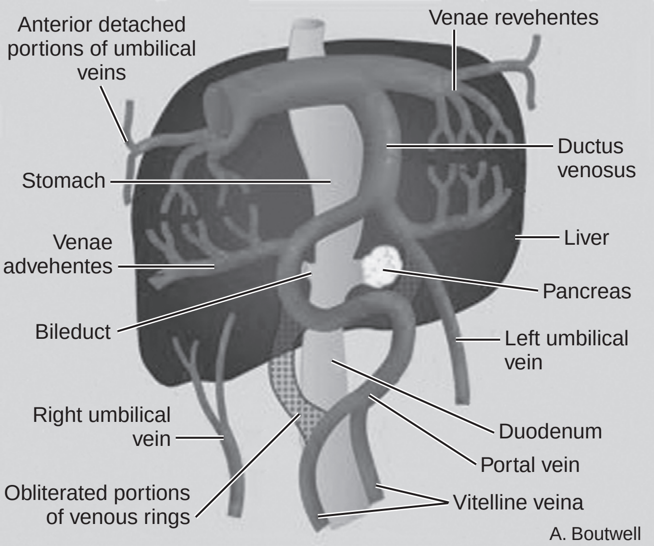

**FIGURE 108-1** The portal vein forms from the union of the two vitelline veins draining blood from the yolk sac. The left vitelline vein joins with the splenic vein to form the extrahepatic portion of the portal vein. The intrahepatic portal vein forms from the umbilical veins. In addition, the left umbilical vein communcates with the sinus venosus, allowing placental blood to bypass the liver during intrauterine life. The right vitelline and umbilical veins involute.

Despite the relative variability in the anatomy of the liver's arterial supply, the portal vein anatomy varies little. The principal extrahepatic vein divides into a left and a right branch. The left branch supplies the left lobe as it courses under the surface of segment IV of the liver; turns anteriorly in the recessus of Rex among segments II, III, and IV; and ends by dividing into the branches that supply those segments. The right branch divides into the posterior and anterior sectoral branches at or just before the liver plate at the capsule.

A cavernous venous malformation may be the result of a disordered sequence of biologic steps. Thrombus in the postnatal umbilical vein may also propagate into the hepatic portal vein and occlude flow in the extrahepatic portion of the vein. Both processes may lead to the syndrome of extrahepatic or prehepatic portal hypertension.

## Definition

Portal hypertension occurs whenever the resistance to the flow of blood from the mesenteric venous circulation through or to the liver increases. The causes of portal hypertension are most commonly obstructive in nature. That is, there is an impediment to the forward flow of blood from the omphalomesenteric vascular bed through the liver and toward the heart. However, portal hypertension can also be caused by an increase in the volume of blood going to the liver or by a direct communication between the arterial and venous supplies to the liver that exposes the venous bed to abnormally high pressures.

Portal hypertension may be defined as pressure in the portal venous bed that exceeds 5 to 8 cm $H_2O$ or a pressure gradient of more than 5 cm $H_2O$ between the hepatic veins and the portal circulation. When the pressure in the portal circulation exceeds those values, a series of physiologic changes leads to the symptoms common to all forms of portal hypertension, regardless of the cause.

## Collateral Circulation

As a consequence of the resistance to flow and the increase in pressure in the mesenteric venous circulation that includes the superior mesenteric, inferior mesenteric, splenic, and coronary veins, blood that normally goes to the liver from the portal vein must find alternative or additional routes back to the heart. The abnormal communications that form between the mesenteric and systemic venous systems are called varices or "shunts" because blood is shunted away from the liver and back to the heart. The hemorrhoidal plexus in the rectum, the paraumbilical network between the portal vein and the paraumbilical veins that form through the recanalization of the umbilical vein and ligamentum teres (forming the "caput medusa" around the umbilicus), and the communications in the gastroesophageal area between the coronary and splenic veins through the esophageal and paraesophageal veins back to the hemiazygous system are the typical areas where the abnormal shunts between the systemic and mesenteric venous systems occur.

Other locations of spontaneous shunts are between the veins of the colon and duodenum and the left renal vein; the accessory portal system of Sappey, whose branches in the round ligament unite with the epigastric and internal mammary veins through the diaphragmatic veins to unite with the azygos vein; the veins of Retzius, which connect the intestinal veins with the inferior vena cava and its retroperitoneal branches; the inferior mesenteric veins and the hemorrhoidal veins that open into the hypogastrics; and, rarely, the patent ductus venosus, affording a direct connection between the portal vein and the inferior vena cava.

## Causes: A Spectrum of Disorders

Portal hypertension can be divided into two categories: (1) portal hypertension from hepatocellular injury and liver fibrosis and (2) portal hypertension from primary vascular causes (Table 108-1).

### HEPATOCELLULAR INJURY

Table 108-2 illustrates some of the common liver disorders in children that can lead to portal hypertension. Hepatocellular injury from a variety of toxins leads to cell death, initiation and progression of fibrosis, and ultimately cirrhosis. Progressive injury to hepatic tissue and replacement of normal liver with fibrous tissue lead to increased resistance to blood flow through the liver. The process of deposition of collagen in response to hepatocyte injury appears to be a complex process mediated through the transcription of proinflammatory cytokines such as osteopontin and through stellate cells.[6] The stellate cell, a normal constituent of hepatic sinusoids, is the primary source of excess extracellular matrix proteins in liver fibrosis.[7] It can change its phenotype from one that is fairly quiescent during normal liver homeostasis to one that

**TABLE 108-1**
**Classification of Portal Hypertension**

| *Type* | *Description* |
|---|---|
| Hepatocellular | Intrinsic liver disease with increased liver fibrosis (see Table 108-2) |
| Vascular | |
| Prehepatic | Extrahepatic portal vein thrombosis |
| | Cavernous transformation of portal vein |
| | Extrinsic compression of portal vein |
| Posthepatic | Budd-Chiari syndrome |
| | Intrinsic web |
| | Stenosis of hepatic vein orifice |
| High-flow (hyperkinetic) | Arteriovenous communication—intrahepatic or extrahepatic |
| | Congenital |
| | Acquired |

**TABLE 108-2**
**Hepatocellular Diseases Leading to Portal Hypertension**

| |
|---|
| Biliary atresia |
| Postinfectious cirrhosis |
| Congenital hepatic fibrosis |
| Congenital disorders of bile acid metabolism |
| Sclerosing cholangitis |
| Autoimmune hepatitis |
| Drug toxicity |
| Metabolic diseases (e.g., alpha-1 antitrypsin deficiency) |

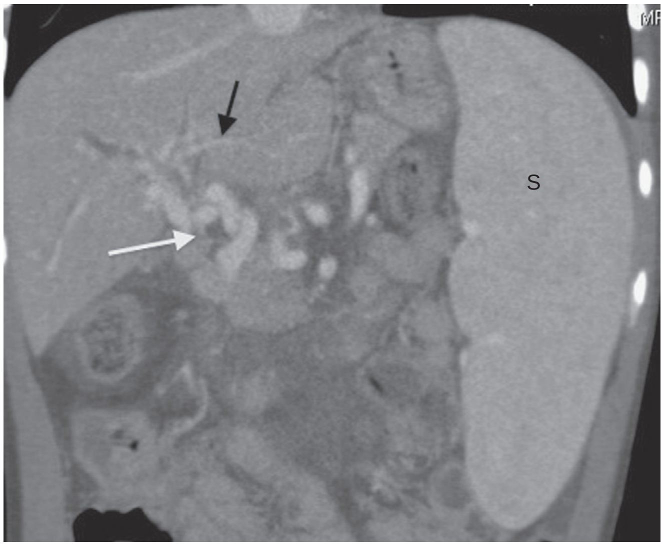

FIGURE 108-2 Preoperative computed tomography scan of a child with extrahepatic portal vein thrombosis showing the typical cavernoma, the tangle of varices in the hilum of the liver (*white arrow*) that replaces the normal portal vein. Also of note is the typically small size of the intrahepatic portal vein branches (*black arrow*) and the large spleen (*S*) that appears larger than the liver.

undergoes myofibroblastic differentiation or activation during episodes of hepatocyte injury. Dysregulation in the activity and number of stellate cells through faulty apoptosis or perpetuation of the insult that led to hepatocyte injury leads to ongoing deposition of proteins in the extracellular compartment of the liver. Ultimately, excess deposition of collagen in sinusoids results in portal hypertension.

## VASCULAR CAUSES

### Prehepatic Portal Hypertension

Prehepatic portal hypertension is caused by obstruction at the level of the portal vein proximal to its branching at the liver plate. Extrahepatic portal vein thrombosis has been recognized and treated in both adults and children; it may be a congenital lesion or acquired at a later time. Even though the symptoms may be dramatic, patients, particularly children, tolerate the bleeding from varices well because of the well-preserved hepatic function.[8] Occlusion of the main trunk of the portal vein may lead to recanalization of the vein and its transformation into a series of smaller collateral veins that assume the appearance of a venous cavernoma visible on ultrasonography or CT scanning (Fig. 108-2). In most instances the intrahepatic architecture of the portal vein is preserved. Thrombosis of the portal vein is associated with omphalitis, instrumentation and cannulation of the umbilical vein at birth including umbilical vein catheters for intravenous access,[9,10] sepsis and dehydration in infancy, and mass lesions that exert extrinsic compression on the vein. These lesions may be inflammatory or malignant; examples include reactive enlargement of the lymph nodes in the hilum of the liver from histoplasmosis or compression from non-Hodgkin lymphoma involving the hilum of the liver.

Unlike children with preexisting liver disease, children with extrahepatic portal vein thrombosis are usually completely well before the sudden onset of symptoms. More than 50% of children present with unheralded hematemesis or hematochezia from gastroesophageal varices.[11] Others are diagnosed with splenomegaly of unknown cause and may be referred to an oncologist for suspected hematologic malignancy.

### Posthepatic Portal Hypertension

Posthepatic portal hypertension is caused by occlusion of large or small veins draining blood from the liver into the inferior vena cava. Obstruction at this level leads to passive congestion of the liver and necrosis of the hepatocytes in the central areas of the hepatic lobule. Acute venous obstruction may lead to massive hepatic necrosis and cell death unless it is relieved in an urgent fashion. The Budd-Chiari syndrome, sometimes referred to as *Chiari disease,* was first described in 1845.[12,13] It is uncommon in children.[14] Outflow occlusion is caused by congenital venous webs in the hepatic veins, hydatid disease,[15] myeloproliferative diseases, hypercoagulable states, and increased estrogen levels, most commonly from oral contraceptives. It can also occur after liver transplantation (Fig. 108-3).

Microvascular nonthrombotic occlusion of hepatic venules is termed venoocclusive disease, and it is being seen with increasing frequency in patients following bone marrow transplantation.[14,16] Cytoreductive regimens involving busulfan and cyclophosphamide are thought to induce obliterative phlebitis in the small veins of the liver, and damage to the endothelial cells is induced through the depletion of endogenous

FIGURE 108-3 Acute hepatic venous obstruction after split liver transplantation, caused by a blood clot in the left hepatic vein of a segment II-III transplant that resulted in hepatic necrosis. The child was retransplanted.

glutathione S transferase stores within the cells.[17] Other causes of venoocclusive disease such as ingestion of herbal teas containing pyrrolizidine alkaloids have been described. Other diverse agents including contrast media, estrogen, and thioguanine have also been associated with the development of venoocclusive disease. This disease has a high mortality rate, and treatment is limited to withdrawal of the offending agents, if possible, coupled with implementation of thrombolytic therapy and transjugular intrahepatic portosystemic shunting if feasible.[18–20]

### High-Flow States

A congenital or acquired communication between an artery and vein in the mesenteric circulation is a rare but known cause of portal hypertension (Fig. 108-4). Portal hypertension from such abnormal communications between arteries and veins in the portal circulation is termed *hyperkinetic*[21] because of the hyperdynamic circulation responsible for the increased portal pressure. Patients have well-preserved liver function and present with bleeding from gastrointestinal (GI) varices, ascites, or splenomegaly. The site of the communication between the artery and vein is quite varied. The splenic and gastric arteries have been reported as sites of these fistulas, as well as the more common site of the hepatic artery within the parenchyma of the liver. Arteriovenous fistulas causing portal hypertension have been reported in all age groups.[22–24] Most often they are congenital, but some are thought to be acquired through a pathologic process or iatrogenically.[25,26] Patients may present with varied symptoms that depend on the site of the arteriovenous communication. Bleeding from varices may be severe, and because of the exposure to arterial pressures, the usual therapeutic maneuvers may be inadequate to control it.[27]

Treatment of high-output fistulas requires interruption of the abnormal communication between the artery and vein. Although surgical procedures including hemihepatectomy[22] and surgical ligation of extrahepatic fistulas[27,28] have been described as a means of removing the fistula, access by radiologic means and the use of selective transcatheter embolization to interrupt flow has become the treatment of choice for this condition.[29,30]

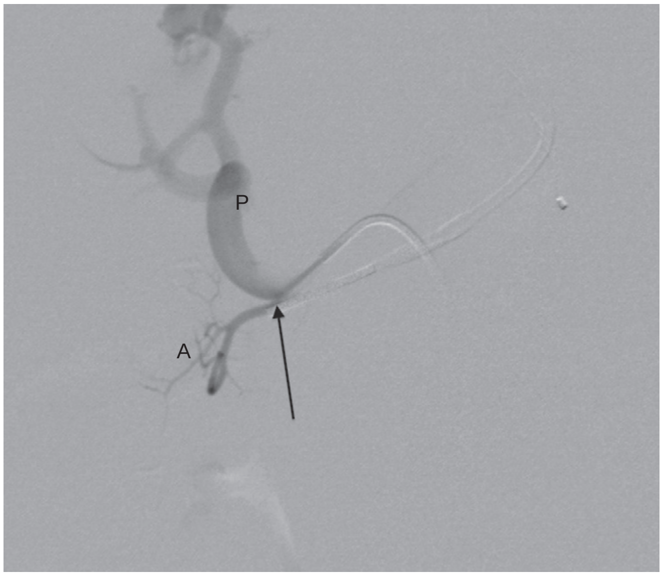

FIGURE 108-4 Contrast flow directly from the smaller hepatic artery (*A*) into the larger portal vein (*P*) without traversing the parenchyma of the liver. This child had an arteriovenous fistula of unknown etiology resulting in esophageal and gastric varices. The fistula was treated by embolizing the branch of the hepatic artery.

# Clinical Presentation

## GASTROINTESTINAL HEMORRHAGE

Bleeding from the GI tract is one of the most common, dramatic, and ominous signs of portal hypertension. Bleeding most commonly occurs from varices in the distal esophagus and gastric cardia. Although the incidence of bleeding in adults with portal hypertension from nonvariceal sites may be as high as 25%, there is no evidence that the same holds true in children. In one study of children presenting with upper GI bleeding, the vast majority of unselected patients had bleeding from varices secondary to portal hypertension, with no other source.[31] The importance of portal hypertension as a cause of upper GI bleeding in children may vary in different parts of the world. Peptic ulcer disease is still a frequent finding at endoscopy in children in the Western Hemisphere.[32] In children with portal hypertension of any cause, upper GI bleeding is almost universally caused by variceal hemorrhage, although portal hypertensive gastropathy may cause less acute bleeding. Therefore variceal hemorrhage is usually the only source of bleeding in children with portal hypertension, and it is the most common cause of bleeding from the upper GI tract in nonhospitalized children older than 2 years.

Variceal hemorrhage may take the form of hematemesis, hematochezia, melena, or chronic anemia. Bleeding most commonly originates from the lower esophagus and the cardia of the stomach. Thin-walled varices that contain blood under raised venous pressure are eroded from gastric acid or medications such as aspirin or nonsteroidal antiinflammatory drugs, and blood fills the stomach. In the absence of advanced liver disease, the blood clots and gathers in the stomach, producing gastric distention and eventually hematemesis.

The bleeding may be sudden and dramatic and is usually not accompanied by abdominal pain. A previously well child can vomit large quantities of altered or fresh blood. Although this can be extremely frightening to both the child and the parents, the bleeding usually stops spontaneously. Varices may be present in the lower GI tract as well. Rectal bleeding is less common and occurs from rectal and sigmoid varices. Melena or the passage of gross blood through the rectum or accompanying a bowel movement may occur in the absence of hematemesis.

Although most patients with portal hypertension have varices, not all varices bleed. Predicting the risk of bleeding from varices is based on Laplace law, which states that the transmural tension in the wall of a vessel is directly related to the pressure inside the vessel and inversely related to the thickness of the vessel. Unfortunately, intravariceal pressure cannot be easily measured[33]; therefore the risk of bleeding in adults has been linked to the size of the varix, the severity of liver disease, and the appearance of red wale markings on the vessel wall, which may indicate epithelial thickness.[34] More recently, detailed measurements of the cross-sectional diameter of the varices have been correlated with the risk of bleeding[35] in adults. Similar studies are necessary in children.

Predicting which patient is likely to bleed from varices is important in determining treatment options, particularly for those who may be candidates for prophylactic therapy of any kind.[36] It is estimated that 30% to 50% of patients bleed from varices once they are diagnosed[37] and that 10% to 50% of patients with liver disease die every year after the first hemorrhage.[38]

Aggressive therapy is indicated after the first bleed in patients with or without liver disease. This may include medical therapy in addition to local control of varices with banding or sclerotherapy, portosystemic shunting in patients with stable and well compensated cirrhosis, or liver transplantation in those with more advanced disease. There may be a role for noninvasive or even invasive surgical therapy in those who are at high risk for bleeding but have not yet bled, provided the morbidity and mortality associated with bleeding can be reduced with an acceptably low risk of complications.

In children with portal hypertension from extrahepatic portal vein thrombosis, mortality from bleeding is much less than in those with liver disease and bleeding is generally well tolerated. However, the same principles apply: early intervention and implementation of a long-term plan to reduce hospital admissions and invasive procedures. Because these children have a vascular problem rather than hepatic disease, they are more amenable to surgical intervention and generally obtain excellent long-term results.

### Portal Hypertensive Gastropathy

The gastric mucosa develops distinct pathologic changes in the presence of portal hypertension and liver disease. The symptoms include chronic blood loss and iron deficiency anemia, but occasionally portal gastropathy may also cause acute GI bleeding and hematemesis. The diagnosis is generally made during endoscopy, when the severity of the lesion can also be graded. The severity of the lesion has been correlated with the severity and frequency of bleeding and the necessity of treating the consequent anemia.

### Hypersplenism

Silent splenomegaly without any other history suggestive of portal hypertension is often the first sign of a serious underlying disorder. Splenomegaly may be detected in infancy or early childhood and can easily be misinterpreted as a sign of hematologic malignancy, particularly in children with extrahepatic portal vein thrombosis and no other stigmata of liver disease. With the advent of Doppler ultrasound examinations of the abdomen, portal vein thrombosis is more readily diagnosed and can be appropriately monitored. In addition to splenic enlargement, patients may present with severe thrombocytopenia and leukopenia from splenic sequestration of platelets and white blood cells. Children are often prevented from engaging in sporting activities for fear that even slight trauma to the abdomen may result in splenic rupture and catastrophic intra-abdominal bleeding, exacerbated by raised venous pressure and low platelet counts. It is hard to find documented cases of splenic rupture in which the underlying portal hypertension contributed to massive bleeding and death.[39] Splenic artery aneurysm is a rare complication in patients with portal hypertension and spontaneous hemorrhage, and suggested treatments have been reported.[40]

### Encephalopathy

Encephalopathy is extremely unusual in the absence of signs of advanced liver disease such as jaundice and low levels of liver-dependent coagulation factors or low albumin levels. Learning disabilities and behavioral abnormalities are manifestations of encephalopathy in children, in contrast to the traditional signs of disorientation, memory loss, and drowsiness commonly seen in adults. Children may also have accompanying hyperammonemia.[41]

### Bleeding from Nongut Sites

Severe thrombocytopenia can lead to hematuria, menorrhagia in adolescent girls, epistaxis, and hematochezia. In severe cases, spontaneous intracranial bleeding can also occur, with serious neurologic consequences. Liver-dependent coagulation factor deficiencies also lead to bleeding, typically from the genitourinary tract or from the nose. In cases of advanced liver disease, hemorrhagic complications in the lungs may cause severe respiratory compromise.

### Ascites

Children with ascites may have advanced liver disease with synthetic failure. Ascites may be accompanied by a low serum albumin level and decreased plasma oncotic pressure. Dilated lymphatics in the abdomen from increased hydrostatic pressure in all portal tributaries can lead to transudation of fluid across capillary membranes and accumulation of fluid in the abdominal cavity. Additional mechanisms include increased nitric oxide production in capillaries, causing vasodilatation, and an increase in renal tubular absorption of sodium in patients with decompensated cirrhosis. Ascites can also occur in the setting of Budd-Chiari syndrome and outflow obstruction. Ascites is an alarming symptom that may herald the onset of liver decompensation on a wider scale.

### Pulmonary Disorders

Pulmonary hypertension can occur in children with both cirrhotic and noncirrhotic forms of portal hypertension.[42,43] Pulmonary hypertension may be secondary to an increase in vasoactive substances that exert a vasoconstrictive or direct toxic effect on pulmonary vessels.[43a] An increase in blood levels of prostaglandin $F_{2\alpha}$, thromboxane, and angiotensin I in patients with portal and pulmonary hypertension suggests that these agents play a role in mediating pulmonary hypertension by reaching the pulmonary circulation in blood shunted around the liver. In experimental studies, portal hypertension induced by portal vein ligation was associated with increased amounts of inducible nitric oxide synthetase and heme oxygenase-1 messenger RNA and protein in the lungs, compared with animals in the control group.[44] This suggests that the pulmonary pathology seen with portal hypertension is associated with the production of nitric oxide and carbon monoxide in the lung.

Patients with both pulmonary and portal hypertension may develop pulmonary symptoms before there is any evidence of bleeding from portal hypertension. Symptoms may include exertional dyspnea or chest pain, or there may be no symptoms other than unheralded syncope or sudden death.[45] Treatment of portal hypertension may be problematic in children with advanced pulmonary hypertension, and medical treatment for both conditions may be limited in scope and duration.[46]

The hepatopulmonary syndrome includes persistent hypoxemia from arteriovenous shunting in the lungs. Both pulmonary hypertension and arteriovenous shunting are potentially reversible after the portal hypertension and shunting are eliminated, although in cases of cirrhosis, a liver transplant may be necessary.[47,48]

# Diagnosis

The diagnosis of the underlying cause of portal hypertension depends on the synthesis of the clinical information gathered from the parents and the child and the results of imaging tests and laboratory investigations.

## CLINICAL INFORMATION

### Hepatomegaly

An enlarged liver is usually a sign of hepatocellular disease, although patients with cirrhosis may present with impalpable shrunken livers. If the liver is hard or nodular to palpation, this is further evidence that the cause of the portal hypertension is a diseased liver. Children with congenital hepatic fibrosis often present with enlarged livers that may extend as far as the iliac crest on palpation. Children with venous outflow obstruction may also present with easily palpable liver enlargement.

### Splenomegaly

Enlargement of the spleen is a common finding in children with portal hypertension and is often the first abnormality found on a routine physical examination before the onset of bleeding. Splenomegaly occurs in all forms of portal hypertension and is not helpful in diagnosing the cause.

### Jaundice

Jaundice and portal hypertension usually do not occur together unless there is advanced liver disease. Children with extrahepatic portal vein obstruction may have mild elevation of the total bilirubin level, but jaundice is not a clinical feature. If jaundice is a prominent symptom in a child with portal hypertension, it may indicate that the liver function is severely compromised and consideration should be given to a liver transplant evaluation.

### Abdominal Examination

Patients with portal hypertension often have protuberant abdomens. Causes include splenomegaly, ascites, and enlargement of the liver. Distended abdominal veins are a frequent finding, and the direction of blood flow away from the abdomen or umbilicus is easily demonstrable. In patients with congenital hepatic fibrosis, the combination of enlarged liver and spleen and often large polycystic kidneys contributes to making the abdomen extremely protuberant.

### Encephalopathy

Clinically evident encephalopathy is a sign of advanced liver disease. Signs of encephalopathy may be hard to discern or quantify in young children. Advanced psychometric testing may detect subclinical encephalopathy that may be manifest as impaired attention span, poor school performance, or behavioral issues that may be present even in children with no underlying liver disease or patients with well-compensated cirrhosis.[49] Although advanced encephalopathy may be exacerbated or unmasked by acute bleeding because of the increased protein load in the gut, it usually signifies advanced hepatocellular disease that may require the patient to be evaluated for liver transplantation.[50]

## LABORATORY INVESTIGATIONS

Laboratory tests are useful adjuncts in evaluating patients with portal hypertension. Tests may indicate the severity of the accompanying liver disease or may indicate the cause of the underlying liver disease in many instances. In the acute setting of a GI bleed, a complete blood count and electrolyte levels will be necessary as a guide to blood and fluid replacement. A complete metabolic panel including renal function tests is helpful in guiding fluid resuscitation and to assess the underlying status of the kidneys. In patients with established cirrhosis from underlying systemic diseases like cystic fibrosis, blood gases may be necessary. Low blood glucose levels may indicate impending liver decompensation or an underlying glycogen storage disorder.

Children with long-standing portal hypertension may have nothing more than thrombocytopenia and leukopenia, particularly those with extrahepatic portal vein thrombosis. An increase in the direct bilirubin fraction, a low albumin level, and a long prolongation in prothrombin time all indicate significant hepatocellular disease and possible cirrhosis as the underlying cause of the portal hypertension. A raised serum ammonia level indicates significant portosystemic shunting and may occur with all forms of portal hypertension, although severely increased ammonia levels are generally only seen in patients who have decompensated cirrhosis or those in fulminant hepatic failure.

Children with extrahepatic portal vein thrombosis may have laboratory evidence of disordered synthesis of liver-dependent coagulation factors in both the procoagulant and plasminolytic pathways, but this is generally not evident clinically without detailed testing.[51]

## ENDOSCOPY

Endoscopy is indispensable in establishing the cause of GI bleeding and to confirm the presence of varices in the esophagus and stomach. In cases of acute bleeding and after stabilization in the intensive care unit, upper GI endoscopy provides direct confirmation of the bleeding source. Varices, if present, will be most prominent in the distal third of the esophagus and in the cardia of the stomach. Endoscopy should be done only by those who are well trained in the procedure and familiar with the equipment. Endoscopy provides an opportunity to intervene therapeutically, as well as to rule out other sources of bleeding such as peptic ulcers, Mallory-Weiss tears of the esophagus, or hemorrhagic gastritis.

If endoscopy is done before the onset of bleeding because of suspected portal hypertension, the appearance of the varices provides valuable clues about the likelihood of future bleeding. Variceal diameter greater than 5 mm, the appearance of red wale markings, and more advanced liver disease based on Child-Pugh class indicate a greater chance for future bleeding and may justify the institution of prophylactic treatment.[52–54]

## IMAGING

The first imaging study in any child who presents with hematemesis should be abdominal ultrasonography. The status of the portal vein is one of the most important radiologic considerations in arriving at a diagnosis. Cavernous transformation of the portal vein and portal vein thrombosis are best diagnosed by ultrasonography with Doppler interrogation of the vessels of the liver. A complete evaluation of the intra-abdominal vasculature including the hepatic veins, the patency of the splenic and superior mesenteric veins, and the inferior vena cava is possible. In addition, information about the size of the spleen can be obtained to confirm the clinical examination. Liver parenchymal abnormalities such as nodularity, inhomogeneity, or the presence of cysts can be seen. The appearance of the kidneys can yield useful diagnostic clues because children with congenital hepatic fibrosis may also have autosomal dominant polycystic kidney disease and other renal abnormalities.

Computed tomography (CT) and magnetic resonance (MR) angiography are excellent diagnostic tools and have supplanted conventional digital angiography for most purposes. Both modalities provide excellent information about all the intra-abdominal vessels and detailed information about the liver anatomy including the bile ducts. CT-angiography has several advantages; it can be done more quickly and is less prone to image degradation from motion artifact than is MR angiography, unless the MR study is done under general anesthesia with ventilatory arrest for the duration of the study.

Conventional angiography is an invasive modality that has few indications as a diagnostic tool in children with portal hypertension. The exceptions are rare cases of unusual vascular malformations such as arteriovenous communications in the abdomen or liver that may best be delineated by angiography. Also, angiographic visualization is essential as a prelude to angiographic embolization or stenting of a vascular abnormality.

Splenoportography is a technique that was written about extensively in the past but is almost never used for diagnostic purposes today.

Transjugular hepatic venography is a test that can be used to measure free and wedged hepatic vein pressures indicating the gradient across the hepatic veins. This technique is limited in small children where the size of the child and the veins makes the performing of this test more challenging. Wedge hepatic vein pressure can rule out parenchymal disease and high sinusoidal pressure as a contributing factor to portal hypertension. Sinusoidal pressures are normal in cases of prehepatic portal venous obstruction.

Retrograde transjugular portal venograms can also be used to obtain high-quality definition of the intrahepatic portal vein (Fig. 108-5). Hepatic vein angiography can also be used therapeutically for the placement of a transjugular intrahepatic portosystemic shunt (TIPS) or the dilatation of congenital or acquired strictures causing venous outflow obstruction.

## LIVER BIOPSY

Many children who present with portal hypertension do not need a liver biopsy to establish a diagnosis. For example, in children with biliary atresia a biopsy is not necessary as an adjunctive test after the onset of portal hypertension. In children with a known underlying metabolic disease such as cystic fibrosis or alpha-1 antitrypsin deficiency, a biopsy will not necessarily add useful information to aid in formulating a treatment plan.

However, if a biopsy is considered helpful, it can be done percutaneously in most cases. In children with mild coagulopathies that can be corrected with vitamin K, fresh frozen plasma, and platelets, the procedure can be performed with close monitoring, where any bleeding from the biopsy site can be treated promptly. Children with more profound

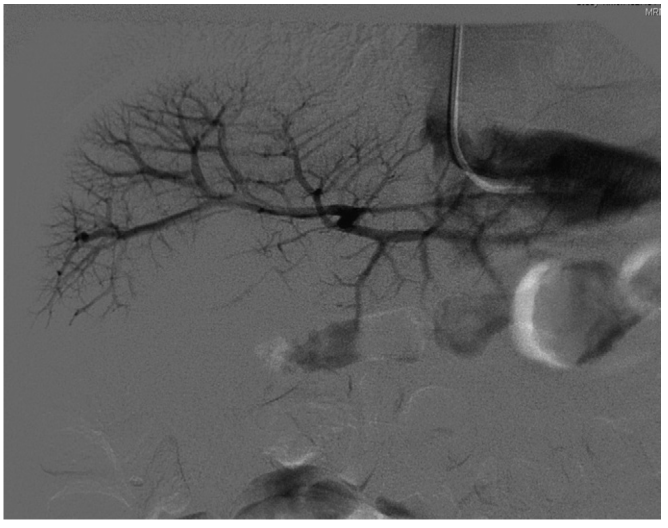

**FIGURE 108-5** A catheter has been advanced into the left hepatic vein, and contrast is injected under pressure filling the entire intrahepatic portal vein.

coagulopathies, as manifested by a prothrombin time in excess of 20 seconds, should have a transjugular biopsy in the interventional radiology suite or an open biopsy in the operating room. In general, the limiting factor in the radiologist's ability to do a transjugular biopsy is the patient's size. The difficulty and technical limitations are greatest in infants and babies.

# Treatment

The treatment of a child with portal hypertension is predicated first on the underlying pathophysiology of the disease and then on the severity of the symptoms.

Children with liver disease and portal hypertension do not tolerate bleeding as well as those with essentially normal livers whose portal hypertension is caused by primary vascular malformations. Acute hemorrhage adversely affects liver function, which may already be abnormal. The prognosis of a child with liver disease and portal hypertension depends entirely on the hepatic reserve. Children with relatively stable cirrhosis and preserved synthetic function require a completely different therapeutic approach from those with hypoalbuminemia, growth failure, and coagulopathy. The Child-Pugh score[55] was devised in an attempt to categorize patients according to degree of hepatic reserve and thus arrive at a prognosis for survival if left untreated or with surgery.[56] More recently, a pediatric-specific score (pediatric end-stage liver disease [PELD]) has been developed to stratify children on liver transplant waiting lists in a way that accurately reflects the severity of the underlying liver disease.[57] Children with age-appropriate growth, normal coagulation, and no jaundice have low PELD scores; their treatment for the complications of portal hypertension is different from that of children with high scores, who would be better served by liver transplantation.

In children with Child-Pugh scores of 5 or 6 or PELD scores lower than 10 who have a predicted 1-year survival of more than 90%, it is justified to consider complex surgical therapy to alleviate the symptoms of portal hypertension. The expectation is that these children will survive the surgery and have a good long-term prognosis without the need for liver transplantation in the short term. For children with portal hypertensive bleeding from varices and who also have ascites, advanced coagulopathy or poor synthetic function as indicated by hypoalbuminemia, endoscopic banding or sclerosis of esophageal varices in addition to aggressive medical therapy of portal hypertension is indicated as they await transplantation. Operation is not indicated in children with advanced liver disease because it would be poorly tolerated and not address the underlying issue of poor hepatic reserve.

Pediatricians and pediatric gastroenterologists closely follow all patients with portal hypertension and liver disease. When portal hypertension becomes symptomatic, it is rarely a surprise and the parents are usually well versed in the medical issues. Under ideal circumstances, surgery can be considered for the control of symptoms when bleeding is imminent or likely to recur. Selective shunting is generally the procedure of choice, as discussed later.

In contrast, patients with noncirrhotic forms of portal hypertension can develop symptoms quite unexpectedly and as the first manifestation of a serious underlying condition.

## MEDICAL MANAGEMENT OF BLEEDING VARICES

Patients admitted with acute variceal hemorrhage require intense resuscitation with blood and crystalloids, replacement of coagulation factor deficiencies with fresh frozen plasma, and control of the bleeding. Bleeding from varices may be exacerbated by disseminated intravascular coagulation, fibrinolysis, and a decrease in circulating platelet counts. The availability of exogenous recombinant factor VII to treat those with compromised liver synthetic function has enhanced the care of these patients. Factor VII replacement decreases the amount of sodium and fluid necessary to correct the liver-dependent factor deficiencies, although its use is limited to some extent by its cost.[58]

Patient care is best delivered in the intensive care unit, where vital signs including central venous and arterial pressures, hourly urine output, and oxygen saturation can be monitored. Monitoring of mental status is also essential in those with cirrhosis because bleeding into the GI tract may exacerbate or unmask encephalopathy.

Cessation of bleeding is the most important therapeutic goal, along with the replacement of extracellular fluid and blood. In the past, Sengstaken-Blakemore tube tamponade of varices was the most effective method of short-term control of blood loss. Pharmacologic therapy has proved to be just as effective in adults,[59] rendering the balloon method almost obsolete. Pharmacologic control of variceal bleeding has improved greatly with the use of intravenous octreotide, the octapeptide analogue of somatostatin. It has a longer half-life than somatostatin and fewer side effects. Octreotide has largely replaced vasopressin in the management of acute variceal bleeding because of the severe vascular side effects of the latter drug.

Octreotide and other somatostatin analogues such as vapreotide reduce hepatic blood flow and wedged hepatic vein pressure and constrict splanchnic arterioles by a direct effect on arteriolar smooth muscle. Somatostatin analogues are effective in reducing and temporarily stopping the bleeding from portal hypertension and can be used in the initial 24 to 72 hours while awaiting direct endoscopic management of varices.[60–63] More recently, terlipressin, a vasopressin derivative, has also been proven effective in the acute bleeding situation, although experience in children is limited.[62,64,65] Octreotide is started as a continuous infusion at 1 to 2 μg/kg/hr, up to a maximum of 100 μg/hr, and continued for as long as symptoms of bleeding persist. Antibiotics and acid suppression are also recommended.[62]

The long-term medical management of children with portal hypertension includes the use of nonselective beta blockers such as propranolol or nadolol, either alone or in combination with nitrate vasodilators such as isosorbide-5-mononitrate. Some authors, however, have shown that local control of varices with banding is equivalent to long-term pharmacologic management. In a majority of patients, surveillance endoscopy and intermittent banding may be sufficient,[37] with equivalent survival and rebleeding rates in endoscopically managed and pharmacologically managed groups. The role of beta blockers in reducing splanchnic blood flow and wedge hepatic vein pressure is well documented; their use may decrease the incidence of recurrent bleeding by as much as 50% and lessen the need for liver transplantation in patients with liver disease.[66]

Assessment of wedge hepatic vein pressure reduction has been promoted as the best way to determine the impact of medications on portal pressure and to guide and refine pharmacologic management,[67] but these studies are all adult based and may represent a less practical approach in children.[68]

## PROPHYLACTIC TREATMENT OF VARICES

Intervention of any kind before the onset of bleeding is controversial. However, the benefit to the patient of preventing a first bleed may be considerable and justifies early prophylactic management. Studies in both adults and children have demonstrated that prophylactic treatment of varices by pharmacologic means and with endoscopic ligation reduces the frequency of bleeding but may not diminish mortality in patients with advanced liver disease without transplantation.[69,70] Primary procedures for the prevention of an initial bleed are more controversial if there is no other primary goal such as the treatment of severe hypersplenism.

## ENDOSCOPIC SCLEROSIS OR BANDING OF VARICES

Surgeons were involved in the earliest attempts to control variceal bleeding by injecting sclerosing solutions into the tissue around a varix or directly into a varix to obliterate the vessel lumen.[71] This method has proved to be effective and safe in children in the acute phase of bleeding.[52–54,72–81] Sclerosing solutions include sodium morrhuate, ethanolamine, sodium tetradecyl sulfate, and polidocanol. Long-term follow-up in children after sclerotherapy for the control of initial bleeding has demonstrated success in almost 90% of patients. Initial sclerotherapy should be followed by repeat endoscopy at regular intervals until all the varices are obliterated or too small to inject and then at longer (yearly) intervals for at least 4 years to check for reappearance of varices. Generally, two to three injections at 1 mL per injection are required for each varix, up to a maximum of 10 to 15 mL per session. The endoscopist should proceed circumferentially from the distal esophagus at the gastroesophageal junction to the more proximal esophagus.

Sclerotherapy is associated with a fairly high incidence of complications, both major and minor, in at least one third of patients. Acute complications include chest pain, esophageal ulceration, and mediastinitis; chronic ones include esophageal strictures from fibrosis after multiple injection sessions.

Esophageal banding has become an increasingly popular method of treating varices. In one prospective trial in children with portal hypertension from extrahepatic portal vein thrombosis, banding was found to be a more effective, more rapid, and safer method of reducing the chance of bleeding from varices.[82] The incidence of complications and of long-term rebleeding was lower with banding. New technology, such as the multiband ligator scope, has made it possible to apply bands to multiple varices; this method was first used in adults but has recently been extended to children.[83,84] This technique increases the speed and safety with which esophageal varices can be ligated in children as young as 3 months old; obliteration of varices was accomplished in almost 100% of children after only two sessions.

Esophageal banding in concert with pharmacologic control has become the procedure of choice in the early therapy of bleeding esophageal varices. Subsequent sessions are aimed at ligating residual varices or varices that arise after the larger ones are tied off. Ligation is effective in most children and is not associated with many of the adverse side effects of sclerotherapy.

## INJECTION THERAPY FOR GASTRIC VARICES (TIPS)

With the advent of more effective means of controlling esophageal varices, bleeding from varices lower in the GI tract has become more problematic. Injection with N-butyl-2-cyanoacrylate has had modest success in adults with bleeding from gastric varices and results in children have been encouraging.[85,86] Gastric varices may coexist with esophageal varices in up to 15% to 20% of patients, or they may be isolated. Gastric varices may emerge after the obliteration of esophageal varices, or they may persist after esophageal varices have been ligated. Experience in adults suggests that in patients with gastric varices, cirrhosis, and advanced liver disease, bleeding can be controlled with minimal morbidity, but there is a high incidence of rebleeding at 1 year after treatment.[87] In adults, injection of gastric varices results in relatively poorer control of bleeding in patients with extrahepatic portal vein thrombosis (35%) than in those with liver disease (75%).[88] Given the fact that extrahepatic portal vein thrombosis is a more important cause of bleeding varices in children than in adults, injection therapy for gastric varices in pediatric patients is not justified, except in the setting of a formal study to determine its safety and efficacy compared with surgery or other medical therapies.

## TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNTS

The percutaneous insertion of vascular stents to create channels between the portal vein and hepatic veins within the parenchyma of the liver heralded a new way of treating patients with advanced liver disease and portal hypertension.[89,90] The main indication for TIPS is variceal hemorrhage recalcitrant to more conservative therapy with endoscopy or octreotide. It is usually reserved for patients with advanced liver disease and serves as a bridge to transplantation.[91] Other indications include refractory ascites, hepatic venous outflow obstruction in both transplant and nontransplant patients, and hepatorenal syndrome.

In children, the experience is limited. TIPS may act as a bridge to transplantation in children with portal hypertensive gastropathy or in those whose variceal bleeding is difficult to control by other means. The TIPS method has been used in children with cystic fibrosis,[92] biliary atresia,[93] and congenital hepatic fibrosis[94] with apparent success and in infants as young as 1 year.

Its primary limitation is the high rate of shunt thrombosis. Vigilance is required to monitor shunt patency and to declot the shunt when it is thrombosed. The other limitation is the aggravation of preexisting encephalopathy in approximately 20% of patients and the hastening of liver failure in patients whose livers are already borderline; TIPS facilitates the

shunting of blood without the benefit of hepatic clearance in these extremely debilitated patients.[95]

Hepatic encephalopathy is less common after TIPS in children than in adults, but the incidence of shunt occlusion is higher because of the smaller shunt diameter.

## SHUNT SURGICAL PROCEDURES

Early shunt operations diverted all the mesenteric blood flow into the systemic circulation, as first described by Eck.[2] Later authors reported the application of portacaval shunting in the setting of severe bleeding from portal hypertension in adults with advanced liver disease,[55,96–99] as well as in children with prehepatic and intrahepatic causes of portal hypertension.[100–104]

Shunts can be described as nonselective or selective. Selective shunts preserve the majority of portal or mesenteric blood flow to the liver while shunting blood from high-pressure gastroesophageal varices into the low-pressure systemic venous circulation. In essence, selective shunts divide the portal circulation into two separate entities, although it is impossible to fully divide all communications. In contrast, nonselective shunts divert a large proportion of mesenteric blood flow away from the liver so that the entire GI tract including the spleen and pancreas is decompressed. Nonselective shunts can be further subdivided into total or partial portal diversions.

### Nonselective Shunts

***Total Diversion*** The end-to-side portacaval shunt as first described by Eck is the classic example of a total portal diversion. Portal blood is completely redirected into the inferior vena cava below the liver, and the hepatic end of the portal vein is oversewn. That operation is almost never done in children and bears no further discussion. All nonselective large-caliber shunts deprive the liver of virtually all mesenteric venous blood flow and increase the danger that the undesirable side effects of portosystemic shunting will be produced. Encephalopathy, pulmonary hypertension, and formation of regenerative nodules in the liver are some of the long-term side effects of complete mesenteric venous diversion away from the liver and can happen even in children with ostensibly normal liver function and no intrinsic liver disease.

***Proximal Splenorenal Shunt*** The proximal splenorenal shunt is another example of a shunt that results in total diversion of mesenteric venous blood into the systemic circulation. The pancreas is mobilized cephalad, exposing the underling splenic vein. All branches between the pancreas and the splenic vein must be tied off meticulously. The splenic vein is divided close to the spleen, and the spleen is removed. The left renal vein is isolated, and the mesenteric end of the splenic vein is sewn to the side of the left renal vein so that all the blood from the superior and inferior mesenteric veins is shunted into the systemic venous circulation through the left renal vein.[105,106] This procedure almost invariably includes a direct attempt to ligate the varices of the esophagus and stomach in the region of the coronary vein.

Although the operation is effective in relieving the symptoms of portal hypertension, it should be used sparingly because it not only exposes the child to the potential drawbacks of complete mesenteric diversion, as outlined earlier, but also results in the loss of the spleen.

***Mesocaval Shunt*** Wide-diameter mesocaval shunts also completely divert mesenteric blood away from the liver. This procedure can be done directly as a side-to-side anastomosis between the two veins or with the interposition of a short autologous vein graft or prosthetic graft.[107,108] Use of an interposition graft is the more common method. Exposure of both the superior mesenteric vein at the root of the bowel mesentery and the inferior vena cava below the duodenum is required.

Mesocaval shunting has been used in children in a wide variety of settings and diseases, with uniformly acceptable results.[109–111] Some prefer this method because it allows an anastomosis between two large-diameter vessels and because the length of the anastomosis can be increased to some extent to facilitate the creation of a large venous fistula, which is technically easier to perform than a proximal splenorenal shunt. In addition, in contrast to the proximal splenorenal shunt, the spleen is preserved, which is thought to be important in preventing postsplenectomy sepsis.

***Side-to-Side Portacaval Shunting*** The side-to-side portacaval shunt allows blood from the intestine and spleen to flow easily into the vena cava. In addition, and unlike with the end-to-side portacaval shunt, the hepatic end of the portal vein is changed into an outflow tract. In cases of Budd-Chiari posthepatic portal hypertension, the liver is decompressed by this operation; this may result in long-term palliation of the disease, with arrest or delay in the progression of hepatic fibrosis and ultimate failure.[14,112,113] Other effective operations for Budd-Chiari syndrome are mesocaval and central splenorenal shunts, which allow portal blood in the liver to empty in a retrograde fashion through the patent portal vein.

***Partial Diversion*** Partially diverting shunts depend on a fixed, narrow communication between a vessel in the portal circulation and one in the systemic venous circulation. The Sarfeh shunt can divert enough blood from the portal circulation to drop mesenteric pressure below 12 cm $H_2O$, thus decompressing the varices and reducing the chance of bleeding while maintaining enough pressure in the portal bed to allow hepatopetal flow and hepatic blood flow preservation.[114] Although there may be less encephalopathy with the Sarfeh shunt because of sustained hepatic portal flow, it is associated with a higher incidence of thrombosis and recurrence of hemorrhage and rarely used in children.[115]

The relationship between deprivation of portal blood to the liver and encephalopathy has long been noted following portacaval shunt surgery. Sarfeh was able to determine the diameter shunt that would preserve forward flow in the portal vein, decompress the portal circulation so that bleeding from varices decreased, and minimize the incidence of encephalopathy.

### Selective Shunts

To diminish the encephalopathy that followed portacaval shunting, Warren and Zeppa[116] described a shunt between the portal end of the splenic vein and the side of the renal vein (Fig. 108-6). The splenic confluence with the portal vein was ligated, and the coronary vein was also interrupted. In this manner, the gastroesophageal varices were decompressed across the short gastric vessels and the spleen was decompressed into the renal vein. Long-term studies have shown

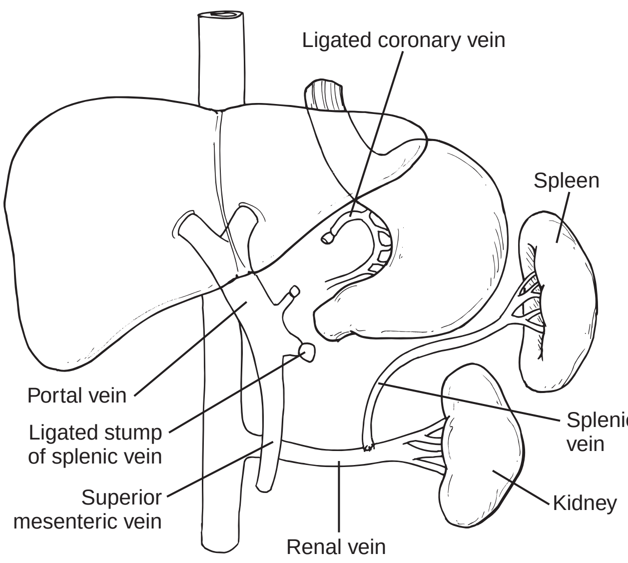

**FIGURE 108-6** Schematic drawing of the distal Warren shunt. Note that the coronary vein has been ligated. The varices are both decompressed by allowing them to drain via the short gastric vessels and splenic vein into the left renal vein and by decreasing blood flow to the varices by tying off the blood that reaches them through reverse flow in the coronary vein.

that the disconnection between the lower-pressure splenic circulation and the higher-pressure hepatic one is not always maintained, and the connection may re-form over time. Hepatopetal flow may decrease and be redirected to the coronary circulation around the stomach; as a result, the hepatic flow decreases, just as in more central shunts.[117,118] In this case, there would be both angiographic and endoscopic evidence of gradual conversion of a selective shunt to a less selective shunt over time. A more complete pancreaticosplenic disconnection may avoid the reestablishment of communication between the splenic and hepatic circulations. Long-term mortality and rebleeding rates in adults are equivalent with selective and nonselective shunts,[119] but the rate of encephalopathy is reduced with selective shunts.[120,121]

In children, the selective shunt as described by Warren or with minor modifications has been used successfully for the treatment of bleeding varices, as well as for the treatment of hypersplenism.[122] Long-term patency rates exceeding 90% have been reported in most series.

Distal splenorenal shunting is used primarily in children with extrahepatic portal vein thrombosis, stable Child-Pugh classification A or B cirrhosis, or less common forms of intrahepatic portal hypertension such as congenital hepatic fibrosis with well-preserved liver function but symptomatic variceal bleeding.

The preservation of neurocognitive function is particularly important in children; thus all forms of nonselective shunting should be avoided whenever possible. Encephalopathy in children may manifest as learning disorders or behavioral abnormalities that are not usually attributed to portosystemic shunting.[123]

Hypersplenism may be particularly problematic in children and has led to splenectomy or splenic embolization in some children[100,124–132] with or without a central splenorenal shunt.

The distal splenorenal shunt has been beneficial in children with advanced hypersplenism as a more physiologic alternative to the splenectomy.[133] Spleen size regresses, and the platelet and leukocyte counts return toward normal. Following splenic decompression by shunting, hematologic indices may continue to improve for years after the procedure.

Splenectomy and splenic embolization were advocated in the past for hypersplenism. However, these procedures are not without complications and may, in the long run, exacerbate bleeding from gastroesophageal varices and leave the child prone to postsplenectomy sepsis. In addition, splenectomy removes the possibility of later distal splenorenal shunting if the child continues to suffer from variceal bleeding. Pediatric surgeons should preserve the spleen whenever possible, leaving splenectomy as the last resort in children who have no other options.

## MESENTERIC-TO-LEFT PORTAL VEIN BYPASS

The treatment of extrahepatic portal vein thrombosis has been evolving since the advent of mesenteric vein-to-left portal vein bypass in 1992. The operation was originally described as a way to revascularize liver transplant grafts after post-transplant portal vein thrombosis,[134,135] but the indications were later expanded to treat children with idiopathic portal vein thrombosis.[136] A growing number of children have been reported in the literature from a small group of institutions worldwide.[11,47,137,138]

Essentially, the operation relieves portal hypertension by redirecting blood from the obstructed mesenteric system to the still patent intrahepatic portal vein. The prerequisites for a successful bypass operation are threefold: (1) no intrinsic liver disease, (2) a patent intrahepatic portal tree, and (3) a suitable vein in the mesenteric circulation to function as a suitable inflow tract for mesenteric blood.

In portal vein thrombosis, the extrahepatic portal vein is replaced by a network of small collaterals that supply the liver with a small amount of mesenteric blood and keep the intrahepatic portal circulation patent. The intrahepatic portal tree in these children is patent but hypoplastic.

The preoperative workup includes CT-angiography to assess the caliber and patency of the intrahepatic portal vein, a liver biopsy to rule out intrinsic liver disease, and a coagulation workup to rule out a hereditary hypercoagulable state.[139] It was once thought that hereditary hypercoagulable states, particularly protein C deficiency, often may have caused the thrombosis of the portal vein.[140–142] However, it has been reported that deficiencies not only in the plasminolytic pathway but also the procoagulant pathway may be secondary to the hepatic deprivation of portal blood and are reversible after the successful restoration of portal flow.[51]

The operation starts by dissecting out the intrahepatic portal vein in the recessus of Rex, where the round ligament inserts between segments III and IV of the liver. Portions of segments III and IV are removed. All the branches to segments II, III, and IV are controlled. If it is suitable, the superior mesenteric vein is dissected out at the root of the mesentery. Alternative sources of blood for the bypass including the splenic, inferior mesenteric, and coronary veins have been described.[143]

Once the inflow vein has been isolated, the jugular vein (either right or left) is removed and sewn first to the intrahepatic portal vein and then to the superior mesenteric vein. The vein graft usually goes through the mesocolon and the

lesser sac, up behind the stomach, through the lesser omentum, and up to the liver. In children with malrotation or other congenital disorders, the route of the graft may vary, depending on the child's individual anatomy. CT or MR scanning in the postoperative period demonstrates the patent shunt (Fig. 108-7).

Unlike portosystemic shunting, the mesenteric-to-left portal vein bypass, or Rex shunt, is restorative rather than palliative. It restores portal flow to the liver and relieves the symptoms of portal hypertension. With proper patient selection, patency rates have been in excess of 90%.[11] Patency depends primarily on the quality of the intrahepatic portal vein and the number of branches that allow for sufficient runoff to permit blood flow to be sustained. The intrahepatic portal vein may be difficult to visualize by preoperative imaging, and a final assessment may be possible only at the time of surgery.

### NONSHUNT OPERATIONS

Nonshunt operations for portal hypertension are generally limited to a direct attack on the varices by operative interruption and ligation, as well as esophageal transection to interrupt the intramural varices within the esophagus.[144–147] In the absence of suitable shunt options, these procedures are useful alternatives.

Sugiura and colleagues[147] described an operation in which all perigastric and periesophageal vessels were separated from the incisura of the stomach to the midesophagus at the level of the inferior pulmonary vein. In addition, the esophagus was divided and reattached. This radical approach to portal hypertension presented an alternative to shunting procedures, but it may have additional morbidity. A modified Sugiura operation in which the esophagus is transected and reanastomosed by a stapling device and in which the spleen is preserved has been described in children. As experience with shunting and other vascular surgery in children has increased, the use of these effective but palliative and unphysiologic operations has decreased.

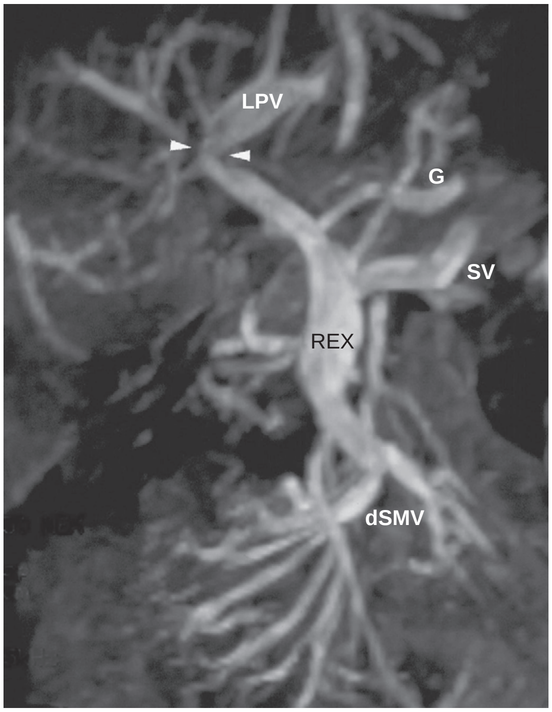

**FIGURE 108-7** The postoperative appearance of a meso-Rex bypass. The blood flows from the superior mesenteric vein (*dSMV*) and recruits blood from the splenic vein (*SV*), the coronary vein (*G*). The vein graft (*Rex*) flows cephalad into the left portal vein (*LPV*). The *white arrows* indicate a mild narrowing near the anastomosis between the jugular vein graft and the intrahepatic portion of the left portal vein.

## Complications of Surgery

### SHUNT THROMBOSIS

Any vascular operation, especially on the venous system, has the potential for thrombosis. Prophylaxis against thrombosis may be instituted in the immediate postoperative period with low-dose heparin and antiplatelet agents such as aspirin or dipyridamole and continued for 3 to 6 months. Once a shunt is thrombosed, it may not be salvageable, and other solutions such as devascularization must be sought if bleeding recurs. Careful follow-up, antithrombotic prophylaxis, and good operative technique to begin with should result in a long-term patency rate of greater than 90%.

### ANASTOMOTIC STENOSIS

Anastomoses can develop narrowing that can cause sluggish flow in the vessels, possibly thrombosis, and recurrence of the original signs and symptoms. Stenoses have characteristic appearances on Doppler ultrasound examinations that include a narrow area at the anastomosis, poststenotic dilatation of the vessel secondary to turbulent flow, and acceleration of the velocity of blood flow through the stenotic area. If the stenosis is believed to be of hemodynamic significance, then it must be dilated either by radiologic or surgical means. Interventional radiologic techniques can study the vessel and the stenotic area, assess the hydrostatic gradient on either side of the anastomosis, and dilate the narrow area by balloon dilatation. The effect of the ballooning can also be assessed by remeasurement of the pressure gradient. Placement of an endovascular stent is also a possibility in recalcitrant strictures (Fig. 108-8). We prefer to avoid stents in smaller children because, once placed, a stent may act as a fixed stenosis as the child grows and cannot be removed.

### ASCITES

Ascites is common after shunt operations because of disruption of the retroperitoneal lymphatic channels. In most cases this resolves spontaneously. Oral diuretics may be necessary for a short time. A reduced-fat diet may also be helpful because all the ascites is chylous in nature. Rarely, paracentesis may be necessary if the ascites is tense and persistent. If so, parenteral nutrition may be used to eliminate any chylous flow for a short time until the lymphatic leak seals. If ascites does not resolve with these measures, it may indicate that the hepatic reserve is small and transplantation may be necessary.

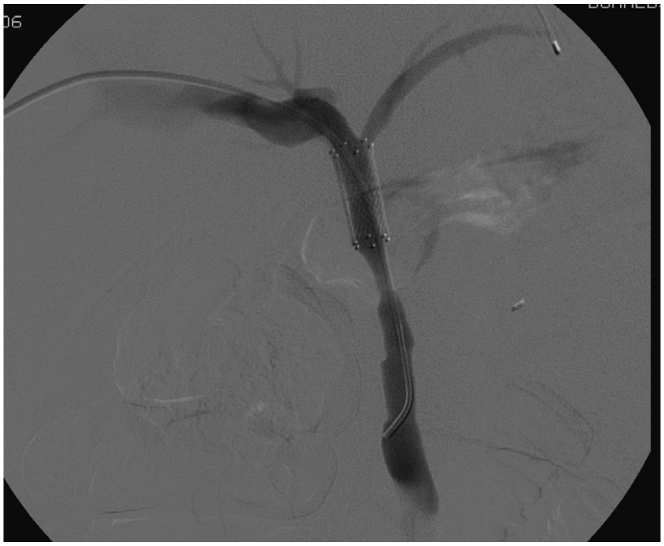

FIGURE 108-8 A transhepatic catheter is entering the liver from the right side of the patient. It has deployed a clearly visible endovascular stent used to treat a stricture in the vein graft or at the anastomotic suture line that was resistant to simple balloon dilatation.

### ESOPHAGEAL STRICTURES

After devascularization procedures accompanied by esophageal transection, it is not uncommon for the esophagus to narrow at the site of transection. Overt leaks are an uncommon but serious complication that requires thoracostomy drainage, prolonged antibiotics, and possibly reoperation. Fortunately, most strictures are manageable by esophageal dilatation, although some may require repeated sessions to achieve satisfactory patency.

## Outcome

The outcome of treatment in a child with portal hypertension depends on the cause of the hypertension and the underlying state of the liver. In the past decade, the care of these patients has improved considerably because of better medical and surgical options and the availability of liver transplantation in children with poor hepatic reserve.

### EMERGENCY BLEEDING FROM VARICES

Medical control of portal hypertension has improved to the point that emergency shunts in children are the exception rather than the rule. Medical therapy and endoscopic control of esophageal varices by ligation is excellent. Emergency shunts, when necessary, are effective in controlling hemorrhage, with good long-term patency rates reported. However, the patency rate of emergency shunts is lower than the 90% or greater patency rate reported for elective operations. Emergency mesocaval shunting is seldom reported today, owing to the availability of medical and endoscopic means of controlling acute variceal hemorrhage.

### INTERMITTENT BLEEDING FROM ESOPHAGEAL OR GASTRIC VARICES

Today, because of the effectiveness of endoscopy and medications, few patients with extrahepatic portal vein thrombosis present with acute, poorly controlled variceal bleeding requiring surgery. Patients are presenting with greater frequency with advanced hypersplenism and well-controlled varices. Controlling variceal bleeding does, however, require numerous endoscopies, occasional transfusions, and treatment with beta blockers and vasodilators.

As surgical options have become more effective and the results more predictable, definitive surgery for extrahepatic portal hypertension should be offered at an earlier point in the disease process rather than waiting until all other therapy has failed.[148] This is especially relevant with the advent of the meso-Rex bypass because this operation restores normal portal pressure and relieves hypersplenism by redirecting mesenteric blood back to the liver. The portal vein delivers 50% of the oxygen and 80% of the total blood supply to the liver. After a successful meso-Rex bypass, the flow in the vein graft increases over time as evidenced by the rapid expansion in portal vein branches inside the liver (Fig. 108-9, *A* and *B*). The effects of restoring portal blood to the liver are not yet apparent and may have far-reaching metabolic consequences during the child's early development. The correction of coagulation parameters back to normal after portal flow restoration may be only one of many ameliorations in hepatic function that take place. The common belief that a child with portal vein thrombosis and portal hypertension has "normal" hepatic function may not be correct.

As experience with the meso-Rex bypass increases, more evidence of the metabolic sequelae of the restoration of portal flow to the liver has become apparent. Both clinical and experimental data point to improved growth, protein synthesis, and neurocognitive function following a meso-Rex bypass.[49,51,149–151] The long-term consequences of portal vein thrombosis on bile and bile ducts are also not well understood, but evidence suggests there is an increased incidence of cholelithiasis and biliary cirrhosis from uncorrected portal vein thrombosis.[152,153]

Recently, the conclusions of a consensus conference held to formulate surgical guidelines in the treatment of children with portal vein thrombosis were published. These take into account both the developing comfort in doing this procedure, as well as the new data that indicate the meso-Rex bypass not only relieves the symptoms of portal hypertension as well as other procedures but also restores to normal many of the metabolic parameters of the liver that have been affected by the long-standing deprivation of portal blood flow.[148]

Selective shunting, through either a distal splenorenal shunt or a coronary-to-vena cava graft, to correct portal hypertension from portal vein thrombosis has been established as a procedure with minimal morbidity and no mortality when done by experienced surgeons. Patency rates exceed 95%, and hospital stays of less than a week are common. In the long run, selective shunting may be better for children than repeated hospital admissions for banding and long-term medication use to control bleeding. In addition, advanced hypersplenism occurs in many of these children when definitive surgical therapy is delayed. Even when variceal banding is instituted prophylactically, bleeding may shift away from the

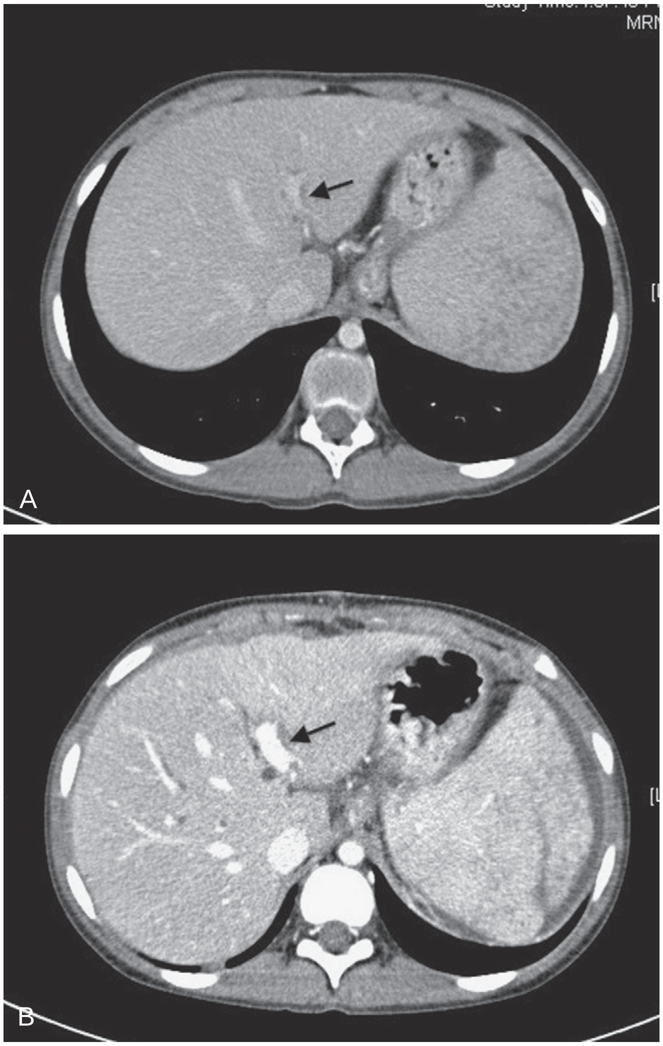

**FIGURE 108-9** These two images of the liver from the same patient before **(A)** and after **(B)** the meso-Rex bypass illustrate the expansion in the intrahepatic portal vein size that occurs quickly after restoration in mesenteric venous flow (*arrows* in both images point to the portal vein in the equivalent area). The change in portal vein size is indicative of an increase in the volume of blood flowing through the liver.

esophagus and into the stomach in many children over time. Surgical therapy (Rex shunt or distal splenorenal shunt) controls bleeding, reduces hospital admissions, decreases the need for medications, and relieves hypersplenism in a physiologic way that does not expose the child to the lifelong risk of overwhelming sepsis after splenectomy.

Shunting for portal hypertension caused by intrinsic liver disease is a more complex proposition because it has to take into account the health of the liver. Selective shunting is excellent at decompressing the child's portal system, with minimal morbidity in patients with low Child-Pugh or PELD scores. Although the theory behind the distal splenorenal shunt is that it separates the splenic and gastric venous drainage from the intestinal and mesenteric venous flow, careful studies have shown that separation between the two systems is not always complete and may disappear over time as the body forms collateral veins to replace the ones that were interrupted. Nevertheless, selective shunts that attempt to preserve hepatopetal flow result in less encephalopathy and better hepatic function than do nonselective shunts in both children and adults.

If a child with well-preserved liver function and portal hypertension cannot have a selective shunt because of a previous failed shunt or because of unfavorable anatomy, it may be better to consider a devascularization procedure to minimize the potential for encephalopathy.[154,155] The only role for nonselective shunts in children may be the rare child with well-preserved liver function and obstructive venopathy that cannot be stented or opened by an interventional radiologic approach. In this case the risk of minimal encephalopathy may be outweighed by the dangers of recurrent bleeding.[156]

### GASTROPATHY

The treatment includes all measures generally applied to bleeding from esophageal varices except that endoscopic treatment is not possible. Measures include drug therapy with somatostatin analogues, acid suppression, antibiotics,[62] and treatment with beta blockers. Long treatment may also include surgical relief of the portal hypertension. This has been shown to reverse the gastropathy.[157] The choice of operation of course depends on the cause of the portal hypertension and the venous anatomy.

### HYPERSPLENISM

As the treatment for esophageal variceal bleeding has improved, more children are presenting with bleeding from gastric varices, portal hypertensive gastropathy, or complications of advanced and debilitating hypersplenism. There is no medical therapy for hypersplenism other than stimulating the bone marrow with granulocyte colony-stimulating factor (GCSF).[158,159] In fact, GCSF may transiently lower the platelet count while it helps with the leucocytes.[160] Surgery is the only alternative.

Almost all shunts have been shown to decrease the severity of hypersplenism when done primarily for the indication of bleeding from symptomatic varices. The same two principles should govern the choice of surgery done primarily for hypersplenism: splenic preservation and the avoidance of encephalopathy. The distal splenorenal shunt has been shown to ameliorate hypersplenism in children. In children with extrahepatic portal vein thrombosis, the Rex shunt has had excellent results in terms of resolving hypersplenism and also improving the neurocognitive parameters associated with portosystemic shunting.

## Summary

A child with portal hypertension presents a unique challenge to the surgeon. The number of treatment options has increased over the past 2 decades and includes a wider variety of effective medications that reduce the pressure in the mesenteric tree and diminish the blood flow in the portal circulation. These options have greatly decreased the need for emergency surgery in children with portal hypertension. Figure 108-10 summarizes the treatment options discussed in this chapter on the basis of the underlying cause of portal hypertension.

Ancillary interventions such as endoscopic ligation of varices and radiologically guided placement of intrahepatic stents have also reduced the reliance on operative control of bleeding

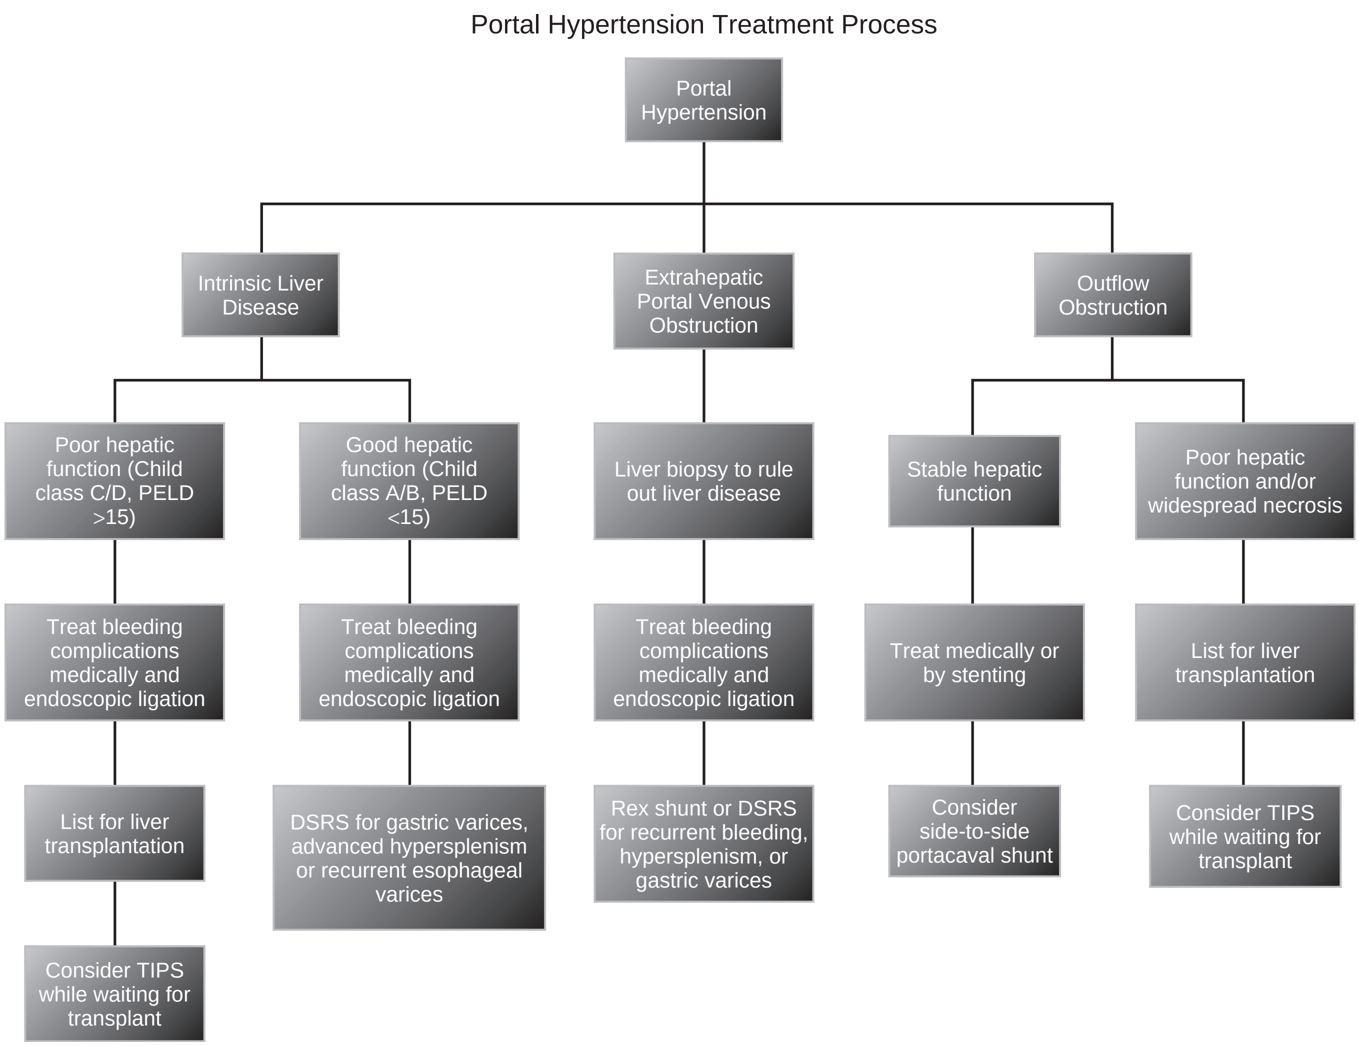

**FIGURE 108-10** Treatment algorithm according to the underlying cause of portal hypertension. Portal hypertension accompanied by advanced liver dysfunction from either venous outflow obstruction or intrinsic liver disease is ultimately treated by transplantation, with or without a transjugular intrahepatic portosystemic shunt (*TIPS*) procedure. If the liver dysfunction is acceptable and not rapidly progressive, an appropriate shunt may be a good long-term solution. For symptomatic portal hypertension from extrahepatic portal hypertension, mesenteric-to-left portal vein bypass is the procedure of choice, followed by distal splenorenal shunt (*DSRS*). PELD, Pediatric end-stage liver disease.

in patients with advanced liver disease. Such interventions increase the chance that these patients will survive to receive a liver transplant.

Although the need for surgical procedures has been reduced, surgical results have improved so that both shunt and nonshunt procedures offer a more permanent solution to bleeding and hypersplenism in patients with prehepatic and posthepatic portal hypertension and in those with well-compensated cirrhosis. With the decreased morbidity associated with portal hypertension surgery, the excellent long-term patency rates reported even in infants and small children after shunt surgery, and the increased number of surgical options available for children, surgery for portal hypertension offers a good alternative to medical treatment, even early in the course of treatment.

CHAPTER 109

# The Pancreas

N. Scott Adzick

## Embryology

The pancreas originates from two endodermal buds that arise from the caudal part of the foregut. One is the ventral bud, which arises from the base of the hepatic diverticulum and is closely related to the bile duct; the other arises from the dorsal surface of the duodenum immediately opposite and in a slightly rostral direction to the liver diverticulum. Both fuse at approximately the sixth or seventh week of gestation. The dorsal bud appears before the ventral bud, grows faster, and becomes larger.[1,2] An axial duct is formed and opens into the gut tube by the beginning of the sixth week of gestation, and short branches appear soon thereafter.[3]

The ventral bud of the pancreas transiently consists of two lobules[4]; small ducts form within these lobules and open into the hepatic diverticulum close to the gallbladder. The ventral bud is carried away from the duodenum by elongation of the proximal part of the hepatic diverticulum from which it arises. This proximal part is called the *common bile duct*. The left ventral bud lobule later regresses completely. Because of rapid growth of the duodenum, which is limited to the left half of its circumference,[5] the right ventral bud and the developing common bile duct rotate backward and become situated close to the posterior and inferior surface of the dorsal pancreatic bud. The outcome of this rotation is to bring the opening of the common bile duct to the same side as the dorsal bud so that the duct lies ventral to and below the opening of its duct. The tip of the right ventral bud lobule eventually rests behind the superior mesenteric artery. During the seventh week of gestation, the smaller ventral bud fuses with the proximal part of the dorsal pancreas.

Secretory acini appear during the third month as clusters of cells around the ends of the ducts from which they are derived.[6] Pancreatic development involves a process in which two morphologically distinct tissue types must derive from one simple epithelium. These two tissue types, exocrine (including acinar cells, centro-acinar cells, and ducts) and endocrine cells, serve disparate functions and have entirely different morphology. In addition, the endocrine tissue must become disconnected from the epithelial lining during its development.[7,8]

### PANCREATIC ANOMALIES

Pancreatic anomalies are numerous and are listed in Table 109-1.

### ANNULAR PANCREAS

During the sixth week of gestation, the common duct and the right ventral bud lobule are carried in a dorsal direction around the circumference of the duodenum. The longer duct of the dorsal pancreas anastomoses with that of the ventral pancreas to establish the main pancreatic duct. Developmental errors at this stage are believed to cause annular pancreas. This anomaly occurs in 1 in 20,000 births and is more frequent in males than females with a ratio of 2:1. The appearance of an annular pancreas in a woman and her child,[9] in siblings, and in members of two successive generations[10] suggests a possible hereditary link, but this has yet to be delineated. Annular pancreas can cause duodenal stenosis or obstructive symptoms in the first days of life.[11]

### PANCREAS DIVISUM

The adult pancreas is derived from ventral and dorsal pancreatic buds that fuse by the end of the eighth week of gestation. Most of the gland is derived from the dorsal bud and includes the superior anterior part of the head, body, and tail; it is drained by the duct of Santorini through the minor papilla. The ventral bud becomes the posterior and inferior part of the head. The ventral pancreatic bud is drained by the duct of Wirsung into the major papilla of Vater. With fusion of the ventral and dorsal pancreas and their duct system, the duct of Wirsung becomes the major duct, and the duct of Santorini usually regresses with the minor papilla in approximately 90% of people. Failure of the two ductal systems to unite results in the anatomic variant known as *pancreas divisum*. In this disorder the duct of Wirsung is small, and the duct of Santorini becomes the major ductal system and maintains communication with the duodenum through the minor papilla. This configuration is found in 4% to 11% of cadavers and in 3.25% of patients undergoing endoscopic retrograde cholangiopancreatography (ERCP).

### CONGENITAL SHORT PANCREAS

Congenital shortening of the pancreas is an unusual anomaly that has been described in individuals with polysplenia syndrome,[12] as well as being an isolated anomaly.[13] It has also

been seen in conjoined twins with a shared duodenum. In this condition the pancreas appears blunted and lacks tissue in the region of the body and tail, which is believed to be caused by agenesis of the dorsal pancreatic bud. Pancreatic function generally remains normal despite partial absence of the pancreatic parenchyma.[14]

# Surgical Anatomy

The pancreas is composed of a head, body, and tail, although these areas have no distinct anatomic borders. The head sits to the right on L2, the body covers L1, and the tail rises to T12 on the left. The abdominal aorta and vena cava provide some cushioning effect against the vertebrae; however, certain forces (such as seat-belt and steering wheel injuries) can cause blunt trauma to the body of the pancreas.

The pancreas is retroperitoneal. Peritoneal reflections from the transverse mesocolon, small intestinal mesentery, and the splenorenal and phrenocolic ligaments are present and establish mesenteric planes for the direct spread of extravasated pancreatic enzymes.[15] These anatomic relationships are important for understanding the pathophysiology of the various radiographic signs seen in patients with acute pancreatitis.

The splenic artery provides most of the blood supply to the pancreas and lies along its superior border with the splenic vein. It seems that the blood supply is generally greatest to the head of the pancreas. The head of the pancreas shares its blood supply with the duodenum through the gastroduodenal artery and superior and inferior pancreaticoduodenal arteries, which may complicate surgery on the head of the pancreas. Blood from the pancreas drains in a posterior direction into the superior mesenteric vein and splenic vein via small, delicate branches.

Several anomalies of the pancreatic (third) part of the common bile duct have been noted: (1) The bile duct may be partly covered by a tongue of pancreas (44%), (2) the bile duct may be completely covered by the pancreas (30%), (3) the posterior surface of the bile duct may be uncovered (17%), and (4) the bile duct may be covered by two tongues of the pancreas (9%).[16] Surgeons must be aware of these variants during surgery involving the head of the pancreas.

# Pancreatitis

Although pancreatitis is uncommon during childhood, it must be considered in every child with unexplained acute or recurrent abdominal pain. The prognosis in children is generally good, with the exception of pancreatitis occurring with multiorgan failure. Regardless of the cause, certain common features are found in all types of pancreatitis. Patient management must be highly individualized because numerous disease entities can cause pancreatitis.

## ACUTE PANCREATITIS

Clinically, acute pancreatitis is defined as a single episode or recurrent episodes of abdominal pain associated with elevated serum pancreatic enzyme levels. The morphologic correlate is acute focal or diffuse swelling and inflammation of the pancreas. Resolution of symptoms and normalization of blood biochemistry and anatomic abnormalities follow an acute episode. A continuum exists between acute and chronic pancreatitis; as a result, recurrent episodes of acute pancreatitis may evolve into the typical clinical and morphologic features of chronic pancreatitis.

### Etiology

Although pancreatitis in adults is usually related to alcohol abuse or biliary tract disease, in children the causes are more diverse.[17–19] Most cases of acute pancreatitis in children result from systemic infection, trauma, choledocholithiasis, anomalies of the pancreaticobiliary duct system, and drugs (Table 109-2). Less common causes include idiopathic

disease, metabolic disorders, and miscellaneous conditions such as familial pancreatitis and Crohn disease.

Six percent to 33% of cases of pancreatitis are related to disorders of the biliary or pancreatic duct,[20] with choledochal cyst and cholelithiasis being the most common. A choledochal cyst is often associated with malunion of the pancreatic and biliary ducts (pancreaticobiliary malunion), and a long common channel may form and permit reflux of bile into the pancreatic duct.[21] The common channel is seen easily on ERCP; this channel is often dilated and contains protein plugs or stones, which may cause obstructive pancreatitis or jaundice.

Cholelithiasis in children is frequently associated with various hemolytic disorders including spherocytosis, alpha-thalassemia, and sickle cell disease. It may also be caused by obesity and the use of total parenteral nutrition.[22] The role of pancreatic duct anomalies such as pancreatic divisum and stenosis of the ampulla of Vater has only recently been appreciated.[23–26] Pancreaticobiliary malunion not associated with a choledochal cyst is drawing clinical attention because it tends to be overlooked on ultrasonography; most patients with the disorder have recurrent abdominal pain as a result of pancreatitis.[24,26–28] Tagge and colleagues[26] found ductal anomalies in 6 of 61 (10%) patients with pancreatitis. They noted that patients with ductal abnormalities usually had recurrent episodes and that relapsing or chronic pancreatitis was also associated with ductal anomalies.

Severe abdominal trauma may cause immediate acute symptoms.[29] However, less severe trauma may result in a delayed onset and subacute manifestation. Child abuse should be considered in all children with acute pancreatitis who have a vague history.[19] Finally, trauma may also be iatrogenically induced during the course of abdominal surgery or ERCP.[30]

Drugs cause 8% to 25% of the cases of pancreatitis. Drugs that cause pancreatitis most frequently include didanosine, azathioprine, mercaptopurine, L-asparaginase, and valproic acid.[20,31,32] Recently, liver transplantation has been reported as a possible cause of acute pancreatitis. The incidence of this complication and the mortality rate in children were 1.9% and 43%, respectively.[33] A strong association between the development of acute pancreatitis after liver transplantation and several risk factors such as the diagnosis of fulminant hepatic failure, retransplantation, extensive dissection at the time of liver transplantation, and the use of infrarenal arterial grafts has been reported.[34]

Certain variants of the trypsinogen gene and cystic fibrosis transmembrane regulation (CFTR) gene may cause acute recurrent pancreatitis. Many patients with the diagnosis of idiopathic pancreatitis have compound heterozygote genotypes in which both alleles of the CFTR gene are abnormal, thus constituting a variant of cystic fibrosis. There are also numerous reports of an association between chronic pancreatitis and a number of CFTR mutations both in patients with cystic fibrosis and in carriers with a single mutation.[35]

In certain conditions, destruction of the pancreas begins antenatally. Infants with Shwachman-Diamond syndrome, an autosomal recessive disorder mapped to the centromeric region of chromosome 7,[36] have pancreatic insufficiency at birth, generally with low serum trypsinogen levels, indicative of nearly total exocrine pancreatic atrophy by birth.

## Diagnosis

The diagnosis of acute pancreatitis is based on the clinical history, physical examination, laboratory test results, and findings of diagnostic imaging investigations. Determination of amylase isoenzymes has also been used to increase diagnostic accuracy by identifying the tissue from which the amylase originates. Serum lipase levels may also complement pancreatitis testing and increase the yield of positive diagnoses.[37] A new scoring system for acute pancreatitis in children has been proposed that has better sensitivity than the Ranson and Glasgow scores.[22] The parameters are age (<7 years), weight (<23 kg), admission white blood cell count (>18,500), admission lactate dehydrogenase level (>2000), 48-hour trough $Ca^{2+}$ level (<8.3 mg/dL), 48-hour trough albumin level (<2.6 g/dL), 48-hour fluid sequestration (>75 mL/kg/48 hr), and 48-hour rise in blood urea nitrogen (>5 mg/dL).

Plain radiographs of the chest and abdomen are obtained to exclude intestinal perforation. Occasionally radiopaque gallstones, a gas-filled right colon, or a distended loop of small intestine (sentinel loop) may be seen. Left basal pleural effusion is relatively common, and mottling of the lung fields is a sign of systemic cytokine release. Radiographic studies enhanced by water-soluble contrast of the upper gastrointestinal tract are occasionally useful, particularly in cases of trauma when injury to the duodenum or small intestine is suspected. Ultrasonography (US) and computed tomography (CT) are useful for detecting pancreatic abnormalities. Trauma-induced injuries to abdominal organs, particularly the pancreas, are readily detected on CT.

ERCP is rarely indicated for acute pancreatitis, but it eventually becomes essential in any child who has pancreatitis with an unclear cause.[23,26] This technique is useful in cases of relapsing pancreatitis associated with pancreaticobiliary malunion.[21,24] ERCP is an invasive method that can aggravate pancreatitis and is often not an option during the acute phase of pancreatitis. Magnetic resonance cholangiopancreatography (MRCP) is a noninvasive method of obtaining images of the pancreaticobiliary tract. MRCP images the common bile duct in more than 96% of patients and detects common bile duct stones with a sensitivity of 71% to 100%, thus exceeding the sensitivity of US (20% to 65%) and CT (45% to 85%). Visualization of the smaller pancreatic duct is successful in more than 80% of patients.[37] Miyano and colleagues[38] have previously evaluated the efficacy of MRCP in pediatric patients with acute pancreatitis. Patients were divided into two groups. Group 1 consisted of seven patients in whom choledochal cysts were sonographically diagnosed, and group 2 consisted of nine patients with no obvious cause of acute pancreatitis. Pancreaticobiliary malunion was detected in six of seven in group 1 and in one of nine in group 2. Pancreatic divisum was detected in one patient in group 1 but could not be confirmed in any of the group 2 patients. Dilatation of the main pancreatic duct was detected in one in group 1 and in three in group 2. These findings indicate that MRCP is a potentially useful method for identifying and ruling out structural abnormalities of the pancreaticobiliary tract in children.

## Treatment

Treatment of acute pancreatitis has two primary goals: (1) to minimize any causative factors and (2) to provide meticulous supportive care including liberal use of analgesics,

administration of parenteral fluids, maintenance of nutrition, prevention of infection, and inhibition of endocrine and exocrine activity.

Parenteral analgesia with narcotics or nonsteroidal antiinflammatory agents is generally required, even in mild cases of pancreatitis, because the pain can be extreme. It is traditional to administer meperidine rather than morphine because the latter produces ampullary spasm. Although nasogastric suction is usually initiated to reduce vomiting and abdominal distention, the value of nasogastric decompression is questionable, unless the patient is vomiting. Aspiration of gastric acid may reduce pancreatic exocrine secretion by limiting the release of secretin. Oral feeding must be withheld to reduce pancreatic stimulation. Total parenteral nutrition should be initiated early to avoid malnutrition.[39] In addition, early placement of a central venous catheter in patients with severe disease will provide access for aggressive intravascular volume support and nutrition. The hematocrit and serum levels of glucose and calcium should be measured, and hourly urine output should be monitored carefully.

Although the advantages of prophylactic antibiotics have not been proved, patients with necrotizing pancreatitis may benefit.[40] Other treatment strategies involving somatostatin, glucagon, anticholinergics, histamine blockers, and protease inhibitors have been recommended, but to date they have not shown conclusive benefit.

Standard medical treatment must be used in patients with acute pancreatitis in an attempt to control the disorder before surgical intervention, which is rarely required in children but is occasionally performed if the diagnosis is uncertain or a complication develops after an acute episode such as a pseudocyst or an abscess. Patients with acute pancreatitis associated with underlying pancreaticobiliary disease generally require surgical correction of the underlying condition before cure can be expected.

In the management of severe acute pancreatitis, a major decision is whether and when surgery for pancreatic necrosis or infection is necessary. Infection of necrotic pancreatic tissue is the major risk factor for mortality in severe acute pancreatitis and is an indication for surgery. On the other hand, there is support for nonsurgical conservative management of sterile pancreatic necrosis including antibiotic treatment. The reported death rate is 1.8% with sterile pancreatic necrosis and 24% with infected necrosis.[41] Early surgery has been associated with increased mortality and should be delayed, if not avoided.[42]

## CHRONIC RELAPSING PANCREATITIS

Chronic relapsing pancreatitis is characterized by recurrent episodes of upper abdominal pain associated with varying degrees of pancreatic exocrine and endocrine dysfunction. Relatively few case series of chronic relapsing pancreatitis in childhood exist, although it is more frequently being suspected in children with recurrent episodes of abdominal pain.[43–45] The disease produces a wide variation of progressive and irreversible structural changes in the pancreas.[44] At present, the most controversial aspect of treatment of this disorder is the choice of an appropriate surgical procedure.

### Causes and Pathophysiology

In children the most common causes of chronic relapsing pancreatitis are trauma, heredity, systemic disease, and malformations of the pancreaticobiliary duct such as pancreas divisum, annular pancreas, and choledocholithiasis. In addition, various unusual conditions including metabolic disease, endocrine disorders, and inflammatory bowel disease[13] may cause the disorder. Causes of chronic relapsing pancreatitis are listed in Table 109-3.

Certain congenital anomalies affect the pancreas and surrounding tissue, several of which are associated with chronic relapsing pancreatitis. Obstruction of pancreatic flow caused by a stenotic papilla of Vater and bile reflux resulting from a common channel are believed to be responsible for the resultant inflammation, which may be reversible if the obstruction is relieved. A relatively common cause of relapsing pancreatitis is pancreas divisum,[46] in which most of the pancreatic fluid flows through the minor duct of Santorini, with the possibility of a relative obstruction to flow because of anatomy and flow dynamics. Some series have reported an increased incidence of pancreas divisum in patients with idiopathic chronic pancreatitis.[46] Annular pancreas, which results from an error of rotation or fixation of the embryologic pancreatic primordium, has also been associated with chronic pancreatitis (Fig. 109-1).[63] Pancreaticobiliary malunion with or without choledocholithiasis may likewise result in relapsing chronic pancreatitis.[24,27]

In the past few years, several genes have been identified as being associated with hereditary and idiopathic chronic pancreatitis: PRSS1, CFTR, and SPINK1. SPINK1 mutations were found predominantly in patients without a family history. These mutations were most common in those with idiopathic chronic pancreatitis, whereas patients with hereditary chronic pancreatitis predominantly had PRSS1 mutations.[47]

A complex anomaly of the pancreatic duct with dilatation (*arrowheads*) and stenosis (*arrows*) is shown. The patient underwent a longitudinal pancreaticojejunostomy (Puestow) procedure.

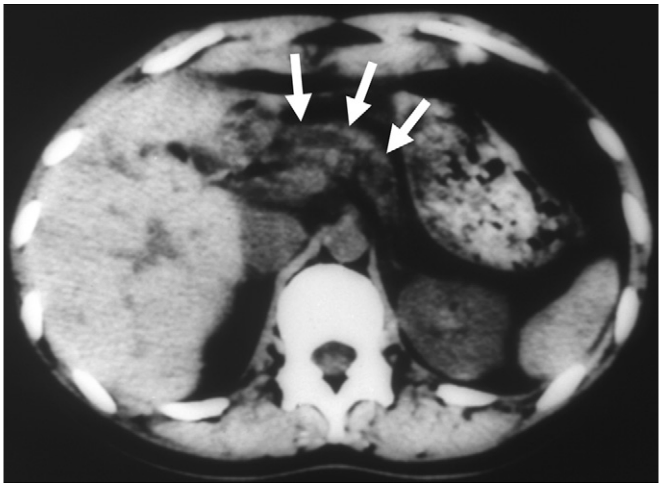

**FIGURE 109-2** Computed tomographic scan of a patient with an irregularly dilated pancreatic duct (*arrows*). The patient underwent a longitudinal pancreaticojejunostomy (Puestow) procedure.

### Diagnosis

The degree of permanent damage to the pancreas may be assessed by blood tests (pancreatic enzymes), stool tests (pancreatic enzymes, fecal fat), and noninvasive tests of pancreatic function such as the pancreatic stimulation (secretin) test. In 30% to 50% of adolescents and adults with chronic pancreatitis, plain radiographs of the abdomen reveal pancreatic calcification. Calcification is diagnostic of chronic pancreatitis, even if clinical evidence of pancreatic disease is absent. However, the incidence of calcification in children with chronic relapsing pancreatitis is low, except in younger children with hereditary pancreatitis, in whom the incidence is high.

US is ideal for examining the pancreas in children. Dilatation of the pancreatic or biliary tracts may be noted, and calcification and complications such as pseudocysts, abscesses, calculi, and ascites can be seen. CT is useful for visualizing the size of the pancreas and its ducts (Fig. 109-2) and for detecting small calculi that may be missed on plain radiographs and US. ERCP is an important tool in the diagnosis and management of chronic relapsing pancreatitis in adults and children.[23] Pancreaticobiliary malunion with or without dilatation of the bile duct may be detected.[24] ERCP is up to 90% accurate in diagnosing ductal abnormalities. However, as described earlier, MRCP has been greatly refined in the past decade. MRCP is considered to be equivalent to ERCP for the diagnosis of many pancreatic and biliary conditions and is preferable because it is noninvasive and safer.[38]

### Surgical Treatment

Surgery for chronic relapsing pancreatitis is done to relieve pain, treat complications, or both. Surgery on the pancreas is generally of three types: (1) sphincteroplasty[45]; (2) pancreatic drainage via longitudinal pancreaticojejunostomy (Puestow),[48] end-to-end pancreaticojejunostomy (Duval),[49] or the Frey procedure[50,51]; or (3) partial or total pancreatectomy. Several groups of investigators have attested to the success of sphincteroplasty in controlling the symptoms of chronic pancreatitis in carefully selected patients. Correct use of this procedure, however, demands that intrapancreatic ductal obstruction be ruled out by pancreatography. O'Neill and colleagues[45] reported good results in six of seven children who underwent sphincteroplasty for chronic pancreatitis.

The general indication for the use of a direct ductal decompression procedure is evidence of pancreatic ductal ectasia with multiple intrapancreatic duct strictures. An important secondary feature of drainage procedures is preservation of existing endocrine function by avoiding major pancreatic resection. Longitudinal pancreaticojejunostomy (Puestow technique) in adults has been successful in eliminating or ameliorating pain from chronic pancreatitis in 70% to 97% of patients in series reported 3 decades ago.[52,53] In children, several authors have shown that either the Puestow procedure[43,54–56] or the Frey procedure[51] improves pancreatic function, decreases hospitalization, and increases body weight toward ideal. Others have reported that distal pancreatectomy and pancreaticojejunostomy are effective.[57] Tailored organ-preserving resective pancreatectomy can also be performed with low morbidity and mortality in pediatric patients with chronic pancreatitis and not responding to medical management. Total pancreatectomy is not generally indicated in children.[58] The individual procedure for chronic pancreatitis should be tailored to the pancreatic ductal anatomy.

## PANCREAS DIVISUM

The embryology of this entity was described in the first section of this chapter. Pancreas divisum is suspected on MRCP or ERCP when the duct of Wirsung fails to be visualized after injection of the major papilla or when it is attenuated and rudimentary. MRCP is a useful and noninvasive diagnostic tool for pancreas divisum (Fig. 109-3), but ERCP can provide detailed information on the pancreatic duct. If pancreas divisum is suspected after injection of the papilla of Vater, an attempt should be made to find and cannulate the minor papilla, but this is possible in less than half the cases because of its small size and the angle at which it meets the duodenum. If the minor papilla can be entered, ERCP will demonstrate that the duct

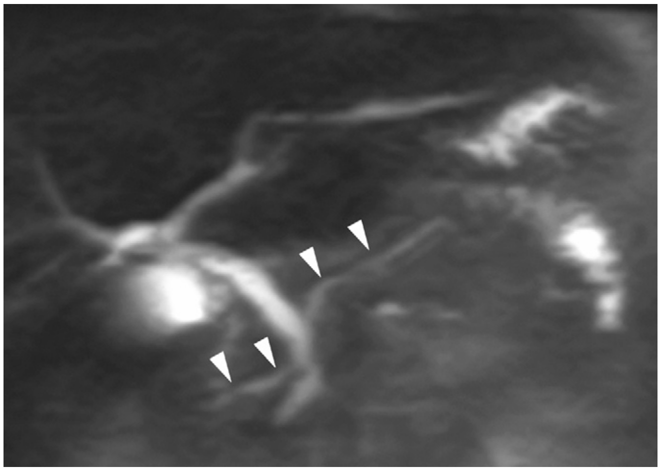

FIGURE 109-3 Magnetic resonance cholangiopancreatography in a patient with recurrent pancreatitis. The duct of Santorini is the dominant duct, and it extends the entire length of the body and tail of the pancreas (*arrowheads*).

of Santorini is the dominant duct and that it extends the entire length of the body and tail of the pancreas. Imaging of the duct of Santorini occasionally demonstrates dilatation, irregularity, or stricture suggestive of chronic pancreatitis.

Autopsy studies have suggested that pancreas divisum, which is found in 4% to 11% of patients, is the most common congenital anomaly of the pancreas. When absence of the duct of Wirsung is associated with pancreas divisum, approximately 10% of affected patients have anomalous anatomy resulting in most or all of the pancreatic secretions draining by means of the accessory papilla.[59,60]

Pancreas divisum should not be regarded as a disease. However, if the orifice of the accessory papilla is stenotic, pancreatitis can result. Stenosis of the minor papilla is probably developmental because the orifice is usually small with no evidence of inflammation. The incidence of pancreas divisum may be significantly higher in patients with unexplained recurrent pancreatitis, and it was detected in up to 25% of patients. Neblett and O'Neill reported that pancreas divisum was identified in 7.4% of all children with pancreatitis and 19.2% of children with relapsing or chronic pancreatitis. In 10 patients with pancreas divisum, 8 had complete pancreas divisum and 2 had incomplete variants.[61]

The primary goal of treatment of pancreas divisum associated with pancreatitis is to establish adequate drainage of the duct of Santorini. The progression of disease to pancreatic insufficiency can be arrested when the obstruction is relieved early. Correction may not only preserve pancreatic function but may also help ensure that normal growth and development occur.

Several reports have shown that adequate drainage of the duct of Santorini can be achieved with accessory papilla sphincteroplasty.[46,59–61] A report by Adzick and colleagues delineated the technical details of the operative procedure.[46] Endoscopic sphincterotomy has been performed, but restenosis and recurrence of symptoms have been reported. If chronic pancreatitis has developed in the presence of a dilated duct, longitudinal pancreaticojejunostomy should be considered. Neblett and O'Neill[61] reported that 8 of 10 patients with pancreas divisum underwent surgery: 7 underwent transduodenal sphincteroplasty of the accessory papilla, along with sphincteroplasty of the major papilla in 2 (plus septoplasty in 1). Three patients underwent longitudinal pancreaticojejunostomy, as a primary procedure in one patient with mid-ductal stenosis and in two because of recurring pancreatitis after sphincteroplasty without endocrine and exocrine pancreatic insufficiency. Surgical intervention is directed toward relief of ductal obstruction and may involve accessory duct sphincteroplasty alone or in conjunction with major sphincteroplasty and septoplasty. Patients with more distal ductal obstruction or ductal ectasia may benefit from pancreaticojejunostomy. In an extremely rare case, Miyano and colleagues treated a patient with coexistence of pancreas divisum, choledochal cyst, and pancreaticobiliary malunion. Figure 109-4 shows the preoperative ERCP and intraoperative cholangiogram. This patient underwent complete excision of the choledochal cyst with a Roux-en-Y hepaticojejunostomy, followed by transduodenal papilloplasty to allow complete drainage of the common channel.[62]

# Cysts and Pseudocysts

Pancreatic cysts are relatively unusual in children. The causes of these cysts tend to be diverse and include both congenital and acquired conditions. Pancreatic cysts can be classified as congenital and developmental, retention, enteric duplication, and pseudocysts.

## CONGENITAL AND DEVELOPMENTAL FORMS

Congenital and developmental cysts of the pancreas are rare and may be encountered in a fetus, infant, child, or adult. Only 25 cases have been reported in the pediatric literature to date.[64–67] These cysts have a female preponderance. They are most common in the body and tail of the pancreas, are more often unilocular than multilocular, and are lined with epithelium. The cysts are usually filled with a cloudy, yellow sterile fluid that has no enzyme activity, and they are remarkably free of adhesions and infection. They have been reported to occur simultaneously in other organs; for example, von Hippel-Lindau disease is characterized by hereditary cerebellar cysts, retinal hemangiomas, and cysts of the pancreas and other organs.[68] The cysts that occur with cystic fibrosis are not considered pancreatic pseudocysts and are not discussed in this chapter.

Clinically, congenital and developmental cysts are detected in the prenatal period as an incidental sonographic finding or as a cause of polyhydramnios. After birth, they may be manifested as asymptomatic abdominal distention, as vomiting or jaundice caused by extrinsic pressure on neighboring organs, or as an asymptomatic mass. Surgical treatment consists of total excision of cysts located in the pancreatic body or tail and either internal drainage or complete resection of those in the pancreatic head.

## RETENTION CYSTS

Retention cysts of the pancreas are rare and believed to result from chronic obstruction of the gland. They contain cloudy fluid composed of pancreatic exocrine secretions and a high concentration of pancreatic enzymes. Such cysts are lined with ductal epithelium unless it has been destroyed by chronic dilatation or inflammation from enzyme exposure.

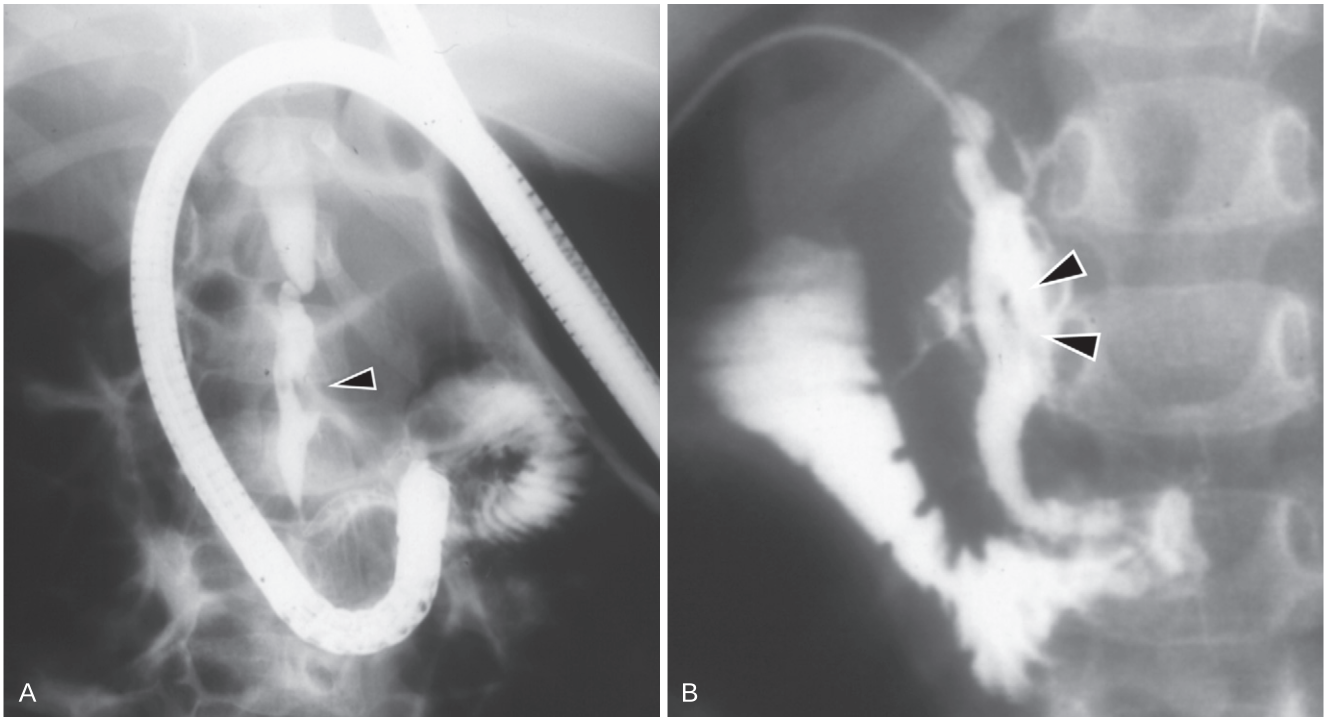

FIGURE 109-4 **A,** Preoperative endoscopic retrograde cholangiopancreatography. **B,** Intraoperative cholangiogram in a patient with a choledochal cyst associated with pancreas divisum. The septum (*arrowheads*) in the intrapancreatic bile duct is also seen.

## ENTERIC DUPLICATIONS

Enteric duplication involving the pancreas is rare and usually associated with gastric duplication.[69] This duplication is most likely to result from failure of regression of an enteric diverticulum formed from the pancreatic duct. Many of the reported cases of enteric duplication involving the pancreas communicate with the pancreatic duct, are lined with gastric-type epithelium, and contain ectopic pancreatic tissue in their walls. Pancreatic duplication cysts have been noted on fetal US.[70]

The most common symptom in these patients is recurrent abdominal pain, often postprandial. Pancreatitis associated with enteric duplication cysts is believed to be caused by obstruction of the pancreatic ducts by viscous secretions from the cyst or by blood and debris from peptic ulceration within the cyst. In patients without pancreatitis, pain may be caused by tension on the wall of the cyst as a result of accumulation of secretions and muscular contraction.[71] CT may help identify the location and size of duplication cysts, as well as any edema of the pancreatic head. ERCP or MRCP is useful to outline ductal anatomy and demonstrate any communication between the duplication cyst and the pancreatic duct to aid in planning the surgical approach. To date, virtually all duplication cysts reported in the literature have been treated by extirpation, and some have required pancreaticoduodenectomy.[69,72]

## PSEUDOCYSTS

### Clinical Features

Pancreatic pseudocysts are localized collections of pancreatic secretions that do not have an epithelial lining and develop after pancreatic injury, inflammation, or duct obstruction. The most common causes of pseudocysts in children are trauma and infection.[73] Drug-induced acute pancreatitis such as with valproic acid is also a rare cause of pancreatic pseudocyst.[74] These cysts typically lie in the lesser sac behind the stomach and are composed of a fibrous capsule surrounded by inflamed connective tissue. The capsule of the cyst may also be formed by neighboring tissue such as the stomach, duodenum, colon, small intestine, or omentum. Pseudocyst fluid is clear or straw colored in most cases and may contain toothpaste-like debris. The amylase level of cyst fluid is typically higher than 50,000 Somogyi U/mL.

### Diagnosis

The presence of a pancreatic pseudocyst is suggested by a history of blunt abdominal trauma; an illness resembling pancreatitis, possibly followed by a symptom-free interval of weeks to months; or palpation of a mass in the epigastrium or left upper quadrant. Abdominal pain is the most common symptom, with jaundice, chest pain, signs of gastric obstruction, vomiting, gastrointestinal hemorrhage, weight loss, fever, and ascites also being features.

US, CT, and magnetic resonance imaging (MRI) are helpful and accurate in diagnosis. These studies are also invaluable for evaluating the thickness of the cyst wall and for observing changes in the cyst during the ensuing period of treatment (Fig. 109-5). ERCP is often useful because it can definitively determine the status of the pancreatic duct and thus guide surgical interventions.[75,76] Rarely, pancreatic pseudocysts can extend into the mediastinum in children.[77]

### Treatment

Optimal management of a pancreatic pseudocyst remains controversial. Treatment options range from conservative medical management to surgical drainage.[78] Conventional

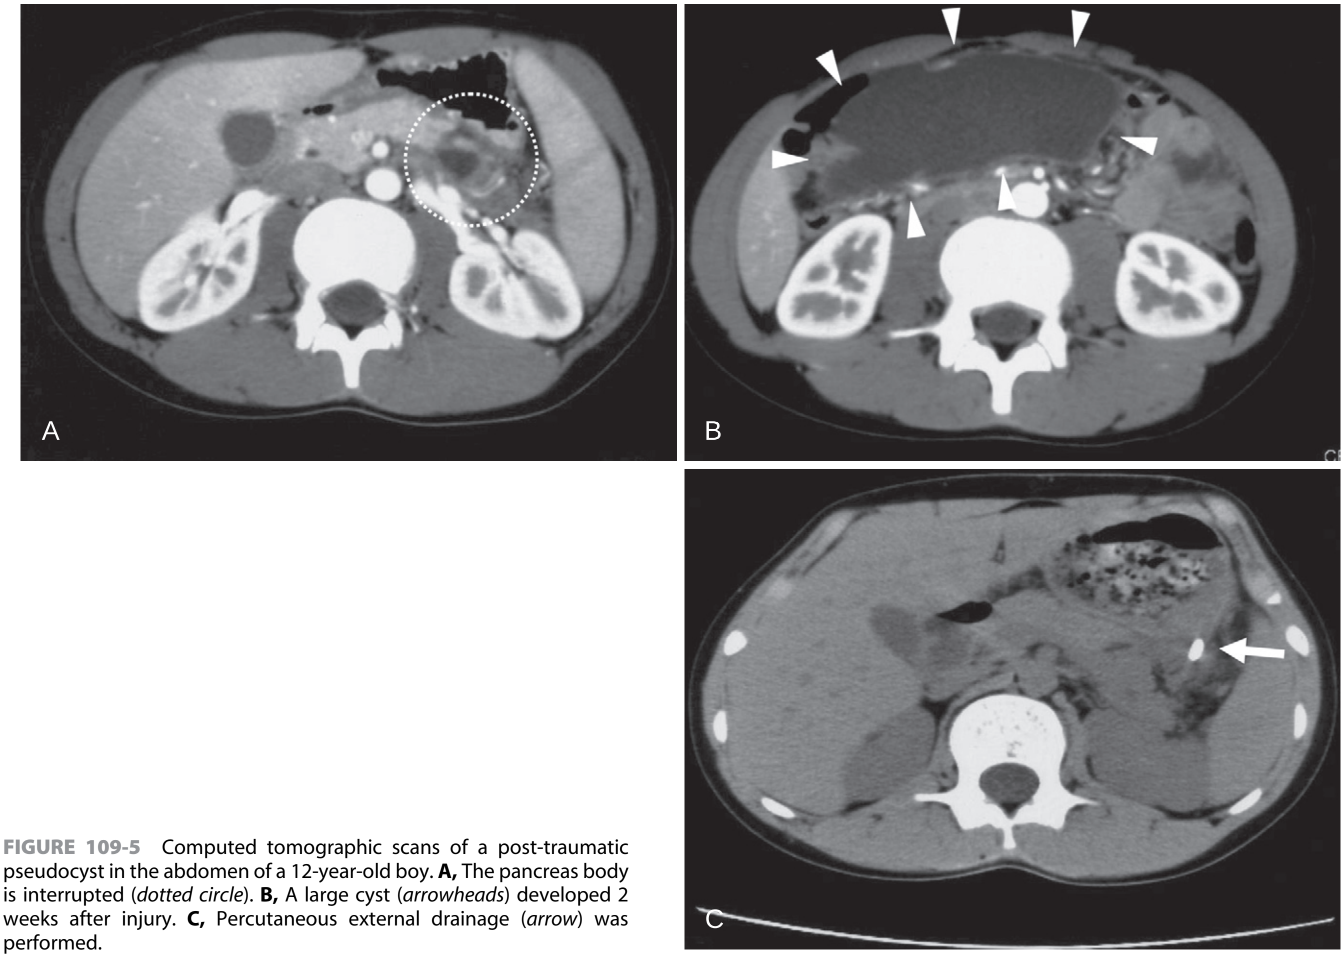

**FIGURE 109-5** Computed tomographic scans of a post-traumatic pseudocyst in the abdomen of a 12-year-old boy. **A,** The pancreas body is interrupted (*dotted circle*). **B,** A large cyst (*arrowheads*) developed 2 weeks after injury. **C,** Percutaneous external drainage (*arrow*) was performed.

management involves supportive therapy over a 6-week waiting period, during which time either the cyst resolves spontaneously or the cyst wall undergoes fibrous maturation, thereby permitting internal surgical drainage to the stomach or jejunum. This 6-week interval is what has traditionally been accepted, but CT may demonstrate thickening of the cyst wall sufficient to hold sutures as early as 3 to 4 weeks. Surgical drainage is usually performed in adults when necessary but is controversial in children because some pancreatic pseudocysts in this group resolve without surgical intervention and have a low risk for recurrence. Pseudocysts from nontraumatic etiologies are more likely to require surgical intervention, whereas traumatic pseudocysts are more amenable to nonoperative treatment.[79] Octreotide acetate, a long-acting analogue of somatostatin, may facilitate medical management of pancreatic pseudocysts.[80]

A significant risk for complications such as infection or major hemorrhage in untreated pseudocysts or persistence of severe symptoms may be an indication for earlier intervention. If the patient cannot withstand major surgery, external drainage is preferred. There is significant evidence indicating that internal drainage, especially transgastric cystogastrostomy or Roux-en-Y cystojejunostomy, is effective in the treatment of pancreatic pseudocyst. Roux-en-Y cystojejunostomy is the most widely used internal drainage procedure for this problem and is associated with the lowest rate of complications and recurrence.[81]

In contrast to this approach, others[82,83] have reported that percutaneous drainage and endoscopic transmural drainage are safe and efficient procedures. However, it is generally recognized that external drainage carries a higher risk for complications such as fistula formation and a higher recurrence rate than internal drainage does. Internal drainage procedures cannot be accomplished until the wall of the pseudocyst has matured. Recent studies have shown that internal drainage should be performed in patients with pseudocysts that are more than 6 weeks old and have a diameter larger than 5 cm because a large proportion of pseudocysts regress during the first 6 weeks after diagnosis and the risks associated with managing the pseudocyst are reduced. Cystogastrostomy has been performed laparoscopically.[84]

Though less commonly used than drainage procedures into the stomach or jejunum, cystoduodenostomy is effective when a cyst is closely adherent to the duodenum. Either pancreaticoduodenectomy or distal pancreatectomy, as indicated by anatomy, is effective in treating patients with pseudocysts under ideal circumstances. Distal pancreatic resection is indicated in patients with a pseudocyst in the body or tail of the pancreas, particularly if associated with multiple small cysts. Pseudocysts involving the head and uncinate process of the pancreas that are not amenable to internal drainage are rare and may require proximal pancreatic resection, but such resection should be done only as a last resort.

## Hyperinsulinism

Congenital hyperinsulinism (HI) is a rare derangement of glucose metabolism, which carries an estimated incidence of 1 to 1.4 in 50,000 live births, leading to about 80 to 120 new cases in the United States each year. Higher rates of 1 in 2500 live births have been reported in areas of high consanguinity such as the Arabian Peninsula. Pancreatectomy for management of persistent infantile hypoglycemia was first performed at the Children's Hospital of Philadelphia (CHOP) in 1950. Inappropriate oversecretion of insulin is the hallmark of HI. The old term "nesidioblastosis" should be discarded. HI is the most common cause of persistent hypoglycemia in neonates and can lead to seizures and irreversible brain damage.[85]

### DIAGNOSTIC APPROACH

#### Genetics

Molecular biologic studies have shown that abnormalities of the $K_{ATP}$ channel, which are encoded by the sulfonylurea receptor 1 *(SUR1)* and *Kir6.2* genes, are responsible for altered control of insulin secretion.[85] In response to elevated glucose levels, the $K_{ATP}$ channel closes, depolarizing the beta-cell membrane and initiating calcium-dependent release of insulin from the beta-cell storage granules. Uncontrolled insulin secretion may occur if either the *SUR1* or *Kir6.2* proteins are defective. The *SUR1*/*Kir6.2* form of HI may not be controlled with medical therapy such as diazoxide, which acts on *SUR1* to suppress insulin secretion, and pancreatectomy is often necessary.[86] In contrast, surgery is not usually necessary in other genetic forms of HI that result from mutations of glucokinase or glutamate dehydrogenase genes that are responsive to diazoxide treatment.

Neonates with HI may have either diffuse involvement of the pancreatic beta-cells or focal adenomatous islet cell hyperplasia. Mutations of the *SUR1*/*Kir6.2* complex are involved in both of these types. Recessive mutations cause diffuse HI, whereas loss of heterozygosity together with inheritance of a paternal mutation causes focal adenomatous HI. Patients with diffuse disease have recessively inherited mutations of the *SUR1*/*Kir6.2* complex, whereas patients with focal disease have normal beta cells, as well as a focal clone of abnormal beta cells that are homozygous for the *SUR1*/*Kir6.2* mutation. The focal lesions arise by a two-hit loss-of-heterozygosity mechanism.[87] First, there is a specific loss of maternal alleles of the imprinted chromosome region 11p15 in cells from the focal lesion but not in the surrounding normal pancreatic cells. Second, there is a transmission of a mutation of *SUR1*/*Kir6.2* in the paternal chromosome 11p; focal lesions have been linked to non-Mendelian expression of paternally transmitted *SUR1* mutation in which there is duplication and reduction to homozygosity of the mutant paternal allele. In the future, molecular biology testing of peripheral leukocytes may help differentiate focal from diffuse disease. However, the search for mutations is currently of limited use in clinical practice because the process takes many weeks and not all mutations are known.

One of the big challenges in diagnosis has been that the diffuse and focal forms of HI are clinically identical. Patients with either focal or diffuse disease are usually large for gestational age, reflecting the effects of HI on fetal growth. We have found that approximately 55% of our patients have focal disease, and about 45% have diffuse disease. Distinguishing focal from diffuse disease is of importance in guiding the extent of surgical resection. Patients with diffuse disease often require near-total pancreatectomy, which has the long-term risk of diabetes mellitus. Conversely, babies with focal disease can be cured with a selective partial pancreatectomy with little risk of subsequent diabetes.

At the Congenital Hyperinsulinism Center at CHOP, we use a multidisciplinary approach (pediatric endocrinology, radiology, pathology, and surgery) for patients with HI to distinguish focal from diffuse disease, localize focal lesions, treat focal disease with partial pancreatectomy, and treat medically refractory diffuse disease with near-total pancreatectomy. During the past 12 years, more than 250 patients (median age 10 weeks) with HI have been treated with pancreatectomy at CHOP. This section on hyperinsulinism will be based largely on the clinical experience at CHOP. We have also crafted an educational DVD regarding the management of congenital hyperinsulinism that is available at the CHOP website (www.chop.edu).

#### Diagnosis and Medical Management by Pediatric Endocrinology

Babies with HI present with severe and persistent hypoglycemia manifested by seizures, lethargy, apnea, and other symptoms resulting from neuroglucopenia.[85] The diagnosis of congenital HI is established if fasting hypoglycemia (glucose $< 50$ mg/dL) occurs simultaneously with an inappropriately elevated plasma insulin ($>2$ μU/mL), low plasma beta-hydroxybutyrate ($<2$ mmol/L) and free fatty acids ($<1.5$ mmol/L), and an inappropriate glycemic response to intravenous glucagon ($>30$ mg/dL rise in serum glucose level). Medical therapy to maintain euglycemia is standardized and involves high continuous intravenous infusions of glucose as measured by the Glucose Infusion Rate (which is the amount of glucose infused in mg/kg/min), frequent oral feedings, and administration of diazoxide, glucagon, and octreotide. Early efforts to distinguish focal from diffuse disease involved the injection of intravenous calcium and tolbutamide (a sulfonylurea) to elicit different types of insulin responses by focal and diffuse disease, but the results were not predictive enough to be clinically useful.

Preoperative assessment of babies with HI reveals that they are large, are often fluid overloaded due to high intravenous glucose requirements, have hepatic enlargement due to steatosis, may be anemic due to frequent blood sampling, and have oral aversion. They are predisposed to central venous line sepsis both preoperatively and postoperatively. Octreotide is the mainstay of medical therapy for HI but can rarely lead to necrotizing enterocolitis because octreotide reduces splanchnic blood flow in a dose-dependent manner.[88]

#### Localization Procedures Performed by Radiology

Diagnostic radiology tests such as US (both preoperative and intraoperative), MRI, CT, contrast angiography, and radiolabeled octreotide scans have all been unsuccessful in identifying focal lesions. For insulinoma localization in adults, intraoperative saline injection into the pancreas followed by tissue aspiration with rapid insulin measurements has been helpful, but this localization technique is untenable in the fragile neonatal pancreas.

Two interventional radiology tests have been used in an attempt to differentiate focal from diffuse disease. The Arterial Stimulation with Venous Sampling (ASVS) technique involves selective pancreatic angiographic stimulation and venous sampling using intra-arterial calcium, which stimulates abnormal islet cells to release insulin. An immediate rise in insulin from stimulation in only one artery suggests focal HI in the corresponding area of the pancreas (gastroduodenal artery—pancreatic head; superior mesenteric artery—uncinate process and neck; splenic artery—pancreatic body or tail), whereas an insulin rise in all three areas suggests diffuse HI. We and others have also used transhepatic portal venous catheterization and selective sampling of the pancreatic veins (THPVS). Both techniques require that the patient be off all glycemic medications (5 days for diazoxide, 1 to 2 days for octreotide) before catheterization under general anesthesia. THPVS requires that glucose levels be maintained at 50 mg/dL during the procedure as compared with 60 to 80 mg/dL for ASVS. For THPVS, the pancreatic venous insulin levels are compared with simultaneously drawn plasma levels of insulin and glucose. Both ASVS and THPVS are technically demanding and have limited specificity and sensitivity for distinguishing between focal and diffuse disease. These techniques are being replaced by a new PET-CT scan technique using 18-Fluoro-L-DOPA.

Neuroendocrine cells have an affinity for taking up and decarboxylating amino acid precursors such as L-dihydroxyphenylalanine (L-DOPA). Decarboxylation of the L-DOPA to dopamine in islet cells allows meaningful localization by means of PET scanning, using the radioactive isomer 18-Fluoro-L-DOPA. The isotope is manufactured by the Cyclotron Facility at the University of Pennsylvania on the day of the PET scan because of the isotope's short half-life, and it is administered to patients under an Investigational New Drug (IND) program approved by the U.S. Food and Drug Administration. Hopefully, 18-Fluoro-L-DOPA will become commercially available in the future so that it can be used in other medical centers. The PET results are dramatic and visually spectacular for preoperative localization of a focal lesion (Fig. 109-6).[89] In more than 140 PET scans for HI, we have found that PET-CT scans read as showing a focal lesion have been 100% accurate in localizing a lesion. However, in about 20% of PET scans that were interpreted as showing diffuse disease, the patient at operative exploration will prove to have a focal lesion that was usually small. This false-negative rate should decrease with greater clinical experience.

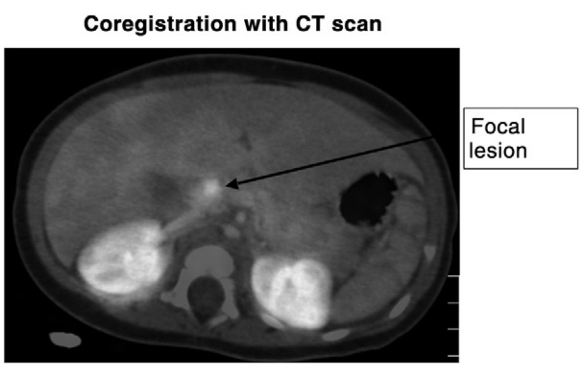

**FIGURE 109-6** Positron emission tomography scan is coregistered with a computed tomography scan that shows a focal lesion (*arrow*) in the head of the pancreas. The kidneys excrete the 18-FluoroDOPA and also light up.

## Histopathology

A focal lesion is characterized by a tumor-like proliferation of islet cells that push exocrine elements aside or haphazardly incorporate them (Fig. 109-7). Unlike insulinomas, the focal lesion retains the lobular architecture of the normal pancreas, and exocrine elements usually remain within the lesion. The lesions often have irregular borders, and the endocrine cells frequently have enlarged nuclei. Islets outside the lesion appear normal. Patients with diffuse disease have abnormal islets containing 5% to 10% of cells with enlarged nuclei present throughout the pancreas. After the surgery, all frozen samples are processed for routine histology and confirmation of findings on the basis of paraffin-embedded sections and insulin immunohistochemistry.

## Surgery

Open operations are approached in a similar manner using a transverse supraumbilical laparotomy.[90–92] The pancreas is exposed by an extended Kocher maneuver, entry into the lesser sac, and mobilization of the inferior border of the pancreas. It is not necessary to mobilize the spleen. The pancreas is inspected under 3.5× loupe magnification in an attempt to visualize a focal lesion, and the pancreas is palpated. If no focal lesion is seen, then 2- to 3-mm-diameter biopsies are taken each from the pancreatic head, body, and tail. Patients with suspected diffuse HI have intraoperative biopsies to confirm the diagnosis and then undergo near-total pancreatectomy. Near-total pancreatectomy (95% to 98%) involves resection of the entire pancreas leaving only a tiny residual piece of the pancreas between the common bile duct and the duodenum. The intrapancreatic course of the common bile duct should be completely dissected for an adequate near-total pancreatectomy to be performed.[90] For children with diffuse disease treated by near-total pancreatectomy, a gastrostomy tube is also placed to make it easier to administer supplemental glucose or night-time feedings if necessary.

When the biopsies demonstrate normal pancreatic histology, a further search for the focal lesion using the preoperative localization data is conducted. Additional biopsies of suspicious areas are obtained until the focal lesion is diagnosed by frozen section. Expert pediatric pathologic interpretation is vitally important. Focal lesions tend to be less than 10 mm in size (although they can be much larger) and are frequently irregularly shaped. Some lesions have octopus-like tentacles that make imperative the intraoperative confirmation of clear margins by frozen section analysis. Although focal lesions may maintain a lobular structure similar to that of the normal pancreas, subtle visual clues (ranging from a slightly reddish color to a marble-like appearance) may permit visual detection of the lesion intraoperatively and accurate preoperative localization studies greatly facilitate the visual search for a focal lesion. In some cases the lesion will feel firmer than the surrounding normal pancreas. However, a tiny focal lesion can be buried within the pancreas and be impossible to see or feel. Greater operative experience has led to more frequent intraoperative visualization or palpation of a focal lesion. Insulinomas differ from focal lesions because they are usually straightforward to identify intraoperatively and occur in older children.

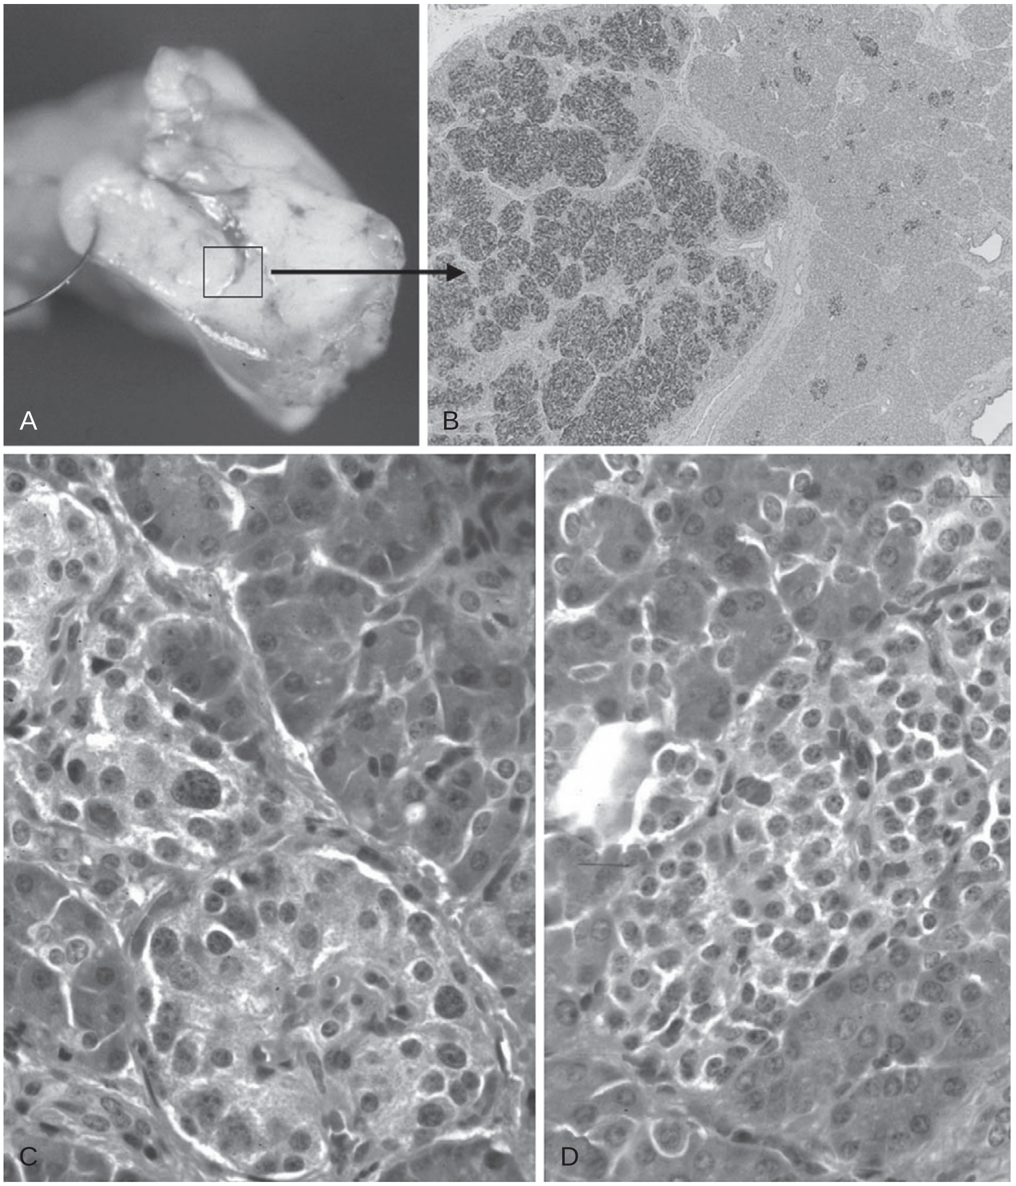

**FIGURE 109-7** **A,** Cut surface of pancreatectomy specimen through a focal lesion (marked by suture). **B,** Chromogranin A immunolabeling highlights the architecture of the focal lesion *(left)* and adjacent normal pancreas *(right)*. Comparison of cytologic features of the endocrine tissue in the focal lesion **(C)** and normal pancreas **(D).** Note enlarged islet cell nuclei in **C.**

Once the focal lesion is identified, a partial pancreatectomy is performed using frozen sections of margins to ensure a complete resection. For periductal lesions in the body and tail, a distal pancreatectomy is performed. With pancreatic head lesions close to the common bile duct or pancreatic duct, it can be tricky to excise all of the lesion, particularly if there are tentacles of diseased tissue that emanate from the lesion. To ensure complete lesion resection in these challenging cases, the surgeon should remove most or all of the pancreatic head followed by Roux-en-Y pancreaticojejunostomy to drain the remaining pancreatic body and tail. In this way, the endocrine and exocrine function of the remaining normal pancreas is saved. In babies the pancreatic duct on the cut surface of the transected pancreatic body is not visible, so the end of the Roux-en-Y jejunal limb is meticulously anastomosed to the capsule of the pancreatic body with fine interrupted monofilament suture to effectively dunk the cut end of the pancreas into the small bowel lumen. Rarely, a focal lesion in the head will extend into the duodenal wall in which case a Whipple procedure may be necessary. Because PET scan localization of focal lesions has proven to be so accurate, focal lesions in the body and tail are now resected using laparoscopic techniques. The drawback to the laparoscopic approach is that there is little tactile feedback to help locate a nonvisible focal lesion.

Because more than 50% of focal lesions involve the pancreatic head, subtotal (50% to 75%) distal pancreatectomy is inadequate therapy in many of these cases. Our experience with several referrals who underwent subtotal pancreatectomy elsewhere with the focal lesion remaining within the residual pancreas are good examples of this potential pitfall.

### Postoperative Care and Follow-up

Postoperative management has been standardized by a clinical care pathway including the use of the Glucose Infusion Rate to quantitate the patient's glucose requirement.[85] Glucose Infusion Rate (GIR) is calculated as % dextrose × IV rate × 0.169/Wt in kilograms. For the initial postoperative period, blood glucose values are determined hourly. The GIR begins at 2 mg/kg/min immediately postoperatively, is increased to a GIR of 5 on the morning of postoperative day 1, and then usually advances to a GIR of 8 by the evening of the first postoperative day. It is not unusual for an intravenous insulin infusion to be necessary for the first few postoperative days. After hospital discharge, a complete response at follow-up is defined as no requirement for glycemic medications, no continuous tube feedings, no diabetes mellitus, and the ability to tolerate an 18-hour fast without hypoglycemia.

In our entire experience, 95% of babies with the focal form of HI are cured after limited pancreatectomy. The vast majority had a less than 50% pancreatectomy. For babies with diffuse HI treated with near-total pancreatectomy (95% to 98%), about one third require no glycemic medications, one third require insulin to treat diabetes, and one third require a glycemic medication (usually octreotide). Long-term follow-up is necessary for all of these children, particularly with regard to neurodevelopmental issues.

# Neoplasms

Pancreatic neoplasms are relatively rare in infants and children. They can be cystic, solid, and benign or malignant and may or may not be hormonally active. In 1990 Grosfeld[93] reported 13 cases of pancreatic tumor in children including 5 insulinomas, 2 mucinous cystadenomas, 2 rhabdomyosarcomas, and 4 carcinomas. In 1992 Jaksic reported 6 cases of pediatric pancreatic tumors,[94] and now more than 200 cases have been reported in the English literature. More recently, pancreatic tumor series have been reported by Shorter (17 cases),[95] Perez (58 cases),[96] and Yu (18 cases).[97] Unlike malignant pancreatic tumors in adults, tumors in children and adolescents are usually resectable and long-term survival is likely.

## CYSTIC NEOPLASMS

Cystic neoplasms of the pancreas are relatively rare.[98,99] Howard[100] classified these lesions into (1) cystadenoma and cystadenocarcinoma, which include benign (microcystic) cystadenoma, benign and malignant mucinous (macrocystic) cystadenoma and cystadenocarcinoma, papillary-cystic epithelial neoplasm, and acinar cell cystadenocarcinoma (not reported in children) and (2) teratomatous cysts.

### Cystadenoma and Cystadenocarcinoma

Cystadenoma of the pancreas is rare in children and adults. Only six cases including one in a newborn have been reported in the pediatric population to date.[93,101,102] Cystadenoma and cystadenocarcinoma should be divided into two groups. Because large mucinous cystic adenomas have considerable malignant potential, these tumors should be distinguished from serous cystadenomas, which are benign; the latter tumors are rich in glycogen and contain little or no mucin.[103]

***Serous Cystadenoma and Cystadenocarcinoma*** Serous cystic neoplasms of the pancreas are rare in children and adults, are more often observed in females, and are found mainly in the body and tail of the pancreas. These tumors consist predominantly of small cysts (microcystic adenomas).[104] Calcification is often demonstrated on CT and US. Serous cysts do not need to be excised unless they create a mechanical obstruction because nearly all of them are benign with no malignant potential.[105] Biopsy is required. Serous cystadenocarcinoma is virtually nonexistent in children, and only a few cases have been reported in adults.

***Mucinous Cystadenoma and Cystadenocarcinoma*** Mucinous cystic neoplasms of the pancreas are usually large and often multilocular. They form papilla lined with columnar, mucin-producing epithelium; are more often observed in females; and are found mainly in the body and tail of the pancreas.[106] Other features are the association of large blood vessels within the capsule and the presence of subepithelial hemorrhage. A common differential diagnosis is pancreatitis with pseudocyst formation. Mucinous cystadenocarcinoma of the pancreas represents 1% of all malignant conditions of the pancreas, occurs at an earlier age than conventional solid pancreatic tumors do, and seems to be approximately half as common as cystadenoma. The clinical and radiologic manifestations of mucinous cystadenocarcinoma are similar to those of mucinous cystadenoma. It is not always possible to differentiate mucinous cystadenoma from cystadenocarcinoma pathologically. It is also common to find apparently benign epithelium[103] in the same tumors as malignant epithelium, thus suggesting that a malignant focus may develop within a mucinous cystadenoma. Therefore mucinous cystadenoma should be considered a premalignant lesion that should be completely excised after incomplete excision or marsupialization.[98,103] However, the prognosis for this form of pancreatic malignancy is significantly better than that for the common typical solid ductal adenocarcinoma because of its slow growth and lack of metastatic potential.

### Papillary-Cystic Epithelial Neoplasm

The first cases of papillary-cystic endothelial tumors of the pancreas were reported by Franz in 1959.[107] Since these tumors were described as solid and cystic acinar cell tumors of the pancreas by Kloppel and colleagues,[108] increasing numbers have been reported in children. They occur predominantly in girls and young women and are manifested as large, encapsulated masses, usually with extensive necrosis and varying amounts of cystic change. Histologically, they are composed of solid areas of rather small cells with pseudorosette formation reminiscent of endocrine tumors and cystic areas with papillary structures.[109] Immunohistochemically, the tumor cells of solid and cystic pancreatic neoplasms contain periodic acid-Schiff-positive granules and often have progesterone receptors. Immunologic hallmarks are immunoreactivity with alpha-antitrypsin, alpha-antichymotrypsin, phospholipase $A_2$, and neuroendocrine markers such as neuron-specific enolase and synaptophysin. However, they are generally free of the usual markers of pancreatic carcinoma

such as carcinoembryonic antigen, CA19-9, and tissue peptide antigen.[110] These tumors seem to be associated with a much better prognosis than the usual type of pancreatic carcinoma but still have malignant potential.[111] The tumor follows a benign course after resection in most cases. Metastasis or recurrence has occurred in 5% of cases in Japan.[112] Thus complete extirpation is necessary because of the slow tumor progression associated with metastatic disease.[113] Liver metastases have been treated with resection and liver transplantation.[114]

### Other Cystic Neoplasms in Children

In 1992 Flaherty and Benjamin[115] reported a case of multicystic pancreatic hamartoma in a 20-month-old girl. In 1990 Mester and colleagues[116] reviewed 10 cases of cystic teratoma of the pancreas including one of their own. Cystic teratomas were usually seen as benign extragonadal germ cell tumors in younger patients; 5 of 10 patients were younger than 11 years.

## HORMONALLY ACTIVE TUMORS

Endocrinologically active tumors are usually identified by their symptoms, and most of them originate in the islet cells. Beta-cell tumors secrete insulin; alpha cell tumors, glucagon; gamma cell tumors, gastrin; delta cell tumors, somatostatin; and delta$_1$ cell tumors, vasoactive intestinal polypeptide (VIP) and possibly substance P and secretin. Glucagonomas and somatostatinomas have not been identified in children.

### Insulinoma

Insulinomas are the most common tumor arising from islet cells and are usually benign (>90%), solitary (80%) lesions that occur in children older than 4 years. A plasma insulin-to-glucose ratio greater than 1 is diagnostic (<0.4 is normal),[117] and the ratio increases with fasting. Concomitant measurement of C peptide levels may be used to exclude factitious hypoglycemia. CT, US, arteriography, and transhepatic portal venous sampling can be used to localize an insulinoma. The tumor is usually discrete and well encapsulated, and most can be enucleated. The introduction of endoscopic and intraoperative US has allowed obscure lesions to be identified. If all methods of tumor localization are unsuccessful, distal pancreatectomy with careful sectioning of the gland is advisable. In that circumstance, measurement of intraoperative insulin levels is recommended to avoid missing lesions. Virtually all infants and children with insulinoma can be cured.

Multiple endocrine neoplasia type I (MEN-I) is characterized by endocrine tissues in the gut and pancreas including insulin-secreting tumors, but expression is usually delayed beyond the first decade of life. MEN-I is rare, with a frequency not exceeding approximately 1 in 10,000. The gene for MEN-I has been localized to the long arm of chromosome 11 and functions as a tumor suppressor gene, unrelated to the functional alterations in the SUR1/Kir6.2 components of $K_{ATP}$ on the short arm of chromosome 11.[118]

### Gastrinoma

The second most commonly reported pancreatic hormonal tumor is the gamma cell tumor. The clinical syndrome related to gastrinoma is often referred to as *Zollinger-Ellison syndrome,* a condition characterized by hypergastrinemia with severe peptic ulcer disease. This syndrome is rare in children. Gastrinoma is part of the MEN-I syndrome and is commonly malignant, multicentric, and metastatic at discovery.[93] The diagnosis is usually made after recurrent episodes of peptic ulceration associated with an elevated gastrin level (>500 pg/mL). Calcium infusion and secretin simulation tests are used for diagnosis. CT, percutaneous transhepatic venous sampling, and gastrin assay have been useful for localization. Although total gastrectomy was originally the most common method of treatment, the development of inhibitors of gastric acid secretion such as $H_2$ blockers and omeprazole has changed the direction of treatment of gastrinoma substantially. Children with gastrinoma generally require lifelong medical treatment, and somatostatin, although beneficial because it decreases gastric acid secretion, also inhibits growth hormone secretion, so it cannot be used long-term. Surgical treatment should thus be aggressive, especially if a solitary tumor is found with no evidence of metastasis at the time of laparotomy. However, total gastrectomy may still be required for patients in whom medical treatment has failed or those with residual tumor or metastatic disease.[93]

### VIPoma

VIPoma in children is far more commonly related to other neurogenic neoplasms such as neuroblastoma or ganglioneuroma than to tumors of primary pancreatic origin. Only a few cases of VIPoma in children have been reported. The VIP that is produced by a pancreatic VIPoma probably originates from neural cells in the islets.[117] Patients have profuse, watery diarrhea associated with hypokalemia and hypochlorhydria (WDHA syndrome), and metabolic acidosis and prerenal azotemia secondary to dehydration are often present. Although medical therapy includes the use of streptozotocin and somatostatin, long-term use of somatostatin is undesirable. Surgical extirpation of the tumor-bearing gland is recommended whenever possible because 50% of pancreatic VIPomas are malignant.[93]

## CARCINOMA

Carcinoma of the pancreas is common in adults but rare in children. The clinical features are different in that obstructive jaundice is the primary finding in adults, whereas an abdominal mass is usually the initial feature in children. Pancreatic carcinoma in children can be divided into four groups: islet cell carcinoma, adenocarcinoma, pancreatoblastoma, and miscellaneous lesions.

### Islet Cell Carcinoma

Islet cell carcinoma in children may or may not be functional. Functioning beta-cell and non–beta-cell islet cell carcinoma occurs in infants and children with hypoglycemia in conjunction with Zollinger-Ellison syndrome, but it is not associated with a palpable mass. A beta-cell carcinoma is usually discovered during laparotomy for insulinoma. Four functional islet cell carcinomas have been described in children; all were treated by surgical extirpation, with good long-term survival.[119–121] Seven of the eight children with Zollinger-Ellison syndrome described by Wilson had non–beta-cell carcinoma with metastatic disease.[122]

Nonfunctioning islet cell carcinomas are more common in children than adults. Because these tumors are usually discovered by palpation of an abdominal mass, they are often

diagnosed late, and many affected infants and children have distant metastatic disease at the time of diagnosis. Most nonfunctional tumors are large, solitary lesions that can appear in any location within the gland. In general, although most of these tumors grow slowly, aggressive surgical therapy is warranted because of their malignant potential.[123]

## Adenocarcinoma

Adenocarcinoma of the pancreas is rare in children. Vejcho[124] reviewed 37 cases of adenocarcinoma in 1993. The clinical manifestations differ from those of adults in that the incidence of pain with jaundice is lower.[121] Abdominal pain and a palpable epigastric mass are the primary findings in children. Classification is still controversial and is based on tumor activity and histopathologic and immunohistochemical findings. Kloppel classified adenocarcinoma into three types: acinar cell carcinoma, solid and cystic tumor (papillary cystic tumor), and pancreatoblastoma.[108] Acinar cell tumors are proportionately more common in children.[111] It seems that children with an acinar cell tumor have a somewhat better prognosis than do those with an adenocarcinoma of the duct cell type. The prognosis for children with adenocarcinoma of the duct cell type is discouraging and similar to that for adults. CT and sonography are useful for diagnosis. For localized lesions, pancreaticoduodenectomy seems to be associated with a favorable prognosis. Infants and children tolerate radical resection of the pancreas somewhat better than adults do and have a lower mortality rate and better long-term survival.

## Pancreatoblastoma

In 1977 Horie[125] reported two cases of pancreatic carcinoma, which they termed pancreatoblastoma, an infantile type of pancreatic carcinoma. In 1984 Buchino[126] reviewed eight patients with pancreatoblastoma, six of whom survived after surgical extirpation. Pancreatoblastoma is the most common pancreatic neoplasm in young children. Pancreatoblastomas have a better prognosis than adenocarcinoma because they have an encapsulated organoid structure that does not directly interfere with the main duct system. The criteria for diagnosing pancreatoblastoma have been described.[126–128] Although there is no agreement on the pathology of these rare lesions, terminology based on recognizable lines of differentiation seems preferable (e.g., islet cell, duct cell, acinar cell, undifferentiated lesions).[111] The recurrence risk after resection is high. These tumors can be responsive to chemotherapy and radiation, but the appropriate role for these modalities is unknown.

## Miscellaneous Carcinomas

The following miscellaneous carcinomas in children have been reported in the literature: one case of carcinoma simplex; one case of medullary carcinoma[129]; six cases of sarcoma (two lymphosarcomas,[129] two with sarcomatous degeneration from cystadenoma,[93,130] and two rhabdomyosarcomas[93]); four cases of undifferentiated carcinoma[121,126]; and two cases of cylindrical cell adenocarcinoma.[131]

CHAPTER 110

# The Spleen

Katherine A. Barsness and Marleta Reynolds

Splenic physiology can be broadly categorized into red blood cell maintenance and reservoir and immunologic functions. Children frequently require splenectomy for disease processes involving abnormalities in red cell deformability or the presence of antiplatelet antibodies resulting in excessive splenic red cell destruction or platelet sequestration. The vital role of the spleen as an immunologic organ has not only led to nonoperative management of splenic trauma but also affected the timing of elective splenectomy and renewed interest in partial splenectomy for certain disorders. The technique of splenectomy has changed significantly with the advent of advanced laparoscopy. The technique of laparoscopic splenectomy and the available evidence comparing it with open splenectomy are discussed in the latter part of this chapter.

## History

The role of the spleen has been the subject of debate for more than 300 years. Billroth is credited with developing the open circulation theory of the splenic microcirculation, and the endothelial cords of the red pulp bear his name. The recognition of the spleen as a functional organ in health and disease has been well documented in the twentieth century. One of the more important observations was that of King and Shumaker in 1952, who noted the susceptibility of infants to infection after splenectomy.[1] The protective role of the spleen in bacterial infections prompted pediatric surgeons to study the role of nonoperative management of splenic injuries,[2] a development that evolved into the preferred method for treating both childhood and adult splenic injuries. Another significant development in the surgical management of splenic disorders was the initial report of laparoscopic splenectomy in 1991 by Delaitre and Maignien.[3] This technique has quickly become the preferred technique for splenectomy in children.

## Embryology and Anatomy

The splenic primordium is first recognized at the 8- to 10-mm stage as a mesenchymal bulge in the left dorsal mesogastrium between the stomach and pancreas. By the 10- to 12-mm stage a true epithelium is noted, and sinusoids are present with communication to capillaries. By 4 months of fetal life, the spleen produces red and white cells; however, this function ceases later in gestation, and the spleen is rarely the site of clinically significant hematopoiesis in childhood. The anatomic arrangement of the spleen is consistent with the various functions of the spleen. Blood enters the spleen through splenic artery segmental vessels that branch into trabecular arteries; and, after further bifurcations, small arteries enter the white pulp. The white pulp consists of lymphocytes and macrophages arranged as a germinal center around the central artery. Branches off of the central artery deliver suspended particulate material into the white pulp, an arrangement that may facilitate antibody formation in response to particulate antigens.[4–7] Approximately 20% of the volume of the spleen is white pulp, and the remainder is the red pulp, consisting of the endothelial cords of Billroth.[8] Blood passing through the spleen traverses in either an “open” or “closed” fashion. Ten to 20 percent of blood passes through the closed system directly from capillaries into venous sinusoids. The remainder passes directly into the red pulp. These cells and other particulate material must pass through in an open fashion within the cords of Billroth and then migrate into the sinusoids, which enter into trabecular veins.

## Function

The function of the spleen is closely related to the anatomic arrangements and can be divided into red cell maintenance, immune function, and reservoir. Derangements in the substrate entering the spleen often lead to excessive function of one of the splenic roles, thus leading to the need for splenectomy. The spleen destroys red cells at the end of their life span and repairs other damaged red cells. Because the spleen selectively removes abnormal cells such as spherocytes, removal of the spleen increases the life span of these cells. As blood passes through the spleen, Howell-Jolly bodies (nuclear remnants), Heinz bodies (denatured hemoglobin), and Pappenheimer bodies (iron granules) are removed, and after splenectomy they are noted in red cells on a peripheral smear.

The immune function of the spleen is characterized by specific and nonspecific responses. The specific immune function of the spleen is primarily related to antigen processing. Antigens come into contact with macrophages and helper T cells in the area of the arterioles of the white pulp. T-cell populations

respond with synthesis of cytokines as part of the cellular response, and activated T cells then circulate to modulate the response. A humoral response can occur as antigens come in contact with macrophages and helper T cells and are then transmitted to antibody synthesizing cells.[9]

The nonspecific function involves removal of the particulate matter from the blood primarily by macrophages. The spleen is also the principal source of nonspecific opsonins, which further activate the complement system, facilitating the destruction of organisms.

The spleen provides another aspect of the immune function, by simply serving as a biologic filter. If little antibody is available for opsonization of bacteria, the spleen assumes a greater role in clearance of bacteria. This may be the basis for the age-related differences in postsplenectomy infections because young children lack adequate antibody response.[5] The spleen also serves as a reservoir, which in humans is primarily limited to platelets. The proportion of platelets in the spleen is increased in cases of splenomegaly, occasionally leading to thrombocytopenia. The spleen also serves as a reservoir for factor VIII.

FIGURE 110-1 Computed tomography scan of a wandering spleen in a 7-year-old boy with intermittent abdominal pain and an abdominal mass. A laparoscopic splenopexy was used to secure a left upper quadrant fixation.

# Anatomic Abnormalities

## ACCESSORY SPLEENS

Accessory spleens represent the most common anatomic abnormality and are present in 15% to 30% of children. They most likely originate from mesenchymal remnants that do not fuse with the main splenic mass. The majority (75%) are located near the splenic hilum or adjacent to the tail of the pancreas; a few are found along the splenic artery, in the omentum, mesentery, and retroperitoneum and have even been noted in the scrotum.[10] Of those with accessory spleens, 86% have one, 11% have two, and 3% have three or more,[11,12] with the hilum the most common site of multiple accessory spleens. Surgeons must be cognizant of these locations and routinely check for their presence because a missed accessory spleen can be a cause of recurrence of immune thrombocytopenic purpura (ITP) or hereditary spherocytosis. Recurrence with ITP is frequently early,[13,14] whereas recurrence with hereditary spherocytosis has been reported as long as 31 years later.[15]

## WANDERING SPLEEN

Wandering spleen is characterized by lack of ligamentous attachments to the diaphragm, colon, and retroperitoneum. The embryologic basis of this is probably related to failure of development of the splenic ligaments from the dorsal mesentery.[16] Children with this condition most often present with diffuse abdominal pain secondary to torsion and infarction, although they may also present with episodic pain and an abdominal mass (Fig. 110-1).[17–22] Although splenectomy is required for infarction, splenopexy is preferred in nonischemic and incidentally detected cases. Splenopexy has been performed with various techniques including placement in an extraperitoneal pocket,[21] use of Dexon mesh basket,[22,23] suture splenopexy,[22,24] and colonic displacement with gastropexy.[22,25] Laparoscopic detorsion and splenopexy can be performed with the use of an absorbable mesh bag that is closed around the splenic hilum and then tacked to the diaphragm and posterolateral abdominal wall.

## SPLENIC CYSTS

Primary splenic cysts have an epithelial lining, frequently with a trabeculated internal appearance. They most likely originate from inclusion of the surface mesothelium into the splenic parenchyma. They may be asymptomatic or may present as pain,[26] rupture,[27] abscess,[28] or symptoms due to gastric compression. Symptomatic cysts are usually greater than 8 cm.[26] Small (<5 cm) simple cysts can be observed; however, larger, enlarging, or symptomatic cysts require definitive treatment. Percutaneous aspiration and sclerosis have been used, but recurrence is common and partial splenectomy has been required.[29] Alcohol sclerosis of a congenital cyst has been reported with success, although the length of follow-up was not specified.[30] Marsupialization can be associated with recurrence if an adequate segment of cyst is not removed.[31,32] Laparoscopic partial cyst excision and cyst resection with partial splenectomy[33–40] have been reported but are accompanied with a 64% to 88% recurrence rate. Partial splenectomy with excision of the cyst at the margin with the spleen can be performed with an electrosurgical device[41–43] or with the use of stapling devices in an open[40,44] or laparoscopic approach.[40,45,46] Use of cautery,[46] sutures, and omental packing of the defect may also be useful.[43] Splenic pseudocysts lack an epithelial lining and most frequently occur after trauma. Enlarging cysts and symptomatic cysts should be excised.[47]

## ASPLENIA AND POLYSPLENIA

Asplenia and polysplenia syndromes have many similar features. Congenital asplenia is usually noted with complex congenital heart disease, as well as bilateral "right-sidedness" including bilateral three-lobed lungs, right-sided stomach, and a central liver.[5] Intestinal malrotation has also been observed.[48] Howell-Jolly bodies are noted on peripheral smear, and infants have the risk of overwhelming infection.

Polysplenia in which the spleen is divided into multiple splenic masses is often associated with biliary atresia. Other associated features included preduodenal portal vein, situs inversus, malrotation, and cardiac defects.[49] These children have adequate splenic immune function.

### SPLENIC GONADAL FUSION

Splenogonadal fusion occurs as a result of early fusion between the spleen and left gonad.[50] The remnant may be continuous with a fibrous band or discontinuous with splenic tissue attached to the gonad. Another abnormality identified has been ectopic splenic tissue in the scrotum apart from a gonadal fusion.

## Indications for Splenectomy

### HEREDITARY SPHEROCYTOSIS

Hereditary spherocytosis is the most common inherited red cell disorder among northern European descendants. Approximately 75% of affected children have an autosomal dominant inheritance pattern; the remainder are new mutations or autosomal recessive. The attendant membrane defects in ankyrin or spectrin proteins result in poorly deformable spherocytes. The degree of splenic hemolysis can range from mild to severe. Most children are noted to have anemia, an elevated reticulocyte count, and a mild elevation of bilirubin. The presence of spherocytes along with a positive osmotic fragility test confirms the diagnosis. In affected children, an aplastic crisis can occur secondary to parvovirus B19 infection, with suppression of red cell production and a resultant low hematocrit due to ongoing destruction.[51] Splenectomy is usually required for moderate to severe anemia. Gallstones are common, increasing in frequency with the age of the child and degree of hemolysis,[52] and thus a gallbladder ultrasound is required before splenectomy. Hereditary elliptocytosis is a similar disorder associated with spectrin defects, but most patients are asymptomatic and without significant hemolysis.

### IMMUNE THROMBOCYTOPENIC PURPURA

ITP occurs when antiplatelet autoantibodies, usually IgG, bind with platelets, leading to destruction in the reticuloendothelial system. The thrombocytopenia can be transient or can persist in a chronic phase. The decision to treat a patient with ITP is based primarily on bleeding complications, not on an absolute platelet count. Childhood ITP is usually a self-limited, acute disorder, and splenectomy is only required in chronic cases. First-line therapies include short-course corticosteroids, which may function by inhibiting the reticuloendothelial binding of platelet-antibody complexes; intravenous immunoglobulin (IVIG), which competitively inhibits the Fc receptor binding of platelets by macrophages; and Rho (D) immunoglobulin in Rh-positive children, which binds to red cells that then saturate the splenic capacity and spares the antibody-coated platelets. Second-line therapies include rituximab, which binds the CD20 antigen on B lymphocytes and is presumed to decrease autoantibody production, and splenectomy. With poor long-term response and concerning drug toxicities associated with rituximab,[53,54] children with chronic ITP (with bleeding complications) resistant to first-line therapies are often referred for splenectomy.[55] Unfortunately, predicting a response to splenectomy has been difficult. In one study, response to corticosteroids, IVIG, or both predicted a 97% response to splenectomy, whereas failure to respond to either predicted a 70% failure rate to splenectomy.[56] Another study noted the response to IVIG to be a better predictor of response to splenectomy than corticosteroids.[57] The most recent study directly challenged these findings with a 100% response rate among children who were nonresponsive to corticosteroids, with postsplenectomy platelet counts inversely related to peak platelet response to steroids.[58] Despite the widely disparate literature, there is a sustained response rate as high as 80% for children with chronic ITP treated with splenectomy.[59]

### SICKLE CELL DISEASE

Sickle cell disease occurs as the result of a substitution of valine for glutamic acid in the β chain of normal hemoglobin A, resulting in hemoglobin S. These red cells become rigid when oxygen saturation decreases, with subsequent capillary occlusion and shortened red cell life. Children with homozygous sickle cell anemia and with hemoglobin sickle cell disease have significant rates of painful crisis and acute chest syndrome. Splenic sequestration with rapid drop in hemoglobin and platelet counts can occur and, if severe or recurrent, merit splenectomy to reduce the chance of further episodes. Postoperatively, children with sickle cell disease are at risk for acute chest syndrome (ACS). ACS is characterized by basilar pulmonary infiltrates and is thought to be secondary to polymerized deoxygenated sickle hemoglobin, causing local tissue infarction in the lung. Treatment is supportive.

### THALASSEMIA

The thalassemias are a group of disorders characterized by abnormal production of α or β chains of hemoglobin. Thalassemia major (Cooley anemia; β-thalassemia) results in the most severe clinical anemia among this group of disorders. Some children develop significant splenomegaly with sequestration. Splenectomy has been used to decrease the need for transfusions in children with severe anemia and those with significant splenomegaly and platelet or white cell sequestration.

### GAUCHER DISEASE

Gaucher disease is a metabolic disorder characterized by deficiency of the enzyme β-glucocerebrosidase, which results in excessive glucocerebroside in macrophages of the spleen, liver, bone marrow, and lungs. It is an autosomal recessive disorder found most commonly in Ashkenazi Jews. Splenomegaly can be severe, and both partial and total splenectomy have been used to alleviate the hypersplenism and increase the red cell, leukocyte, and platelet counts.[60] However, recurrence has been reported after partial splenectomy.

### ABSCESS

Splenic abscesses are rare but have been noted with increasing frequency with the increase in the number of immunocompromised children. Organisms are frequently fungal or

mycobacterial.[61] Children present with fever, pain, and positive blood cultures. An isolated splenic abscess may be treated with percutaneous drainage and intravenous antibiotics.[62] However, diffuse or multifocal abscesses may be better served by splenectomy.

# Splenectomy

## PREOPERATIVE IMMUNIZATION

The risk of postsplenectomy sepsis remains a concern for any asplenic individual. Preoperative immunization has become the standard of care for all patients being considered for elective splenectomy. In case of emergent splenectomy, postoperative immunization is still strongly encouraged. Current recommendations include polysaccharide pneumococcal, conjugate *Haemophilus influenzae* type b, and polysaccharide meningococcal vaccinations.[63] All vaccinations should be completed at least 2 weeks before planned splenectomy. In addition, yearly influenza vaccination is strongly recommended to reduce the incidence of secondary bacterial pneumonia.

## OPEN SPLENECTOMY

A left upper quadrant subcostal incision provides excellent exposure for most spleens even in cases of splenomegaly. The spleen is retracted medially, and the splenorenal, splenophrenic, and splenocolic ligaments are divided. This can usually be accomplished with a relatively small incision, and the spleen is removed from the abdominal cavity by delivering the lower pole first, taking advantage of the concave medial surface of the spleen. The gastrosplenic ligament and short gastric vessels are divided, followed by the hilar vessels. If the pancreas is close to the hilum, it may be necessary to divide the segmental vessels. A careful search is made for accessory spleens, and, if present, they are removed. An alternative open approach uses a lateral muscle-splitting incision,[64] which has been associated with a 2.7-day length of stay, comparable with some laparoscopic series.[65–67]

## LAPAROSCOPIC SPLENECTOMY

### Technique

The laparoscopic technique for splenectomy was initially reported in 1991 [3] and over the subsequent 5 years has become the preferred method at most institutions. Less pain, as reflected in lower pain medication use; shorter length of stay; and improved cosmesis are the main benefits compared with open splenectomy. The laparoscopic procedure has a steep learning curve for those unfamiliar with advanced laparoscopic techniques, can be difficult in cases of splenomegaly, and is associated with longer operative times than the open procedure. The efficacy of accessory spleen detection has been questioned in adult studies,[13,14] although comparison of open and laparoscopic pediatric series has found similar detection rates.[65–70]

The technique of laparoscopic splenectomy has evolved with the development of smaller instruments and advanced technology such as the Harmonic scalpel and the Ligasure. Although preoperative splenic artery embolization was reported in many initial adult series,[71] complications such as pain, abscess, and retroperitoneal necrosis[72,73] have occurred. Some authors have noted no difference in the risk of bleeding or transfusion requirement. Embolization for spleens between 20 and 30 cm in length and open splenectomy if the organ is larger than 30 cm have been recommended, but most childhood spleens in cases of splenomegaly are smaller, so this appears less relevant in children.[73] Hand-assisted procedures have also been described in adults[74] for large spleens, but the accessory incision prolongs the stay[75] and also appears to have no role in children.

Although some initial reports used an anterior approach, most surgeons currently use a lateral approach, as depicted in Figure 110-2. The patient is placed approximately 45 degrees left side up with slight elevation of the right flank to increase access on the left side. The table is rotated to the patient's left side for trocar placement and then to the right to achieve a right lateral decubitus position for the procedure. The general principle is for the assistant to use two grasping instruments through the upper abdominal midline sites (see *A* and *B* in Figure 110-2) to elevate the spleen and provide traction on surrounding tissues. In young children and older patients with small spleens, 3-mm instruments are used at those sites and placed directly into the abdominal cavity through small stab incisions without the use of trocars. If the spleen is large, at least one of the upper midline trocars must accommodate 5-mm instruments. For most of the procedure the surgeon uses the Harmonic scalpel or Ligasure through the left lower quadrant incision. The umbilical port is most commonly a 15-mm port to accommodate the 15-mm diameter endosurgical bag and the endovascular stapling devices. Use of the 5-mm 30-degree telescope allows its use through the left lower quadrant site, which is necessary

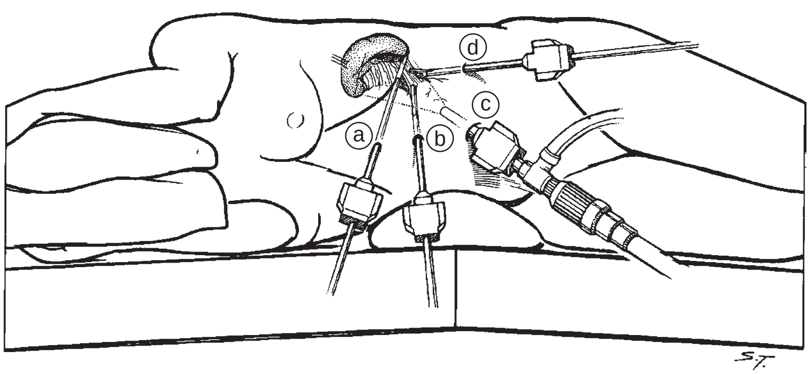

**FIGURE 110-2** Patient position and port size and location for lateral approach: *a* and *b,* 3 or 5 mm midline; *c,* umbilical 12 or 15 mm; *d,* 5 mm left lower quadrant.

when stapling and for placement of the endosurgical bag through the umbilical site.

The splenocolic ligament is divided, allowing the splenic flexure to fall away from the spleen (Fig. 110-3, *A*). The gastrosplenic ligament is then divided (see Fig. 110-3, *B*). The division of the most superior aspect is difficult, owing to the close proximity of the spleen and stomach, and care must also be taken to avoid injury to the diaphragm. Accessory spleens identified at the hilum can often be removed en bloc with the spleen and others from the lesser sac or omentum removed separately, usually through the umbilical trocar.

The spleen is then held up from the superior and inferior poles and the hilum approached, often dividing the inferior set of segmental vessels with either an electrosurgical device or with clips and scissors. The surgeon must decide between the use of clips or an endovascular stapler for the remaining segmental or polar vessels. If the vessels are individually divided, the surgeon must be prepared, should bleeding occur, to control the vessel proximally with a grasper and either clip the vessel or staple the remainder of the hilum. If the stapler is used, the splenorenal ligament can be divided so that the posterior arm of the stapler can easily pass posterior to the hilum. Care must be taken at this step to avoid injury to the tail of the pancreas (see Fig. 110-3, *C*).

The endosurgical bag is placed through the umbilical port; the spleen is then placed in the retrieval bag, and the neck of the bag delivered out the umbilicus. A finger and ring forceps are placed through the external opening and used to fracture the splenic capsule and remove splenic fragments (see Fig. 110-3, *D*). The use of an ultrasonic morcellator and liposuction device[76] to fragment the spleen has been described. Transvaginal removal of the bag has been described.[77] In some cases of splenomegaly it may be difficult to place the spleen in the bag. Hebra and colleagues[78] used a coring device to

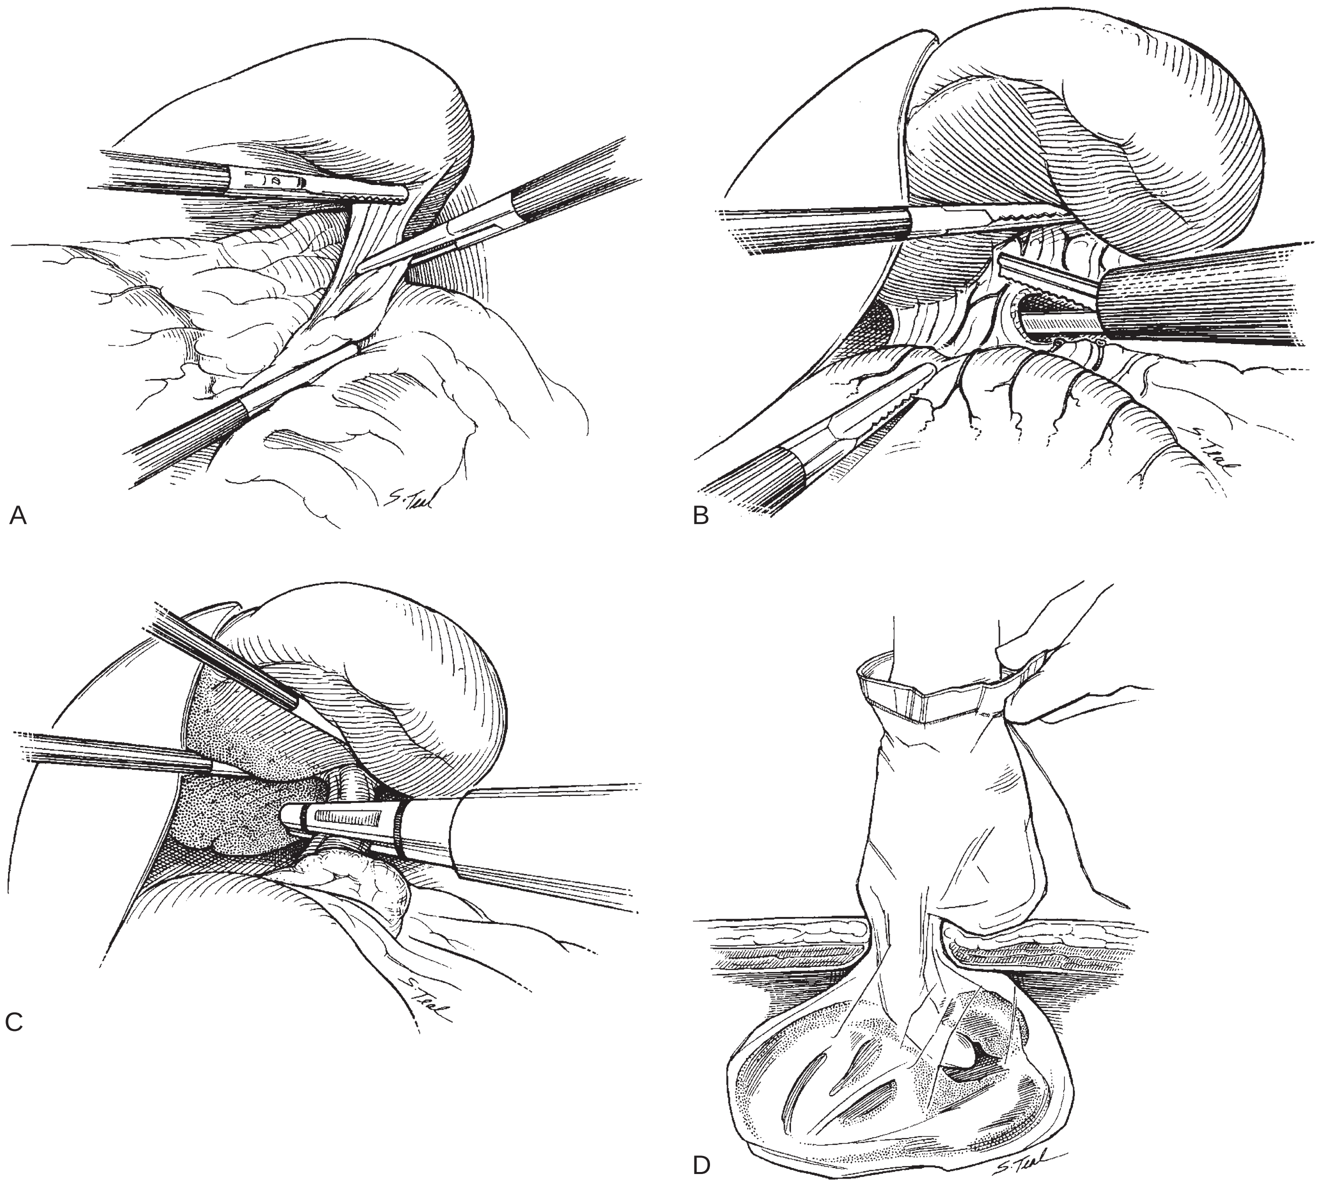

**FIGURE 110-3** Division of the splenocolic **(A)** and gastrosplenic **(B)** ligaments with the Harmonic scalpel. The endovascular stapler is used to divide the splenic hilum **(C)** and, after placement in the retrieval bag, delivered out the umbilical port **(D).** Finger fracture and forceps are used to remove splenic fragments.

remove portions of the spleen before its placement in a bag. This is not recommended in cases of hereditary spherocytosis or ITP in which splenosis could potentially lead to recurrent anemia or thrombocytopenia.

At completion, the fascia at the umbilical site and, if convenient, the anterior fascia layers at the 5-mm sites are closed. The orogastric tube and Foley catheter used intraoperatively are removed at the end of the procedure. Diet is advanced as tolerated the day of surgery, and pain control is achieved with intravenous morphine and nonsteroidal antiinflammatory agents, followed by oral pain medications when the patient is tolerating liquids. The techniques of laparoscopic splenectomy are applicable to other procedures including partial splenectomy for disease or lesions such as cysts, splenopexy for wandering spleen, and treatment of traumatic splenic injuries.[79,80] Single incision or single port techniques are being developed.

### Conversion

Conversion to open splenectomy is most frequently due to splenomegaly or bleeding and is reported in 1.3% to 2.8% in several large series.[68,81–84] Giant spleens with malignancy are more difficult situations, and one author noted a 41% conversion rate in adults with malignancy compared with a 3% conversion rate for benign conditions.[85] In another adult series, Mahon and Rhodes noted that their conversion rate was 0% for spleens weighing less than 1 kg and 60% for those weighing more than 1 kg.[86] A lower conversion rate with increasing surgeon experience has been observed in some series.[72,87]

### Operative Time

Comparative series have uniformly observed longer operative time with the laparoscopic technique,[65–70] and several have noted shorter times with increased surgeon experience.[82,88] In a review of 112 laparoscopic splenectomies, a longer operative time (115 vs. 98 minutes) was noted in the first 50 procedures compared with the next 62 procedures but the differences were not significant.[82]

### Pain

The pediatric reports do not use pain scores but rely on pain medication usage as a reflection of pain. All available comparative studies report lower morphine equivalent dose usage for pain control for laparoscopic compared with open splenectomy, but the difference did not reach statistical significance in two of the five studies.[66,69,70,89,90] This is consistent with an adult study that noted equal quality of life and control of the hematologic disease with less pain in the laparoscopic group.[91]

### Length of Stay

Length of stay ranges from 1.3 to 3.6 days, with more studies reporting 1.7 to 1.8 days.[68–70] All pediatric comparative studies have noted a shorter length of stay with the laparoscopic technique (laparoscopic, 1.3 to 3.6 days; open, 2.5 to 4.9 days), with the reduction ranging from 18% to 56%.[65–70] The underlying disorder can affect length of stay because infants and children with sickle cell disease have been noted to require a longer stay than those with ITP and hereditary spherocytosis (2.5 vs. 1.4 days).[70] This has been due to the occurrence of postoperative acute chest syndrome.

Splenomegaly alone, in children, does not appear to adversely affect length of stay because splenomegaly with hereditary spherocytosis is the most frequent indication for splenectomy and is associated with a short length of stay (1.4 days). A meta-analysis of primarily adult reports (2940 patients; 2119 laparoscopic procedures, 821 open procedures) noted longer mean operative time (laparoscopic, 180 minutes; open, 114 minutes; $P < 0.0001$) but a shorter hospital stay (laparoscopic, 3.6 days; open, 7.2 days; $P < 0.001$) with laparoscopic splenectomy.[92] Unproven benefits of the laparoscopic approach concern the child's return to full activity and the effect of return to school on the parent's return to work. Children undergoing laparoscopic splenectomy have been observed to return to full activity 1 to 5 weeks earlier than with the open procedure.[67] In addition, parents who had themselves undergone splenectomy view the laparoscopic technique better than the open technique.

### Cost

The presumption of most authors is that the shorter length of stay with laparoscopy will offset the higher operative charges related to the longer operative time and the use of disposable materials. Data from comparative studies note three studies with higher[67,90,93] and three with lower[65,69,70] hospital charges with laparoscopy. The method by which individual hospitals determine charges or cost for supplies, operating room time, and inpatient days makes comparison difficult. The available cost data do not appear to confer an advantage to either procedure.

### Complications

A meta-analysis of 26 comparison studies (adult and pediatric) noted a total complication rate of 15.5% for laparoscopic and 26.6% for open splenectomy ($P < 0.0001$).[92] The laparoscopic group had fewer pulmonary, wound, and infectious complications ($P < 0.0001$) but had more hemorrhagic complications when conversions for bleeding were included.

## PARTIAL SPLENECTOMY

Total splenectomy with removal of accessory spleens eliminates splenic hemolysis and sequestration for congenital hemolytic anemias. However, concerns of overwhelming postsplenectomy sepsis, particularly in children younger than 5 years of age, have led to the exploration of partial splenectomy. This has primarily been used for hemolytic anemias such as hereditary spherocytosis but has also been used for Gaucher disease,[60] Hodgkin disease staging,[94] trauma,[95] hypersplenism with cystic fibrosis,[96] as well as excision of splenic cysts,[46] hamartomas,[97] and hemangiomas.[98] When this technique is used for splenic volume reduction, 85% to 95% of the disease-affected splenic mass is removed, leaving approximately 10% to 25% of a normal splenic remnant. Anatomic studies of the splenic blood supply indicate that 86% of spleens have two lobar vessels and 12% have three lobar arteries.[99] In addition, 77% have either four or five segmental vessels, thus allowing preservation of either an upper or lower pole segmental vessel supplying 20% to 25% of the spleen. The spleen is divided with either a stapling device, cautery, or the Harmonic scalpel, and hemostasis is achieved with cautery, argon beam coagulation, or topical agents as needed. If the spleen is totally mobilized, the remnant can be fixed to

the retroperitoneum to prevent torsion. This procedure can be performed laparoscopically using the Harmonic scalpel to both divide the spleen and provide hemostasis (Fig. 110-4).

Long-term follow-up has noted increased red blood cell half-life, higher hemoglobin level, and lower transfusion requirement, reticulocyte count, and bilirubin levels.[100–103] Preservation of splenic phagocytic function has been demonstrated by elimination of Howell-Jolly bodies on peripheral smear and decreased numbers of pitted red cells.[101] Other parameters have included normal IgM and IgG levels of specific antibody titers to *Streptococcus pneumoniae*. Splenic regrowth occurs in all patients with hemolytic anemias, although the degree of regrowth does not correlate with hemolysis. Laparoscopic *partial* splenectomy has higher intraoperative blood loss, morphine use, and longer times to full oral intake, with longer hospital stays when compared with laparoscopic *total* splenectomy in the same institution.[104] Complications of postpartial splenectomy hemolysis can include ongoing development of cholelithiasis (7% to 22%), recurrent anemia with need for transfusion, or subsequent total splenectomy.[101–103,105] Caution must be exercised in the assumption of normal splenic function because one patient with evidence of residual splenic function by scan after partial splenectomy for trauma died of an *S. pneumoniae* infection 13 years later.[106] This patient had not received pneumococcal vaccine. Preoperative immunization is recommended for all partial splenectomy candidates, and postoperative antibiotics are administered at least until splenic immunologic competence is noted.

# Postoperative Considerations

Complications are relatively rare after splenectomy. Thrombosis of the splenic, portal, and mesenteric veins has occurred after splenectomy, with a reported incidence of 1.6% to 11%.[107–110] Symptoms include fever, vomiting, and/or abdominal pain as early as 2 days postoperatively. The diagnosis can be made by Doppler ultrasonography or contrast-enhanced CT of the abdomen. Treatment consists of antiplatelet and antithrombotic therapy. Recannulization of the portal vein can occur with prompt diagnosis and treatment of the thrombus, but long-term complications of portal hypertension have also been described.[110]

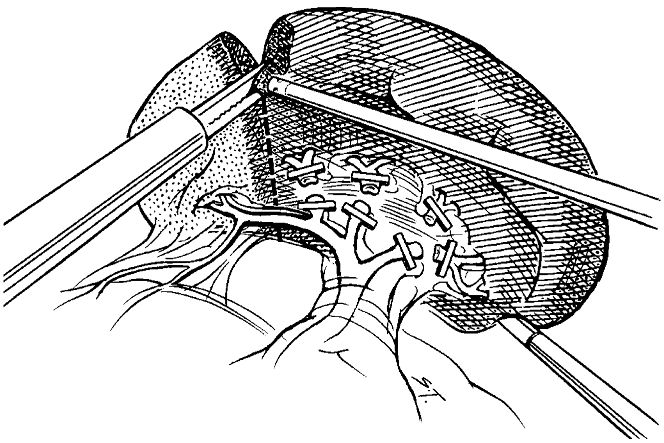

**FIGURE 110-4** Laparoscopic partial splenectomy using the ultrasonic dissector.

Antibiotic prophylaxis is recommended for all asplenic individuals in the immediate postoperative period. Penicillin prophylaxis is given to all children, except for those who are penicillin allergic. In penicillin-allergic children, options are limited. Trimethoprim-sulfamethoxazole can be used, recognizing higher pneumococcal resistance with this antibiotic. There are no universal recommendations on the duration of antibiotic prophylaxis, but most recommend prophylaxis for at least 2 years after splenectomy.[63]

## POSTSPLENECTOMY SEPSIS

The occurrence of overwhelming postsplenectomy infection (OPSI) was first reported by King and Shumacker in 1951 in a series of five infants younger than 6 months of age undergoing splenectomy for hereditary spherocytosis.[1] All five developed serious infections, and two died. Since then numerous reports have documented this risk and the increased risk (60- to 100-fold) in children younger than 5 years of age, as well as during the first few years after splenectomy. The etiology is probably related to decreased clearance of encapsulated bacteria[111] and decreased immunoglobulin levels.[112] The spleen is particularly important in infancy and childhood because the phagocytic function in infection occurs almost exclusively in the spleen.[113]

A cumulative review of the literature reported in the 1970s[114] identified the incidence of OPSI at 3.75%, with a mortality of 1.7%. The rate in pediatric cases was 4.1% compared with 1.9% in adults and a mortality rate of 1.8% in children compared with 1.1% identified in adults. Other studies in the 1980s and 1990s had a wide range of OPSI, and as of the mid-1990s the overall incidence of OPSI ranged from 0.13% to 8.1% in children younger than 15 years of age compared with 0.28% to 1.9% in adults.[115] *S. pneumoniae* was causative in 50% to 90% of all infections and is responsible for 60% of all fatal infections.[114,116–118] *H. influenzae* accounted for 32% of mortality,[119] and the meningococcus and group A *Streptococcus* were also significant pathogens.

The risk of late infectious mortality also varied with the disease state with a rate of 0.51% for spherocytosis and 2.67% for ITP.[120] Others also noted a higher mortality in children younger than 4 years of age (mortality: 8.1% in those younger than 4 years of age, 3.3% in older patients) with most deaths within 4 years of splenectomy.[121,122] In view of this, penicillin prophylaxis was advocated. The increased risk in children relative to adults was documented with an incidence of fatal OPSI of 3.77% in children compared with 0.39% in adults.[123] Many of these early reports were performed before widespread vaccination and use of prophylactic antibiotics, and more recent studies have somewhat lower rates of OPSI of 3.5% to 3.8%.[124,125] Vaccination has been shown to decrease the risk of bacteremia.[126]

A more recent population-based study out of Denmark determined that among all patients undergoing splenectomy (adults and children), excess risk of bacteremia was greatest in the first 90 days after splenectomy, occurring in 10% of all patients.[127] The risk remained higher than the general population for the first year. Different than previous studies, the Denmark study found enteric rods to be the predominant organism isolated from the blood in early and late postsplenectomy infections.

A comparison study of an early era of splenectomy with no immunizations or prophylactic antibiotics compared with a later era with a 70% immunization and a 100% prophylaxis rate noted a decrease in the infection rate (6% to 3.8%) and mortality (3.9% to 0.9%).[124] Even in this more recent study the rate of infection was related to age at splenectomy (birth to 5 years, 13.8%; >5 years, 0.5%). The historical mortality associated with OPSI has been 50% to 70%,[115,118,128,129] but more recently a mortality of around 10% has been observed.[124,130]

# GENITOURINARY DISORDERS

Intentionally left as blank

CHAPTER 111

# Renal Agenesis, Dysplasia, and Cystic Disease

Kenneth I. Glassberg and Grace Hyun

## Renal Development

More than 400 genes have been identified as playing a role in renal development. A defect in any of the more important genes can lead to specific abnormalities of development such as renal dysplasia, hypoplasia, or cystic disease. The kidney develops as a result of cross-talk between the wolffian duct (later, the ureteric bud) and the future metanephric blastema; each sends messages to the other, sometimes simultaneously and sometimes in response to the message received. Each step of renal development is dependent on the expression of different genes and their protein products. For example, the mesenchymal cells of the metanephric blastema persist and proliferate in response to insulin-like growth factor-2 (IGF-2). Expression of the Wilms' tumor 1 gene *(WT1)* suppresses IGF-2 and allows a cascade of events to occur including development of the ureteric bud from the wolffian duct and conversion of mesenchymal cells into epithelial cells. This latter conversion is initiated by the *PAX2* gene.

Ureteric bud formation from the wolffian duct occurs in response to a protein produced by the mesenchymal cells called *glial cell line–derived neurotrophic factor* (GDNF). This protein binds to a tyrosine kinase c-ret receptor on the caudal wolffian duct, inducing the formation of the ureteric bud. The ureteric bud elongates and penetrates the nearby mesenchymal blastema, where it undergoes multiple generations of bud divisions. Mesenchymal (blastemal) cells cluster around the tip of each terminal branch and differentiate into epithelial, stromal, and endothelial cells, the building blocks of the metanephric kidney. The epithelial cells first form into a hollow ball (renal vesicle), which elongates into a prenephron tubular structure that eventually attaches to the terminal branches of the ureteric bud, the future collecting ducts.[1]

Decreased ureteric bud branching will be associated with fewer clusters of mesenchymal cells and therefore fewer nephrons (i.e., hypoplasia). Poor communication between the branching bud tips and the clusters of mesenchymal cells or absence of continuity between the collecting ducts and developing nephrons can lead to persistence of immature structures (i.e., dysplasia). Overexpression or lack of expression of specific growth factors can lead to hyperproliferative renal disorders such as Wilms' tumor and renal cystic disease. For example, the aforementioned gene *IGF2* is overexpressed in most sporadic Wilms' tumor and *WT1,* a tumor suppressor gene, is mutated in many syndromal Wilms' tumors.

## Renal Dysgenesis

Maldevelopment of the kidney that affects its size, shape, or structure is referred to as *renal dysgenesis.* There are three principal forms: hypoplasia, dysplasia, and cystic dysplasia (as well as various other forms of renal cystic disease). Hypoplasia refers to a kidney or a segment of a kidney with a decreased number of nephrons. The hallmark of dysplasia is the presence of primitive ducts, structures thought to represent earlier stages of development and characterized by a surrounding collar of smooth muscle and collagen but lacking elastin.[2] Sometimes cysts appear in dysplastic kidneys or in areas of dysplasia. The cysts may be microscopic or macroscopic, focal or diffuse. When the entire kidney is involved with both dysplasia and cysts, it is referred to as a *multicystic dysplastic kidney.* Multicystic dysplastic kidneys may involute with time to become a "nubbin" of tissue; this is referred to as *renal aplasia.* The latter represents a tiny cluster of cells with no reniform shape. Kidneys that are severely dysplastic have either immature or absent collecting systems.

## Renal Agenesis

A defect of the wolffian ducts, the ureteric bud, or the metanephric blastema can lead to absence of kidney development, or renal agenesis. Renal agenesis occurs bilaterally in 1 of every 4000 births, with a predominance in males.[3] Because of the lack of urine production, oligohydramnios develops. Affected infants are born with immature lungs, pneumothorax, and Potter facies (hypertelorism, prominent inner canthal folds, and recessive chin). Bilateral renal agenesis can also appear as part branchio-oto-renal syndrome.[4] It is universally fatal. Unilateral renal agenesis is compatible with life; its incidence is 1 in 450 to 1000 births.[5] It is difficult to accurately determine

the true incidence of unilateral renal agenesis because in some conditions, such as a multicystic kidney, the organ can regress into a nubbin of tissue that does not appear on imaging studies.

Unilateral renal agenesis is associated with other urologic abnormalities including primary vesicoureteral reflux (28%), obstructive megaureter (11%), and ureteropelvic junction obstruction (3%).[6] Either unilateral renal agenesis or renal ectopia can be associated with ipsilateral müllerian defects and vaginal agenesis; this association is referred to as *Mayer-Rokitansky-Küster-Hauser syndrome.*

# Hypoplasia and Hypodysplasia

With hypoplasia, an entire kidney or a segment of one has a decreased number of nephrons. A hypodysplastic kidney also has a decreased number of nephrons; it may have a reniform shape but contains areas of dysplasia. Kidneys associated with ectopic orifices may be totally dysplastic, hypoplastic, or hypodysplastic. Ectopic orifices may be secondary to an abnormal ureteric bud site on the wolffian duct and are associated with abnormal renal development.

# Renal Cystic Disease

Renal cysts may be congenital, sporadic, or acquired; single or multiple; unilateral or bilateral. The majority arise from nephrons and collecting ducts. Multicystic dysplastic kidneys contain cysts that form from tubular structures before the nephrons develop. Benign multilocular cysts are a form of neoplasia and must be differentiated from possible malignant tumors. The origin of simple cysts is not clear. Most develop in kidneys that are otherwise normal.

Renal cysts vary in size from microscopic to macroscopic. All cysts are lined by epithelial cells. Some actually represent ectatic tubules or collecting ducts and remain continuous with the nephron. Others may pinch off from the nephron and become isolated structures. According to Gardner,[7] any duct that is dilated to four times the normal diameter is considered a cyst.

The classification system used in this chapter is based on that proposed by the Committee on Terminology, Nomenclature, and Classification of the Section on Urology of the American Academy of Pediatrics, which divides the various conditions into genetic and nongenetic disease.[8] Some modifications based on more recent findings have been added (Table 111-1).[1]

**TABLE 111-1**
**Classification of Cystic Disease of the Kidney**

| |
|---|
| Genetic |
| Autosomal dominant (adult) polycystic kidney disease |
| Autosomal recessive (infantile) polycystic kidney disease |
| Juvenile nephronophthisis–medullary cystic disease complex |
| Juvenile nephronophthisis (autosomal recessive) |
| Medullary cystic disease (autosomal dominant) |
| Congenital nephrosis (familial nephritic syndrome; autosomal recessive) |
| Familial hypoplastic glomerulocystic disease (autosomal dominant) |
| Multiple malformation syndromes with renal cysts (e.g., tuberous sclerosis, von Hippel-Lindau disease) |
| Nongenetic |
| Multicystic kidney (multicystic dysplastic kidney) |
| Benign multilocular cyst (cystic nephroma) |
| Simple cyst |
| Medullary sponge kidney |
| Sporadic glomerulocystic kidney disease |
| Acquired renal cystic disease |
| Caliceal diverticulum (pyelogenic cyst) |

From the outset, it must be clarified that although the terms *multicystic* and *polycystic* both mean "many cysts," they describe different conditions. The former refers to a dysplastic entity, and the latter refers to a number of separate entities, most of which are inherited, most of which are associated at some point in life with cysts in communication with nephrons or collecting ducts, but not all of which are associated with dysplasia. The most common conditions associated with the term *polycystic kidney disease* are autosomal recessive polycystic kidney disease (ARPKD) and autosomal dominant polycystic kidney disease (ADPKD). These conditions may progress to renal failure.

The entities with more important surgical implications include the various forms of multilocular cysts and the neoplasms associated with von Hippel-Lindau disease and tuberous sclerosis (TS) . Although multicystic kidneys often present as an abdominal mass, they are rarely removed. The large cysts in ADPKD have been treated with laparoscopic unroofing, but this author is unaware of any unroofing procedures performed in children.

# Autosomal Dominant (Adult) Polycystic Kidney Disease

ADPKD was formerly referred to as *adult polycystic kidney disease* because it is seen predominantly in adults; however, it may manifest in childhood or even in utero. ADPKD is the most common cause of renal failure, accounting for 10% to 15% of patients requiring kidney dialysis and transplantation.[9] Its incidence ranges from 1 in 500 to 1 in 1000 individuals. The condition affects both kidneys, although it may present predominantly on one side before it manifests on the contralateral side.

## GENETICS

ADPKD has been associated with three different mutations: *PKD1* on chromosome 16 accounts for approximately 90% of cases,[10,11] *PKD2* on chromosome 4 accounts for 5% to 10% of cases,[12,13] and *PKD3* has not yet been characterized. Penetrance is thought to be 100%, and 50% of the offspring of affected individuals have the potential of developing the disease. ADPKD will manifest in 96% of affected individuals by age 90 years.[12,14]

## CLINICAL FEATURES

Because 50% of them will eventually develop the disease, the offspring of patients with ADPKD are screened by ultrasonography. By age 25 years, at least 85% of individuals will have cysts, but most will be asymptomatic.[15] Family members of individuals with ADPKD are unable to obtain life insurance

before age 25 years because of the possibility of developing the disease. The majority of individuals present between 30 and 70 years of age with findings that include microscopic and gross hematuria, flank pain, hypertension, and renal colic secondary to either clots or stones. In adults, the disease is associated with colonic diverticula, hepatic cysts, and berry aneurysms. Hepatic cysts appear much more frequently in adults than in children and are more common in females. ADPKD occasionally presents in utero or in infancy; when it does, 50% of the kidneys are large and usually contain macrocysts. Sometimes the large cysts are not apparent, and the kidneys are hyperechogenic due to the reverberation of ultrasound waves caused by the multiple interfaces between dilated ducts and tubules; the latter presentation is more typical for ARPKD (Fig. 111-1). Eventually, the cysts enlarge to macroscopic size. When prenatal ultrasonography identifies a patient suspected of having ADPKD or ARPKD, genetic or ultrasound studies of the parents must be obtained. It is important to monitor these children for hypertension because control of blood pressure delays the onset of renal failure. Those with elevated serum creatinine levels, increased urinary protein excretion, and high blood pressure at a young age tend to decline faster and go on to renal failure. Almost all patients who present in utero or in the first year of life eventually develop renal failure, but with close monitoring, the onset can be delayed.

# Autosomal Recessive (Infantile) Polycystic Kidney Disease

This entity is no longer referred to as *infantile polycystic kidney disease* because it is now realized that some patients can present as adolescents or in their early 20s. ARPKD is a relatively rare disease occurring in approximately 1 of every 40,000 live births.[16] All patients have some degree of congenital hepatic fibrosis. In general, younger patients with severely affected kidneys have the mildest congenital hepatic fibrosis.

## GENETICS

The disease is transmitted by *PKHD1,* a gene located on chromosome 6, with possible involvement of the mTOR pathway, as recently described.[17,18] Both the severe and mild forms of ARPKD are associated with this mutation. Because it is an autosomal recessive trait, one of four offspring is affected and neither parent shows evidence of the disease.

## CLINICAL FEATURES

For infants with ARPKD identifiable in utero or at birth, death in the first 2 months of life from uremia or respiratory failure is not unusual. If they survive the first month of life, their chances of living for a year with proper supportive therapy are improved. Eventually, all infants with ARPKD develop renal failure (Fig. 111-2). In children who present later in life, hypertension presents later and is more controllable and progression to renal failure is slow.

Newborns with ARPKD may have significant nephromegaly. The kidneys can be so large that they compromise breathing or cause a difficult delivery. When severe, oligohydramnios may be present, as well as Potter facies and deformities of the limbs. Rarely, the kidneys are so enlarged that the diaphragm is significantly elevated, resulting in respiratory compromise; in these cases, nephrectomy may be required. Respiratory care helps extend the child's life.

Those with advanced congenital hepatic fibrosis may have portal hypertension, esophageal varices, and hepatosplenomegaly. Variceal bleeding due to portal hypertension may require a splenorenal shunt. The kidneys in utero are typically large and hyperechogenic on ultrasound examination. Hyperechogenicity is due to the presence of numerous small microscopic cysts and dilated ducts and tubules within the kidney, creating reverberations of the sound waves. With time, macrocysts develop. As these patients get older, their kidneys get smaller, contrary to the sequence of events in ADPKD. On histologic examination, the collecting ducts are elongated and very dilated. There is no cure for the condition.

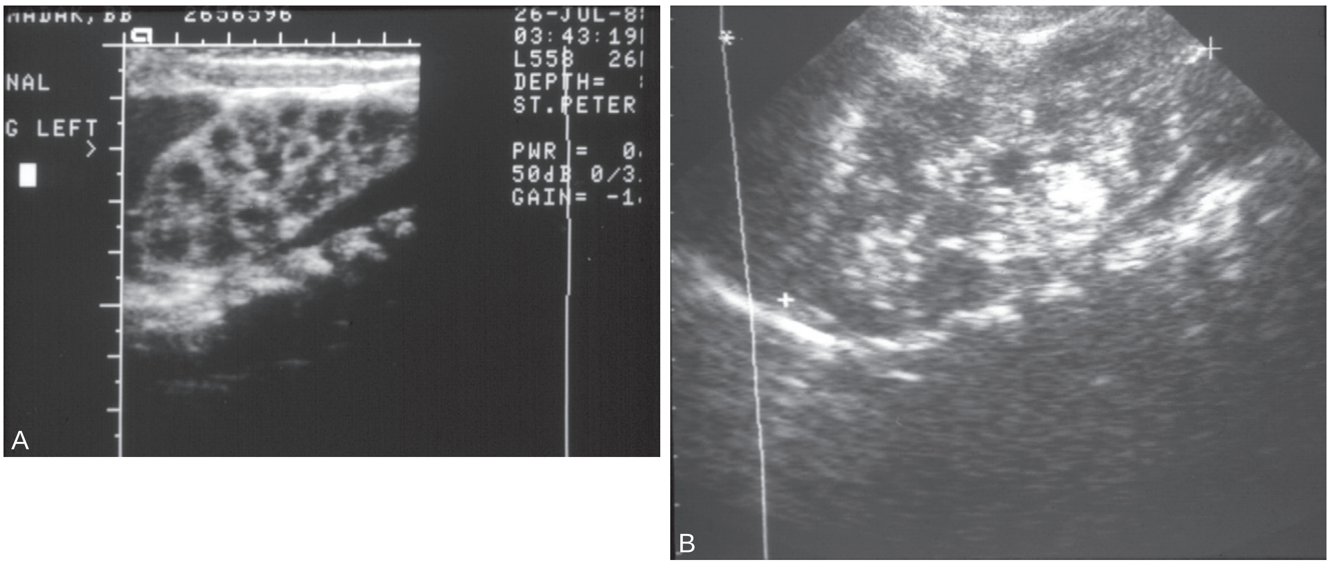

**FIGURE 111-1** **A,** Multiple cysts are seen throughout the left kidney on this ultrasound study in a newborn with autosomal dominant polycystic kidney disease. **B,** Newborn with autosomal recessive polycystic kidney disease. Note the increased echogenicity and the small cysts. (Courtesy Walter Berdon, MD.)

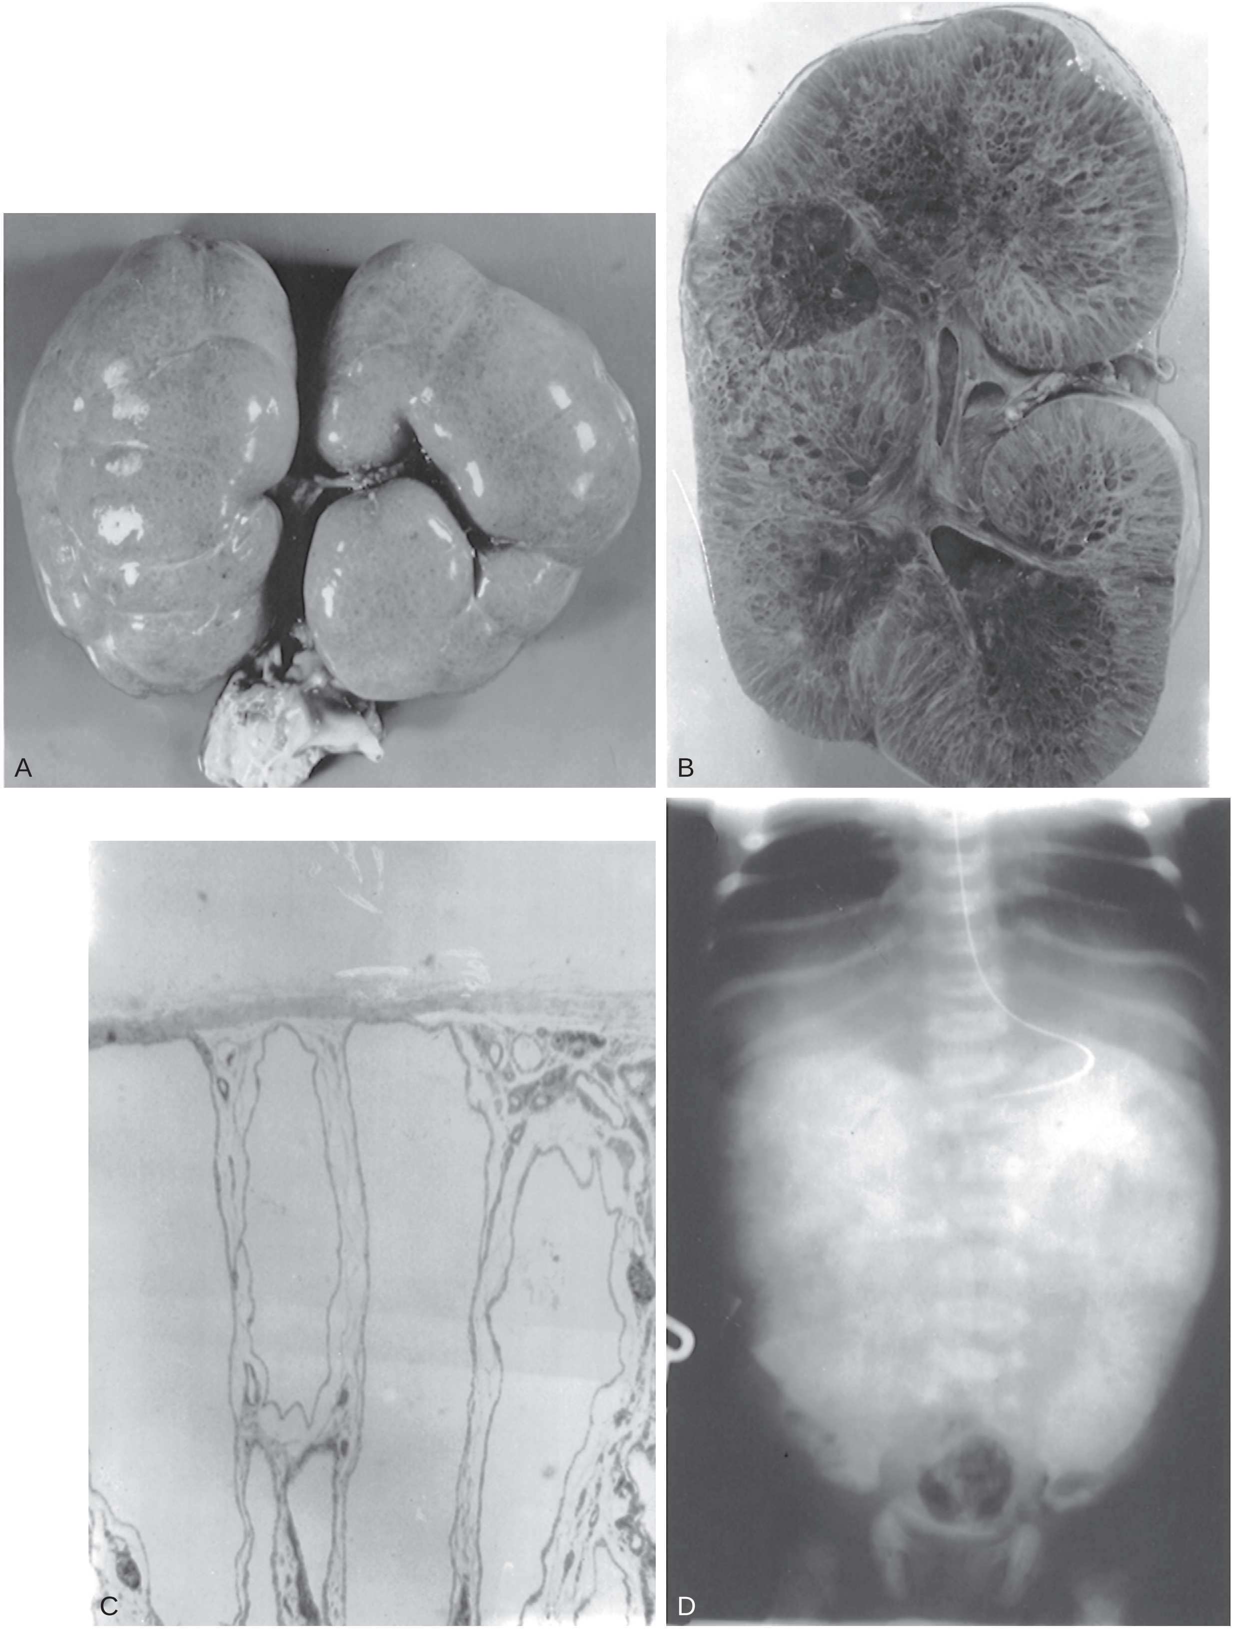

FIGURE 111-2 Autosomal recessive polycystic kidney disease. **A,** Gross specimen with diffuse, small subcapsular cysts. **B,** Radially arranged, elongated, “cystic,” dilated collecting ducts. **C,** On low-power microscopic view, dilated collecting ducts are seen. **D,** On intravenous urography, the characteristic delayed “sunburst” pattern is identified, secondary to contrast pooling in the dilated collecting ducts.

# Multiple Malformation Syndromes with Renal Cysts

A number of multiple malformation syndromes are characterized by renal cysts. Two that are of particular interest to surgeons are TS and von Hippel-Lindau disease.

## TUBEROUS SCLEROSIS

TS is associated with the classic triad of epilepsy (80% of cases), adenoma sebaceum (75% of cases), and mental retardation (60% of cases).[19] Adenoma sebaceum consists of flesh-colored papules of fibroma located on the malar area of the face. The hallmark lesion is a superficial cortical hamartoma of the cerebrum, which looks like a hardened gyrus, suggesting the appearance of a tuber (root). Hamartomas affect other areas of the body as well, especially the kidneys and eyes. Other kidney lesions include angiomyolipomas and cysts.

### Genetics

The trait is transmitted in 25% to 60% of cases and occurs either sporadically or as a genetic condition with variable or incomplete penetrance. Two genes have been identified as being responsible for the autosomal dominant transmission of TS.[20,21] *TSC1* is located on chromosome 9, and *TSC2* on chromosome 16. The latter gene defect is located at a site contiguous with *PKD1*, the mutation most commonly associated with ADPKD.[50] The fact that both TSC gene mutations result in similar clinical manifestations suggests that both genes are involved in a common developmental pathway. When either gene does not produce its normal protein product, similar results occur. Both are considered tumor suppressor genes because a mutation of either can result in tumor development.

### Clinical Features

Twenty percent of patients develop renal cysts, and these usually manifest before 3 years of age. One third of children who present with cysts are younger than 1 year. The disease may be detected on prenatal ultrasonography because of the presence of cysts. When it does present in utero, there is a greater likelihood that it is secondary to a mutation of the *TSC2* gene on chromosome 16. In such cases, defects of the adjacent *PKD1* gene responsible for ADPKD may also be present. The renal cysts rarely cause a problem. In the past, many of these patients died early of central nervous system lesions; however, they are now living longer, and in the future, it may be discovered that renal cysts cause compromised kidney function. On histologic examination, the cysts have a unique appearance and are lined by hypertrophic, hyperplastic eosinophilic cells. In theory, these hyperplastic cells may account for the 2% incidence of renal cell carcinoma in patients with TS. Patients as young as 7 years have been reported with this tumor.

## ANGIOMYOLIPOMA

Renal angiomyolipoma (AML) is a benign hamartomatous neoplasm consisting of varying amounts of mature adipose tissue, smooth muscle, and thick-walled vessels and occurs in 40% to 60% of patients with TS.[22–24] These lesions are rarely seen before 6 years of age and are common after age 10.[25] Fortunately, AMLs can be diagnosed via computed tomography (CT) scan. The presence of fat, −20 HU or lower, within a renal lesion on a CT scan is pathognomonic for an AML, excluding the diagnosis of RCC.[26–28] Life-threatening hemorrhage is the most significant complication of AMLs. Risk factors have been identified specifically, tumors larger than 4 cm, pregnancy, multicentricity, and TS. Therefore proactive intervention should be considered in these patients.[29] Furthermore, a nephron-sparing approach, by either selective embolization or partial nephrectomy, is clearly preferred in patients with small AMLs requiring intervention because of symptoms, in patients with TS or multicentric AML, and in patients for whom preservation of renal function is critical.

## VON HIPPEL-LINDAU DISEASE

This autosomal dominant condition is associated with cerebellar hemangioblastomas, retinal angiomas, cysts of the pancreas, epididymis and kidney epididymal cystadenoma, pheochromocytoma, and clear cell renal cell carcinoma. Its incidence is approximately 1 in 35,000.[30,31]

### Genetics

The *VHL* gene is a tumor suppressor gene located on chromosome 3 and has a dominant transmission; 50% of offspring of affected persons can expect to develop the disease. Individuals are born heterozygous for the disease initially. When the second allele of the *VHL* gene mutates in a specific organ, the typical lesions develop in that site. Different mutations of the *VHL* gene have been found in cases of renal cell carcinoma not associated with von Hippel-Lindau disease.

### Clinical Features

The mean age of presentation is 35 to 40 years; rarely, von Hippel-Lindau disease presents in childhood. Renal cysts are the most common renal lesion and are the first manifestation of the disease in 76% of patients.[32] Pheochromocytomas occur in 10% to 17% of affected individuals but seem to be more common in specific families.[33,34] Some patients present with seizures because of hemangioblastomas of the central nervous system. Because the cells lining the cysts are hyperplastic, these patients have a high risk of developing renal cell carcinoma (RCC).[31] In adulthood, the possibility of bilateral renal cell carcinoma should be considered, even if it is not bilateral initially. Annual or biannual examinations of the kidney, usually by CT, are recommended after age 30 years, particularly when small tumors, representing benign adenomas, are present. RCC is responsible for 30% mortality rate for those patients with VHL.[35]

# Multicystic Dysplastic Kidney

This condition represents an extreme form of dysplasia involving the entire kidney (Fig. 111-3). When occurring in one pole of a kidney, it is likely associated with a duplicated system. When patients have the disease bilaterally, it is incompatible with life and is therefore associated with stillbirth, oligohydramnios, and Potter facies. The condition is usually associated with atretic ureters and no renal pelvis. When a renal pelvis is present, the entity is referred to as a *hydronephrotic*

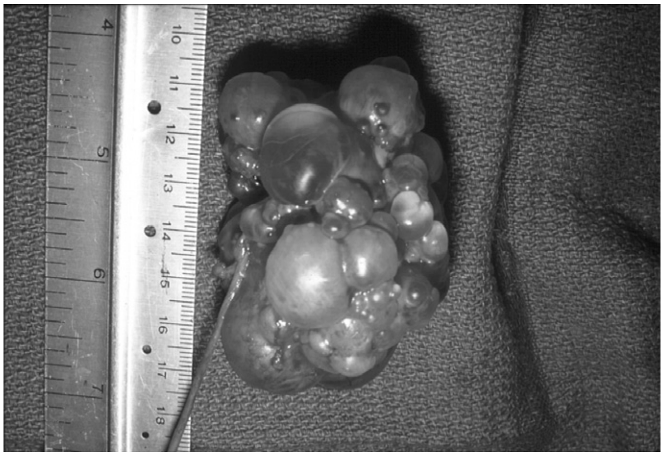

**FIGURE 111-3** Typical multicystic kidney with atretic ureter. Note the "bunch of grapes" appearance. (From Shah SH, Glassberg KI: Multicystic dysplastic kidney disease. In Gearhart JP, Rink RC, Moriquand PDE [eds]: Pediatric Urology. Philadelphia, WB Saunders, 2001, p 279.) *(See color plate.)*

*form of multicystic kidney* (Fig. 111-4). When the kidney appears solid, with fewer cysts, the disease is referred to as *solid cystic dysplasia.* Typically, however, the appearance is that of a bunch of grapes, and on ultrasound studies the kidney has a nonreniform shape; the cysts have a haphazard appearance, with no central or medial cyst, suggesting the presence of a renal pelvis (Fig. 111-5). This form of multicystic kidney must be differentiated from hydronephrosis, in which there is a central or medial cyst—the largest—and there is communication with peripheral cysts, representing dilated calices. In the past, it was thought that the cysts do not communicate; however, injection of contrast into one cyst invariably demonstrates communication between cysts (Fig. 111-6).[15]

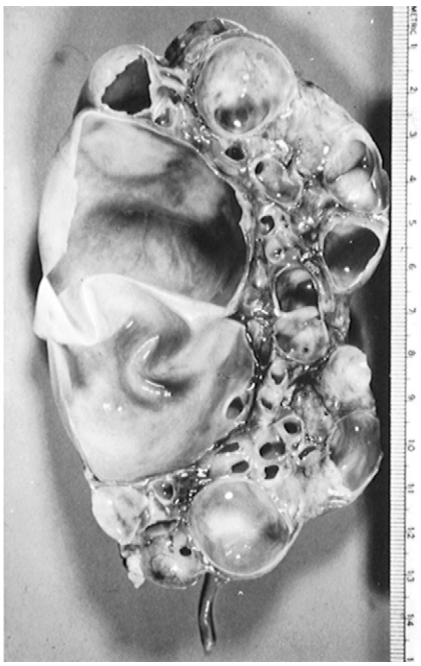

**FIGURE 111-4** Hydronephrotic form of multicystic dysplastic kidney. The largest cyst is located centrally and medially, and the smaller cysts are at the periphery.

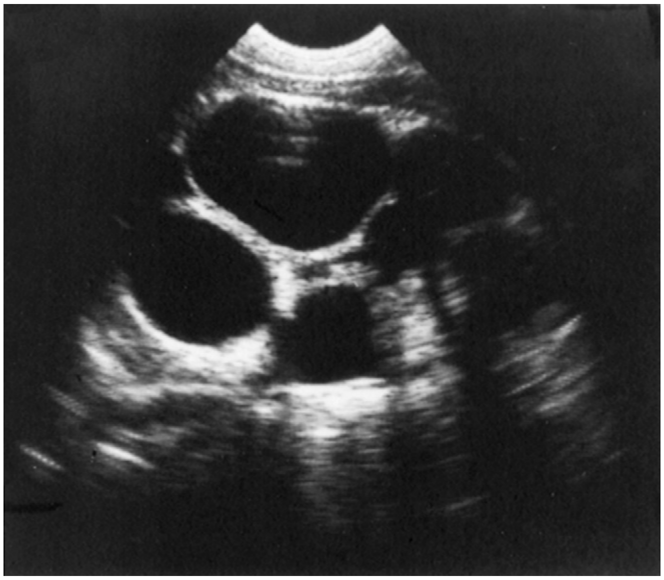

**FIGURE 111-5** Typical ultrasound appearance of a multicystic kidney. Three large cysts are seen, with some smaller cysts in between. Little parenchyma is identified.

## CLINICAL FEATURES

Multicystic dysplasia is the most common form of renal cystic disease, and it along with ureteropelvic junction obstruction are the most common causes of a palpable abdominal mass in an infant. It is important to evaluate the contralateral system because 3% to 12% of infants with multicystic kidney disease have a contralateral ureteropelvic junction obstruction, and 18% to 43% have contralateral vesicoureteral reflux.[11,36–38] Because of the latter finding, voiding cystourethrography should be obtained in all infants diagnosed with the entity. Historically, these kidneys were detected in the first year of life by palpation. Before the use of ultrasonography, most multicystic kidneys were removed because it was hard to confidently differentiate them from renal tumors and because of rare reports of Wilms' tumors being identified in multicystic kidneys. To help differentiate a multicystic kidney from a

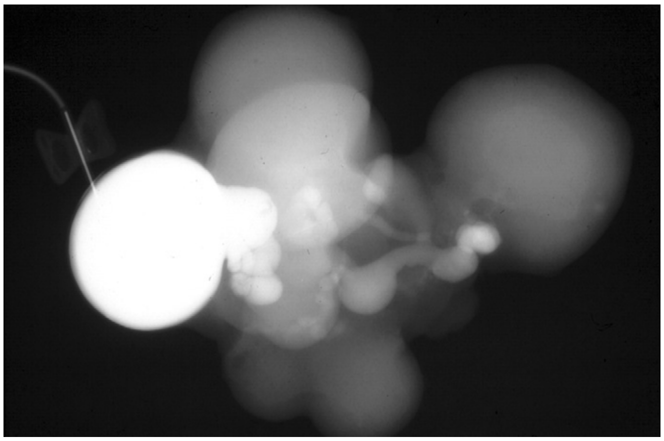

**FIGURE 111-6** Multicystic dysplastic kidney. Contrast material injected into one cyst is identified moments later in all cysts, demonstrating a duct-like communication between them. Although the cysts do not appear to communicate on ultrasonography, they are invariably found to communicate when contrast material is injected into excised specimens.

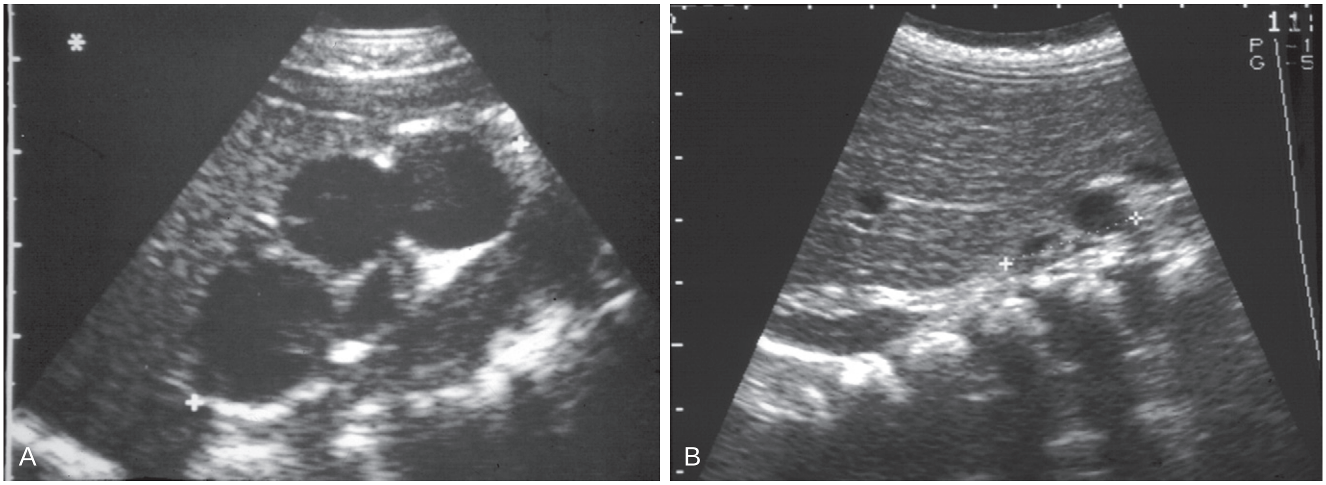

**FIGURE 111-7** **A,** Multicystic kidney identified on ultrasonography in a newborn. **B,** At age 9 months, the cysts have shrunken, and the kidney is barely visible. (From Shah SM, Glassberg KI: Multicystic dysplastic kidney disease. In Gearhart JP, Rink RC, Moriquand PDE [eds]: Pediatric Urology. Philadelphia, WB Saunders, 2001, p 284.)

hydronephrotic kidney, a dimercaptosuccinic acid (DMSA) scan is obtained. Little, if any, function exists in a multicystic kidney, whereas a hydronephrotic kidney rarely has no function. The decision must be made whether a multicystic dysplastic kidney requires removal. With ultrasonography and other imaging studies providing a more definitive evaluation, the incidence of nephrectomy for an inconclusive diagnosis has fallen dramatically. Most cases of Wilms' tumor in multicystic dysplastic kidneys have occurred in kidneys that were not previously known to be multicystic. Thus it is unclear whether the multicystic dysplastic kidney led to the development of the Wilms' tumor. Two reports in the literature that imply that these kidneys should be removed describe a total of 120 patients, 5 of whom were found to have nephrogenic rests of nodular renal blastoma.[39,49] One had Wilms' tumorlets in the hilar region. However, renal blastomas have been reported to occur in normal kidneys as well, so it is not clear that the presence of these rarely seen tumorlets in multicystic kidneys implies a greater risk of developing Wilms' tumor. According to Beckwith,[40] only 5 of 7500 Wilms' tumor specimens in the Wilms' Tumor Registry occurred in multicystic kidneys. Beckwith calculated that multicystic kidneys have a fourfold increased risk of developing Wilms' tumor, and this low incidence does not justify prophylactic nephrectomy. He pointed out that even if Wilms' tumor did develop, the current survival rate is now greater than 90% with treatment. Zerres and colleagues[17] and Aslam and colleagues[41] suggest conservative therapy for multicystic kidneys as long as there is follow-up ultrasound surveillance every 3 months until 8 years of age. They calculated a $2000 to $5000 cost for such surveillance, in comparison with a simple nephrectomy at $5000 to $7000.

There have been isolated case reports of hypertension developing in association with a multicystic kidney, with removal of the kidney curing the hypertension. In the National Multicystic Kidney Registry of the Section on Urology of the American Academy of Pediatrics, most neonatal cystic kidneys became smaller or stayed the same size over a 5-year period, with a small percentage becoming larger.[16] Therefore many kidneys that become smaller will disappear from view on ultrasonography. This does not mean that the kidney itself has disappeared; it implies that the cysts have disappeared (Fig. 111-7). The cells that lined the cysts persist, however; this amorphous group of cells forms a nubbin of kidney without any function (renal aplasia).

Although it is customary to follow multicystic kidneys with ultrasound studies every 3 to 6 months during the early years of life and at progressively longer intervals until 8 years of age, it is not clear whether it is necessary to follow a patient whose kidney disappears on imaging studies, or even when those findings persist. Because these cells remain without the cyst fluid, their presence, by itself, should not determine whether to obtain ultrasound follow-up.

## Benign Multilocular Cyst (Cystic Nephroma)

A benign multilocular cyst is a neoplasm of the kidney that is not associated with renal dysplasia. The lesions are large and circumscribed by a thick capsule. There is usually normal renal parenchyma adjacent to the lesion. The loculi, which represent cysts within the lesion, can measure a few millimeters to a few centimeters in size and do not intercommunicate. The cysts are lined by cuboidal or low columnar epithelial cells. The septa of a benign multilocular cyst are composed of fibrous tissue, and no poorly differentiated tissues or blastema cells are present.

It is important to note that when a multilocular cystic lesion is identified on an imaging study, particularly ultrasound, it is impossible to determine whether it is a benign multilocular cyst, a multilocular cyst with partially differentiated Wilms' tumor, a benign multilocular cyst with nodules of Wilms' tumor, or a cystic Wilms' tumor. Thus multilocular cystic lesions can be considered a spectrum of entities, and there have been no reports of one entity converting into another (Fig. 111-8). Because imaging studies cannot differentiate them, it is essential that these lesions be removed (Fig. 111-9). If they are located in one pole of the kidney and there is a large remaining portion of normal parenchyma present, a partial nephrectomy should be considered. Even when the lesion is not a typical benign multilocular cyst, there is little chance of the disease being aggressive. None of these conditions involves expansive nodules, and metastasis rarely if ever occurs.[42] The lesion

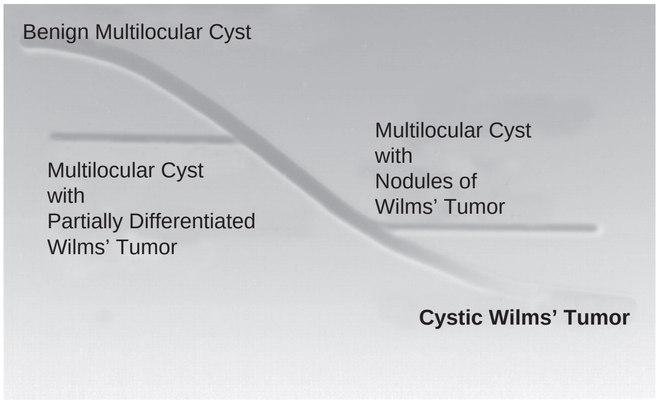

FIGURE 111-8 Spectrum of multilocular cystic lesions in childhood. Because imaging studies cannot differentiate one type of lesion from another, the diagnosis must be made under the microscope.

should not be confused with a Wilms' tumor that contains necrotic areas, which can simulate cysts on ultrasonography; the latter represents a more aggressive tumor.[43] The age distribution is bimodal, occurring primarily in boys during the first 2 to 3 years of life, and again after the fourth decade, usually women.[42] Children tend to present with an asymptomatic abdominal mass detected on routine physical examination, whereas symptomatic presentation is more common in adults.[44]

## Simple Cyst

Simple cysts are discrete findings within the kidney that usually appear oval to round with a smooth border. The cysts usually contain clear or straw-colored fluid, and when they manifest in utero, they usually disappear by birth. When they appear during childhood, they should be evaluated just as in

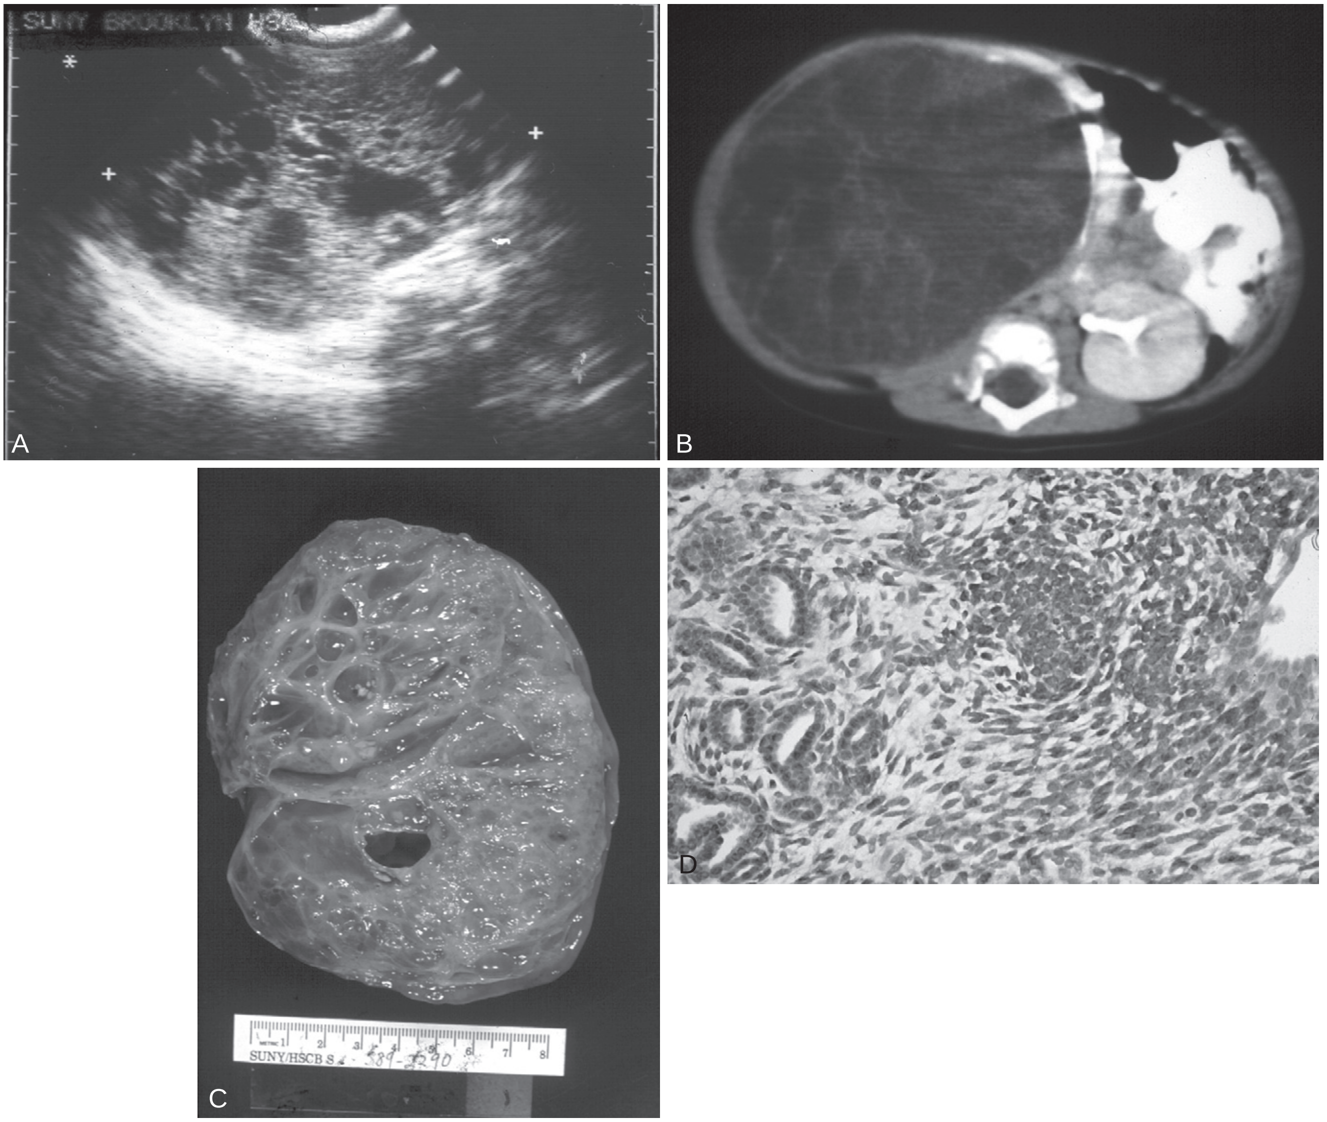

FIGURE 111-9 Multilocular cyst with partially differentiated Wilms' tumor. **A,** Ultrasound image identifies a mass in the kidney with cystlike structures within it. **B,** On contrast-enhanced CT, a large, smoothly outlined renal mass is seen with fine septa within it; note the caliceal system compressed on its edge. **C,** Cross section of the mass reveals noncommunicating loculations. **D,** On microscopy, nests of blastema cells with tubular elements are seen between the loculi, findings typical of multilocular cyst with partially differentiated Wilms' tumor.

adults with simple renal cysts. Because cysts were once considered such an infrequent finding in children, and because the ability to clearly define a cyst was limited, most simple renal cysts were operated on in the past. In children, renal cysts are rarely symptomatic. When more than one simple renal cyst is present in a kidney, the patient should be followed and the contralateral kidney carefully evaluated with imaging studies, because unilateral multiple cysts may represent an initial asymmetric presentation of ADPKD.

The sonographic criteria for a classic benign simple cyst are as follows:

1. Sharply defined, thin, distinct wall with smooth and distinct margin
2. Absence of internal echoes
3. Good transmission of sound waves through the cyst with acoustic
4. Spherical or slightly ovoid shape (Fig. 111-10)

If all these criteria are met, the chance of malignancy is negligible.[44] Sometimes there is a cluster of renal cysts at one pole of a kidney, and this must be differentiated from a multilocular cystic lesion. When the cysts are all simple, the condition may be referred to as *unilateral renal cystic disease,* a variant of simple cysts.[45] Although follow-up recommendations have not been established with evidence-based reports, it seems reasonable to follow these patients with sequential ultrasonography with decreasing frequency, mainly to ensure the stability of the simple cyst and screen for an asymmetric presentation of ADPKD.

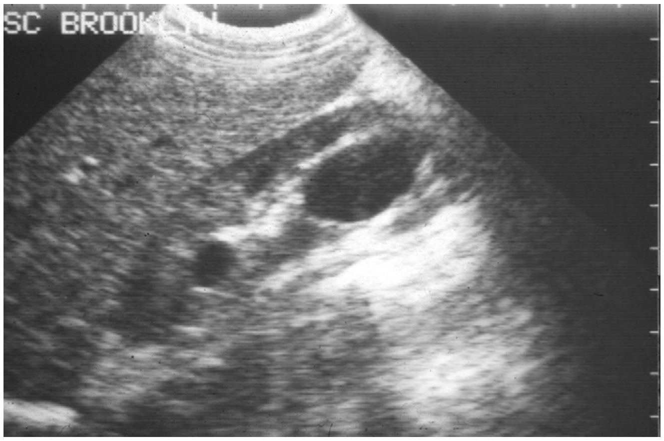

**FIGURE 111-10** Two simple renal cysts in a 7-year-old. Note the whiteness (hyperechogenicity) just outside the kidney on ultrasonography. This is referred to as acoustic enhancement, a finding typical of simple cysts. It occurs secondary to increased sound wave reverberation through the cyst, and it interfaces with the kidney. It is important not to confuse this finding with an atypical, asymmetric presentation of autosomal dominant polycystic kidney disease.

## Acquired Renal Cystic Disease

Acquired renal cystic disease is common in dialysis patients with chronic renal failure. There are few reports on acquired renal cystic disease in children, but as in adults, the incidence increases with the length of time on dialysis.[31] Young patients exposed to dialysis may develop the condition later in childhood. Once renal cysts develop, the kidneys should be followed regularly with imaging studies to rule out tumors. After renal transplantation, the cysts regress in size. New cysts can form in transplanted patients, but they tend to be small.

## Caliceal Diverticulum

A caliceal diverticulum is a cystic, smoothly outlined sac, usually located at one of the poles, most frequently the upper one. It communicates with the pelvicaliceal system by means of a narrow neck. It has also been referred to as a *pyelogenic cyst;* that term, however, is best used when the lesion communicates with the renal pelvis. These diverticula have the same lining as calices, with a smooth layer of transitional epithelium. Caliceal diverticula are benign lesions, and small diverticula are usually asymptomatic and discovered as an incidental finding. The diagnosis is best made by excretory urography or CT with delayed images. Whereas simple cysts do not take up contrast, calyceal diverticula will fill with contrast specifically on the delayed images. Asymptomatic patients do not require treatment. Over time these diverticula tend to progressively distend with trapped urine. Infection, hematuria, flank pain, milk of calcium (crystallization of calcium salts without actual stone formation), and true stone formation are complications of stasis or obstruction that can produce symptoms[46] and are indications for surgical intervention. Percutaneous removal of the stones and ablation of the mucosal surface[47] and ureteroscopic enlargement of the diverticular communication with removal of the stones[48] are the modern treatment options available.

CHAPTER 112

# Renal Fusions and Ectopia

Pierre Mouriquand and Nicoleta Panait

## Embryology

The embryology of congenital anomalies of the kidneys involves two protagonists and three events. The two protagonists are the nephrogenic material (pronephros, mesonephros, metanephros) and the ureteral buds (wolffian structures). The three events are induction of metanephric tissue (renal construction), ascent of the kidneys (cephalad migration), and positioning of the kidneys (partition and rotation). Incidents occurring during these three phases (first 8 weeks of gestation) may affect the presence, number, and location of the kidneys.

The nephrogenic cord is divided into three parts (Fig. 112-1)[1]: The most cranial segments collectively constitute the pronephros; the intermediate segments, the mesonephros; and the most caudal segments, the metanephros or kidney. This classification is purely topographic, and the nephrogenic material arises from the same source and exhibits identical properties throughout its craniocaudal extent.[2] The pronephros (eight-somite–stage embryo) degenerates completely (day 24 to 25); however, its duct contributes to the formation of the mesonephros. In an embryo with 23 somites, the mesonephros produces small quantities of diluted urine and forms mesonephric vesicles and excretory tubules, which also degenerate with a few embryonic remnants left such as the paradidymis in the male and the paroöphoron in the female.[3] The metanephros develops from the portion (metanephric blastema) of the nephrogenic cord caudal to the mesonephros.

The ureteral buds arise from the mesonephric duct near its junction with the cloaca during the fourth to fifth week of gestation. The cranial end of the ureter then ascends to meet the nephrogenic cord, which begins to develop into the metanephros and continues its cephalad migration. The cranial end of the ureteral bud begins a series of branchings to form the renal pelvis, the calices, and a portion of the collecting ducts.[4] The cephalad migration of the kidneys ends at the eighth week of gestation, as well as their axial rotation of 90 degrees medially. During their ascent, the kidneys receive their blood supply from the neighboring vessels. Blood is initially supplied by the middle sacral artery, then the common and inferior mesenteric arteries, and finally the aorta. Renal development is closely related to the location of the origin of the ureteral buds.[5] The ureteral ducts (which in the first phases of development are permeable until the 35th day) subsequently undergo a process of obstruction and recanalization of their lumen until the embryo is 41 days of age.[6,7] The muscular and neurologic construction and maturation of the urinary excretory system are a slow phenomenon (Fig. 112-2) that, when impaired, may affect the entire anatomic organization of the urinary tract. Any delay or mislocation of these complex events may lead to the following renal anomalies[8]: renal agenesis, multicystic dysplastic kidney and other renal cystic diseases, small congenital kidney, supernumerary kidney, and renomegaly. Anomalies related to abnormal ascent and abnormal fusion[9] are discussed in the following sections. Many genes are likely to control all these events, although few are identified.[10] Renal metanephric development results from the expression of many genes in the ureteral bud and metanephric blastema with each sending messages to the other to induce organogenesis.[11] The transcription factor BF2[12] studied in the mouse model seems to play an important role in this embryonic construction.

## Anomalies Related to Abnormal Ascent of the Kidneys (Ectopic Kidneys)[13]

### PELVIC KIDNEY

A pelvic location (sacral or pelvic) below the aortic bifurcation is the most common site of ectopic kidneys.[14] A pelvic kidney (Fig. 112-3) is generally unilateral with a slight predilection for the left side. It is found bilaterally in 10% of cases.[15] In addition to its abnormal location, a pelvic kidney is frequently small, with an irregular shape, variable rotation, and extrarenal collecting system.

### LUMBAR OR ILIAC ECTOPIC KIDNEY

These kidneys are fixed above the crest of the ileum but are below the level of L2 and L3. Such kidneys can be difficult to differentiate from an ptotic kidney, which has a normal ureteral length, is not malrotated, is mobile, and can usually be manipulated into its normal position.[15]

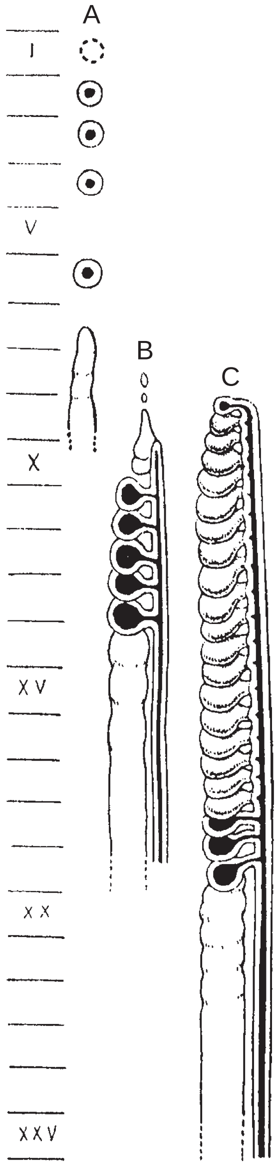

**FIGURE 112-1** Schemes showing early development of the human nephros. **A,** Ten-somite embryo. **B,** Twenty-somite embryo. **C,** Twenty-five-somite embryo. The Roman numerals indicate the level in somites. The circles indicate nephrotomes that do not contribute to the nephros (based on Torrey[85]). (From Hamilton WJ, Boyd JD, Mossman HW [eds]: Human Embryology, 3rd ed. Cambridge, England, Heffer, 1962.)

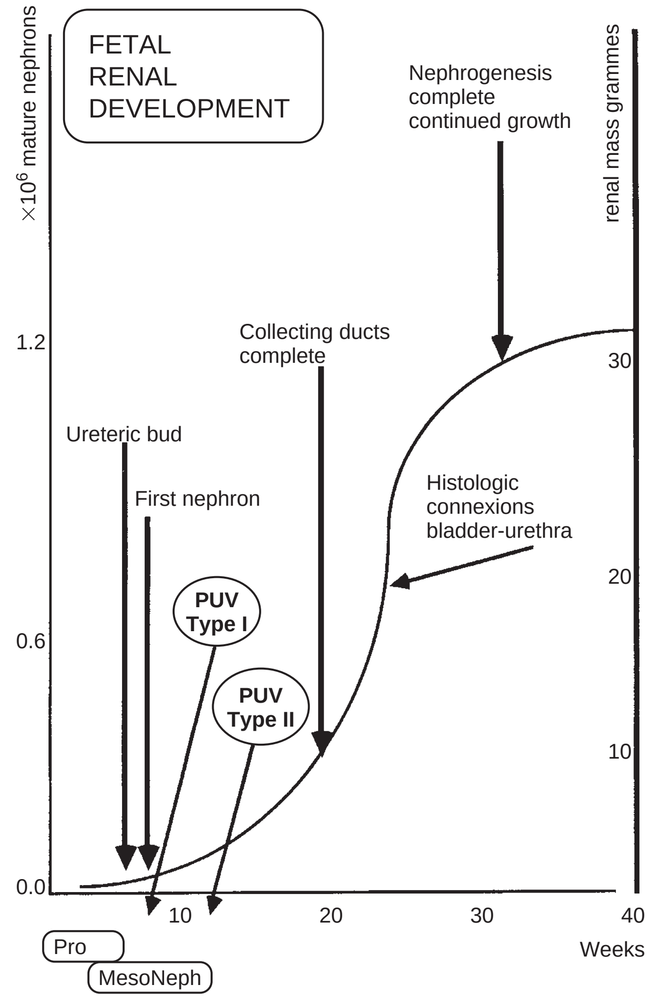

**FIGURE 112-2** Chronology of development of the urinary tract. PUV, posterior urethral valves.

## THORACIC KIDNEY

Thoracic kidneys (Fig. 112-4, *A* and *B*) are rare (1 in 16,000)[16–19] and may be related to delayed mesonephric involution (i.e., persistence of the nephrogenic cord).[20] Thoracic kidneys may be associated with cardiovascular, pulmonary, diaphragmatic,[21,22] and spinal anomalies.[23,24]

## ASSOCIATED ABNORMALITIES

Ectopic kidneys are often associated with genital and contralateral urinary abnormalities such as the absence of a vagina,[25] retrocaval ureter,[26] bicornuate uterus, supernumerary kidney,[27] and contralateral ectopic ureter.[28] An ectopic kidney can be a component of a more complex syndrome such as the Mayer-Rokitansky-Küster-Hauser syndrome,[29–31] Fanconi anemia,[31,32] or conjoined twins.[33] Cephalad kidneys have also been reported in patients with omphaloceles.[34]

## DIAGNOSIS OF ECTOPIC KIDNEYS

Ectopic kidneys may be an incidental finding that requires no surgery or may be associated with impaired drainage or reflux that may require surgical correction. Isotope studies, antenatal and postnatal ultrasonography, magnetic resonance imaging (MRI) (Fig. 112-5), and intravenous urography usually allow identification of the ectopic renal parenchyma. These investigations can be complemented by retrograde contrast studies when required. Computed tomography (CT) has been reported as a possible method for identifying ectopic renal tissue, especially in the thoracic cavity.[17] An ectopic kidney can be suspected antenatally, especially if the abnormality is associated with some degree of dilatation.

# Anomalies Related to Abnormal Fusion of the Kidneys

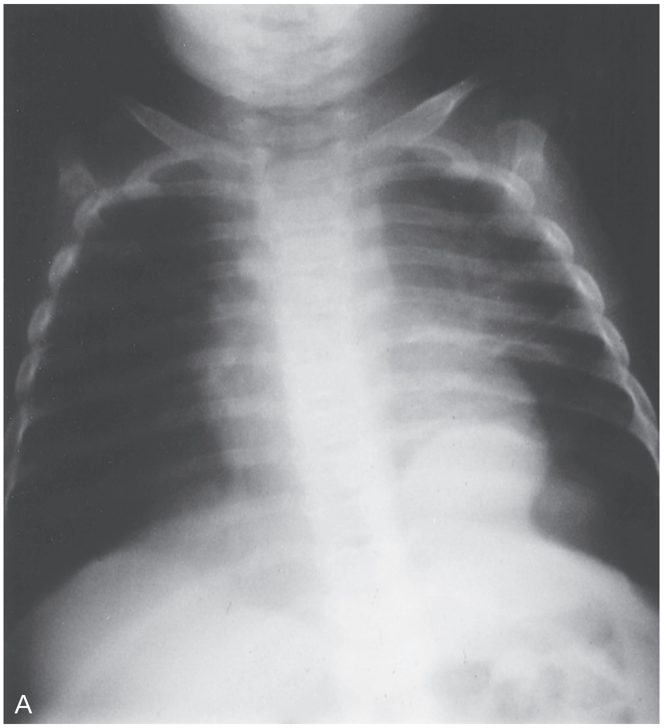
## HORSESHOE KIDNEY

A horseshoe kidney is the most common fusion defect of the kidneys. The incidence of horseshoe kidneys (Figs. 110-6, *A* and *B* and 110-7, *A* and *B*) varies from 1 in 400 [35] to 1 in 1800 [36] autopsies. The condition is more common in male patients. Horseshoe kidney and other renal fusion abnormalities such

FIGURE 112-3 Pelvic kidney. (Courtesy Professor I. Gordon, Department of Radiology, Great Ormond Street Hospital, London.)

as crossed ectopia have been reported to occur in more than one member of a family including apparently identical twins. These findings suggest a genetic influence.[37–39] In 95% of cases, the lower poles of the two kidneys are joined by a bridge of renal tissue that can be either normal renal tissue or dysplastic or fibrous tissue. In approximately 40% of cases, the isthmus lies at the level of L4, just beneath the origin of the inferior mesenteric artery; in 20% of cases, the isthmus is in the pelvis; and in the remaining cases, it lies at the level of the lower poles of normally placed kidneys.[25] Although the isthmus usually passes anterior to the great vessels, it may pass posterior to the aorta or inferior vena cava.[40] It is postulated that the inferior mesenteric artery obstructs the isthmus and prevents further ascent. A few horseshoe kidneys have fusion at their upper poles. Ureters arch anteriorly to pass over the isthmus.[41] The blood supply of horseshoe kidneys varies considerably, a fact that must be borne in mind at the time of surgery: 30% of patients have a renal blood supply that consists of one renal artery for each kidney. However, the supply may be asymmetric, with duplicate or even triplicate vessels. The isthmus may be supplied by the aorta or by the renal, inferior mesenteric, common or external iliac, or sacral arteries. In addition, the entire blood supply may enter through the isthmus.[42] Duplication of the horseshoe kidney and communicating renal duplication have also been mentioned in previous reports.[43,44] One part of the horseshoe kidney may be dysplastic and nonfunctioning.[45]

Associated abnormalities are common and occur in 78% of cases.[46,47] The most common involve the central nervous system, gastrointestinal tract, and skeletal and cardiovascular systems. In children with trisomy 18, the incidence of fused kidneys is 20%.[48,49] More than 60% of patients with Turner syndrome have renal abnormalities[50] including horseshoe kidneys (7%).[51,52] Horseshoe kidneys can be complicated later in life by aortic aneurysms.[53]



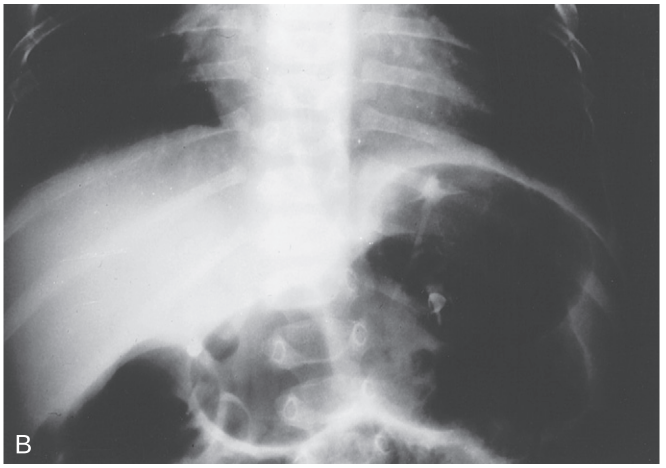


FIGURE 112-4 **A** and **B,** Thoracic kidney (intravenous urography). (Courtesy Professor I. Gordon, Department of Radiology, Great Ormond Street Hospital, London.)

Horseshoe kidneys are diagnosed with the same investigations mentioned earlier; isotopic studies usually give the clearest information. On intravenous urography, the diagnosis is clearly indicated by malrotation of each kidney with a projection of the calices medially to the renal pelvis, a renal axis that is more vertical or shifted outward, and the low position of the excretory cavities. The course of the ureters varies, but their upper segments seem to be laterally displaced by the parenchymal bridge. Association with a dilated renal pelvis is common and due to either anterior projection of the ureter (which can be kinked) or obstruction of the pyeloureteric junction caused by an anomaly of the junction itself or the disposition of the blood vessels around the junction. It is usual in these cases for the horseshoe kidney to be associated with some degree of impaired urine flow, and thus the diagnosis can be suspected antenatally. Vesicoureteric reflux is also commonly associated with horseshoe kidneys (10% to 80% of cases).[43,52,54]

FIGURE 112-5 Magnetic resonance image of a pelvic kidney *(arrow)*. (Courtesy Professor J. P. Pracros, Department of Radiology, Debrousse Hospital, Lyon, France.)

The prognosis of patients with horseshoe kidneys depends on the associated anomalies. Most horseshoe kidneys are asymptomatic throughout life. However, associated hydronephrosis, reflux, lithiasis, or dysplastic tissue may lead to surgical intervention because of recurrent urinary tract infections, pain, or hematuria. A horseshoe kidney carries a conceivably increased risk for nephroblastoma and an approximately threefold to fourfold higher risk for cancer of the renal pelvis.[55,56] Overall, the risk of Wilms tumor in a horseshoe kidney is approximately twice that of the normal population. Tumors that arise, mostly in the bridge of a horseshoe kidney, can mimic the symptoms of an intra-abdominal disease process. A parenchymatous renal isthmus that is the result of an abnormal migration process may be predisposed to the development of renal cell carcinoma.[51] The risk for primary renal carcinoid tumor is even greater, and it might arise from neuroendocrine cells within foci of metaplastic or teratomatous epithelium within the kidney.[57] Association with ganglioneuroblastoma has also been reported.[58] Although these tumors have a higher risk in a horseshoe kidney, the frequency does not justify routine surveillance. An infected caliceal diverticulum can be associated with this malformation.[59] Xanthogranulomatous pyelonephritis in a horseshoe kidney is another possible, though a rare complication that represents a response of the parenchyma to chronic infection.[60]

Robotic, laparoscopic, or open correction[61–63] of ureteropelvic junction obstruction is the most frequent indication for surgical intervention in a patient with a horseshoe kidney. Division of the isthmus is no longer recommended in most cases because the isthmus probably does not contribute to the obstruction.[64] If the position of the kidney is within normal limits and the procedure is unilateral, the traditional

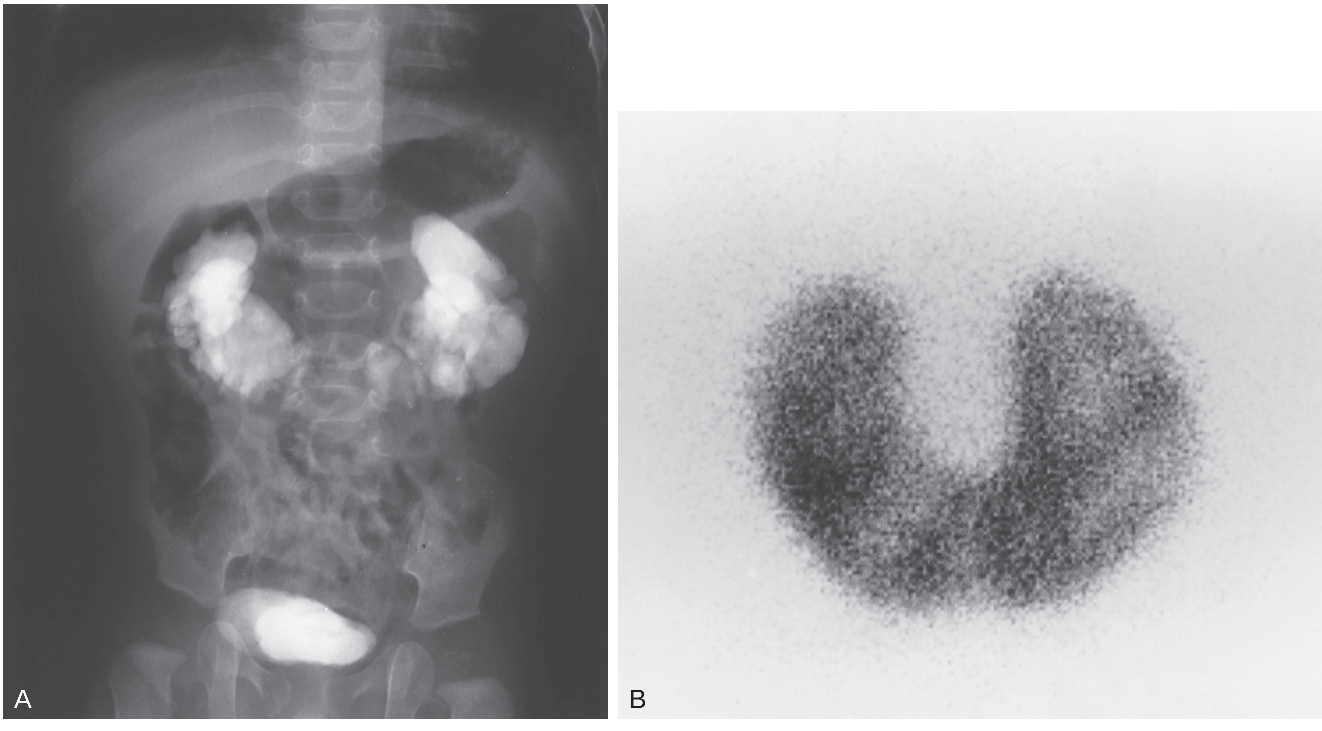

FIGURE 112-6 Horseshoe kidney. **A,** Intravenous urogram. **B,** Dimercaptosuccinic acid [DMSA] scan. (Courtesy Professor I. Gordon, Department of Radiology, Great Ormond Street Hospital, London.)

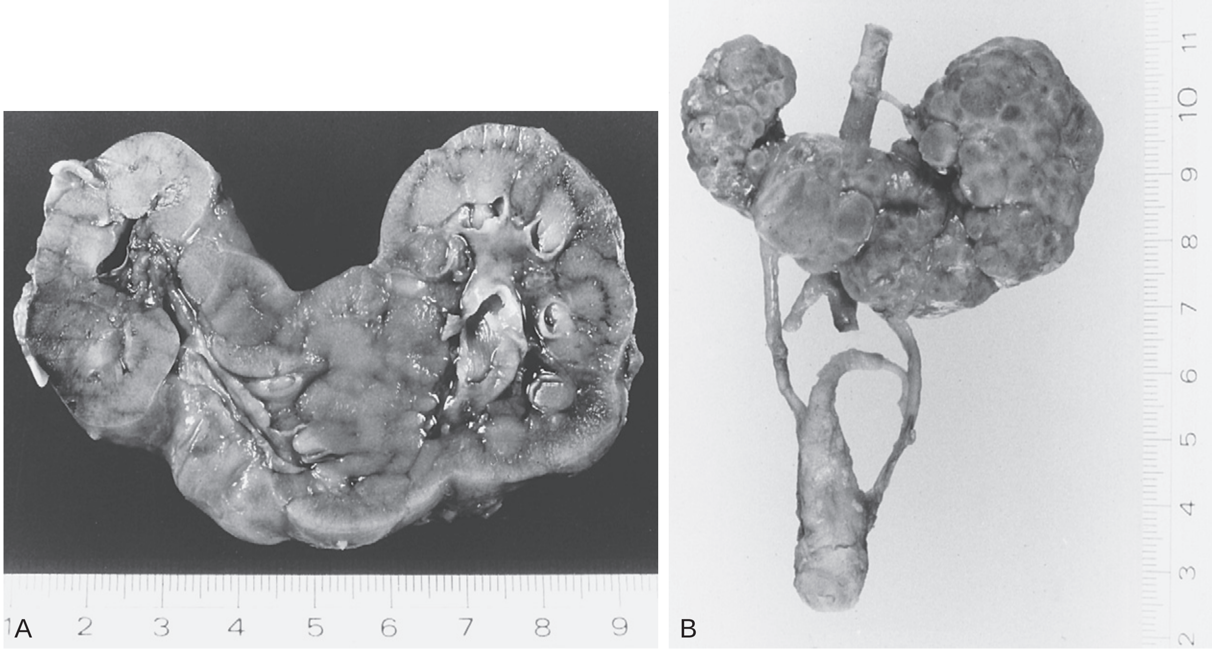

**FIGURE 112-7** **A** and **B,** Horseshoe kidney pathology specimens. (Courtesy Professor A. R. Risdon and Dr. G. Anderson, Department of Histopathology, Great Ormond Street Hospital, London.)

anterolateral extraperitoneal approach is recommended. If the kidney has a more awkward position or if the procedure is bilateral, a transperitoneal approach is preferable. Ureterocalicostomy is an excellent alternative for achieving dependent drainage of the urinary tract.[65] Endopyelotomy is another alternative but is best reserved for older children[66] because the recurrence rate is relatively high. Urolithiasis develops in 20% of patients with a horseshoe kidney[15] and can usually be treated by extracorporeal shock wave lithotripsy or percutaneous surgery. Laparoscopic heminephrectomy for benign disease of a horseshoe kidney is an elegant option for experienced surgeons.[67] Experienced surgeons are required because of the increased incidence of visceral and vascular surgery associated with these anomalies.[61,63]

## CROSSED RENAL ECTOPIA

Crossed renal ectopia (Fig. 112-8, *A* and *B*) is the second most common fusion anomaly after horseshoe kidney.[15] Its incidence is around 1 in 7000 autopsies. There are four varieties of crossed renal ectopia: (1) with renal fusion (85% of cases), (2) without fusion (<10%), (3) solitary, and (4) bilateral.[1,68,69] It has a slight male preponderance, and crossing from left to right occurs more frequently than from right to left. The fusion is usually located between the upper pole of the crossed kidney and the lower pole of the normally positioned kidney (unilateral fused type). The renal pelvises remain in their anterior position with incomplete rotation. In the sigmoid or S-shaped kidney, the fusion is the same but both kidneys have completed their rotation; thus the two renal pelvises face in opposite directions. Various degrees of fusion have also been reported rarely (e.g., lump kidney, L-shaped kidney, and superior ectopic kidney).[15] Pseudo-crossed renal ectopia secondary to ureteropelvic obstruction has likewise been reported.[70] Intravenous urography, isotopic studies, ultrasonography, MRI, and CT allow definition of the anatomic type of ectopia. This process is often difficult, however. The vascular supply varies and may also cross the midline.[71] Most cases of crossed renal ectopia are discovered incidentally and are asymptomatic. When surgery is indicated, laparoscopy may have some targeted indications for crossed fused renal ectopia.[72]

Associated anomalies are common including orthopedic and skeletal abnormalities, imperforate anus, cardiovascular anomalies,[1,73] genital anomalies,[68,74] spina bifida,[86] vesicoureteric reflux, reflux nephropathy,[75] crossed ectopic ureter, multicystic dysplasia,[76] renal tumors,[77,78] incarcerated ureter,[79] retrocaval ureter,[26] and testicular tumor.[80] Renal ectopia may also be a component of more complex syndromes such as vertebral abnormalities, anal atresia, cardiac abnormalities, tracheoesophageal fistula and/or esophageal atresia, renal agenesis and dysplasia and limb defects (VACTERL) syndrome[81]; agenesis of the corpus callosum[82,83]; and caudal regression. The complexity of some of these anomalies can explain some of the complications reported such as accidental ureteral ligation during repair of an inguinal hernia in a patient with crossed fused renal ectopia.[84]

# CHAPTER 113

# Ureteropelvic Junction Obstruction

Travis W. Groth and Michael E. Mitchell

Hydronephrosis is defined as dilation of the renal collecting system. Clinically, this may result from obstruction or reflux of urine. The physiology of obstruction (hydronephrosis) is complex resulting from interactions between glomerular hemodynamics and alterations in tubular function.[1] In children, hydronephrosis is typically discovered during maternal-fetal ultrasound and accounts for approximately 0.5% to 0.6% of all uropathies seen in the neonatal period. However, one in five neonates with the prenatal diagnosis of hydronephrosis will demonstrate spontaneous resolution of the hydronephrosis.[2] In the neonates with persistent hydronephrosis, ureteropelvic junction (UPJ) obstruction represents 44% of all postnatal causes of hydronephrosis.[3] UPJ obstruction is, therefore, the leading cause of postnatal hydronephrosis.

The natural history of hydronephrosis secondary to UPJ obstruction varies. High-grade UPJ obstruction results in hydrostatic distention, increased intrapelvic pressure, and poor outflow of urine. Chronic increases in intrapelvic pressure can result in irreversible damage to the kidney. However, with low-grade UPJ obstruction, the developing kidney can remain in a homeostatic state and often shows temporal growth and improvement. Between these two extremes there exists a spectrum of pathology—hence the debate regarding the clinical management of kidneys with UPJ obstruction. The inevitable questions remain, “which patient requires surgical intervention, and which can be observed?”

## Etiology/Incidence

The incidence of UPJ obstruction is 1 in 1250 births.[4,5] It occurs more commonly in males (M/F = 2:1). There is a predilection for the left side in children (66%), whereas the reverse is true for UPJ obstruction of adults.[6–8] Bilateral cases of UPJ obstruction occur in 10% to 36% of patients, with the highest percentage occurring in the younger age group.[6,9]

Koff described two types of UPJ obstruction, intrinsic and extrinsic, discovered at the time of surgical exploration (Fig. 113-1).[10] The most common UPJ obstruction is the *intrinsic type*, classically known as the “adynamic” segment. This adynamic segment interferes with the proximal ureteral peristalsis. At surgery, these segments are of variable length and usually narrower than the rest of the ureter. Additionally, these segments are poorly distensible but are typically probe patent. Histologically, they are deficient in circular muscle fibers, which tend to be disorganized and dysmorphic.[11,12]

The second type of UPJ obstruction is the *extrinsic type,* typically related to such mechanical factors as crossing vessels, adhesive bands, arteriovenous malformations, and uretal folds.[13,14] Extrinsic factors create an abrupt angulation by kinking or compressing the UPJ, which leads to obstruction of urine flow and progressive hydronephrosis. Similarly, Östling described pleatlike ureteral folds that occur at the level of the UPJ (Fig. 113-2).[14] Teleologically, these folds are thought to allow the dramatic increase in axial growth that children experience during the first 2 years of life. Östling folds are typically not felt to be obstructive and tend to disappear with patients’ increase in linear growth; however, if persistent, they can result in obstruction.

Aside from the intrinsic and extrinsic types of UPJ obstruction there are *intraluminal* causes of proximal ureteral obstruction, which include ureteral valves and benign fibroepithelial polyps.[15,16] Both lead to partial, intermittent obstruction and typically require surgical intervention (Fig. 113-3).[17]

Another way to characterize types of obstructive processes is by their volume-dependent (extrinsic) and pressure-dependent (intrinsic) characteristics.[10,18] Experimental and clinical observations led Koff to conclude that these parameters, or a combination thereof, may explain the many differences observed in the clinical spectrum of UPJ obstruction.[18]

## Embryology

During human embryogenesis, there are three sequential and interdependent kidney systems: the pronephros, mesonephros, and metanephros or definitive kidney. The earliest and most transient kidney is the pronephros. Sequentially the pronephros is replaced by the mesonephros by the third week of gestation. The mesonephros elongates to form a tubular structure, which eventually forms the caudal end of the mesonephric, or wolffian, duct. At the fifth week of gestation, the

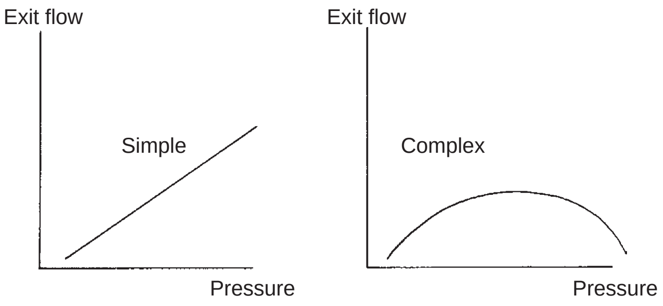

FIGURE 113-1 Diagrammatic representation of simple and complex pressure-flow patterns in human hydronephrosis. (From Koff SA: Pathophysiology of ureteropelvic junction obstruction: Clinical and experimental observations. Urol Clin North Am 1990;17:269.)

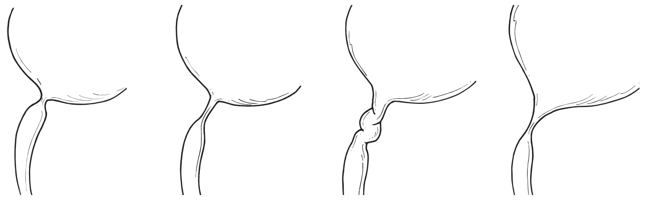

FIGURE 113-3 Ureteropelvic junction obstruction secondary to stenosis: simple, segmented, serpiginous, and shelving. (Courtesy Dr. F. Douglas Stephens.) (From Fung LCT, Lakshmanan Y: Anomalies of the renal collecting system: Ureteropelvic junction obstruction [pyelocalyectasis] and infundibular stenosis. In Belman AB, King LR, Kramer SA [eds]: Clinical Pediatric Urology, 4th ed. London, Martin Dunitz, 2002, p 561.)

dorsomedial wall of this ductal system gives rise to a diverticular outgrowth called the ureteric bud. The "ureteric bud" seems to have an important bidirectional inductive role, which results in differentiation of the mesonephric duct (to form the trigone, posterior bladder neck and proximal urethra) and to initiate the development of the metanephrosis into the kidney. Therefore just as the mesonephric system moves into the bladder to form the trigone, posterior bladder neck, and urethra, the ureteric bud elongates in an ascending fashion toward the primitive metanephric anlagen. On contact, the two structures initiate a cascade of events known collectively as *nephrogenesis*. The ureteric bud ultimately forms the ureter, renal pelvis, and calyceal system.

In this developmental process, mechanical obstruction may occur at three different anatomic sites: the pelvocaliceal, ureteropelvic, and ureterovesical junctions.[19] Each of these sites represents a confluence of two or more embryologic structures (i.e., ureter and bladder and ureter and kidney). The cellular and molecular mechanisms are incompletely understood at this time; however, complex cellular "crosstalk" and induction initiated in a bidirectional manner normally

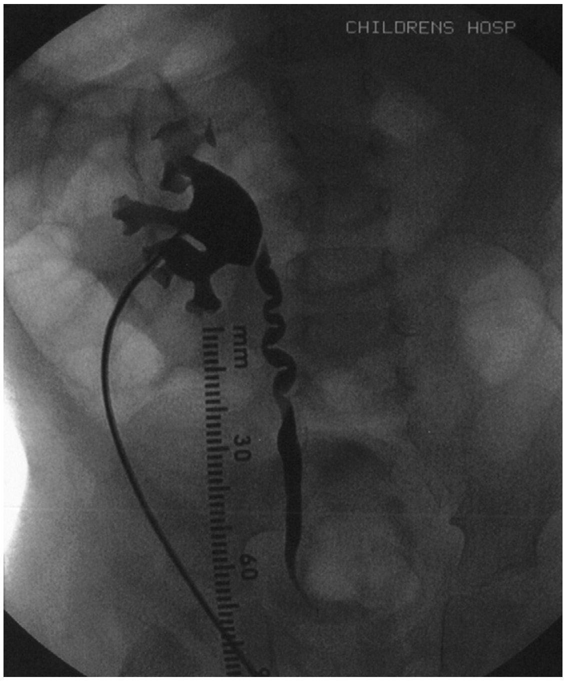

FIGURE 113-2 Percutaneous nephrostogram demonstrating Östling's fetal folds. (Courtesy Children's Hospital and Regional Medical Center, Seattle.)

culminate in appropriate anatomic junctions. However, minor imprecision because of the inherent variables of the process can result in two of the more common pathologic conditions in pediatric urology, namely, vesicoureteral reflux (VUR) and UPJ obstruction.

At one time it was thought that bidirectional recanalization of the ureter explained the frequent obstruction at the last segments to recanalize the UPJ and ureterovesical junction (UVJ).[20] More recently, however, it has been shown that bidirectional recanalization does not occur. Recanalization occurs only at the middle portion of the ureter.[21] None of the current experimental models or theories of ureteral development explain why the UPJ is the most common site of congenital ureteral obstruction. This continues to be an active area of research. For example, a new study using an animal model of obstructive nephropathy has reported a possible genetic component of hydronephrosis.[22] Chang and colleagues[22] describe a mouse model in which the gene encoding the calcineurin B type 1 isoform (Cnb1) has been deleted from the mesenchyme lining the urinary system. Hydronephrosis develops in these animals because of the lack of peristalsis. This study not only points to the renal pelvis as a regulator of peristalsis but may also explain congenital obstruction in which no obvious physical obstruction is identified.

Recently, Wang and colleagues[23] examined the role of bone morphogenic protein 4 (BMP4) signaling by examining a BMP4 murine knock-out mouse model. Antagonism of BMP signaling with Nogin protein inhibited ureteral smooth muscle formation around the ureter and localized antagonism of BMP signaling demonstrated similar histologic findings as intrinsic UPJ obstruction from an adynamic segment.[23] Even though these data support a molecular cause for UPJ obstruction, there has yet to be one molecular theory explaining how and why different UPJ obstructions form.

## Clinical Features

UPJ obstruction can affect infants, adolescents, or adults. The presentation of each differs. Typically, infants are asymptomatic and are now diagnosed by prenatal ultrasonography. Thirty years ago, however, most infants with UPJ obstruction were initially diagnosed with a palpable abdominal mass at initial evaluation or, less often, on workup for urinary tract infection, failure to thrive, feeding difficulties, and nephrolithiasis.[7] With the advent of prenatal fetal ultrasonography, most infants born with UPJ obstruction are detected antenatally. The other population in which UPJ obstruction is detected

consists of children with a variety of symptoms. Accordingly, there seems to be a bimodal age distribution of UPJ obstruction: asymptomatic postnatal infants and symptomatic school-aged children.

## ANTENATAL MANIFESTATIONS

At the eighth week of intrauterine life, fetal urine is produced by the mesonephros. Once this transient kidney regresses, urine is made by the metanephros and continues to be made throughout gestation. Fetal urine production increases from 5 mL/hr at 20 weeks gestation to a rate that may approach 50 mL/hr at 40 weeks of gestation.[24] Thus maternal-fetal sonography should initially be performed between 16 and 20 weeks of gestation when adequate urine production has been established.[25] Most centers performing maternal-fetal ultrasound can detect normal kidneys at 17 to 19 weeks, whereas markedly dilated collecting systems can be identified as early as 12 to 14 weeks.[26]

The first report of antenatally detected urinary tract anomalies was in 1970.[27] Since that time, the American Institute for Ultrasound in Medicine's Bioeffects Committee has concluded that prenatal ultrasound screening is safe. This endorsement has led to the common practice by obstetricians, as well as the expectation by the general population, that screening ultrasound be performed during the second trimester. Despite the fact that protocols for maternal-fetal ultrasonography continue to evolve in this country, they still depend in part on specific conventions and random institutional idiosyncrasies.[4]

Prenatal ultrasound can detect hydronephrosis and abnormal anatomy, but it is not specific for the diagnosis of particular disease processes. Sonographic features suggestive of UPJ obstruction include (1) unilateral or, less frequently, bilateral pelviectasis; (2) normal amniotic fluid volume; (3) no evidence of ipsilateral ureteral dilation; and (4) normal thickness of the bladder wall and normal cycling of the bladder. In cases in which the classic features of hydronephrosis are established, the diagnosis of UPJ is straightforward. Differentiation between true obstructive uropathy and transient hydronephrosis of the neonate is not possible. Additionally, prenatal ultrasound cannot distinguish between UPJ obstruction and multicystic dysplastic kidney (MCDK). Sequential renal ultrasound and other complementary radiographic imaging studies may be required for follow-up.

The Society of Fetal Urology (SFU) organized consensus guidelines for grading different degrees of hydronephrosis (Table 113-1) (Fig. 113-4A to D).[28,29] Once these in utero criteria are established, a prenatal diagnosis of hydronephrosis with a possibility of UPJ obstruction should be entertained by the physician and reported to the parents. In

**TABLE 113-1**
**Society of Fetal Urology (SFU) Grading of Hydronephrosis**

| *SFU Grade* | *Description* |
|---|---|
| 1 | Slight splitting of the central renal complex without calyceal involvement, normal parenchyma |
| 2 | Splitting of the central renal complex with extension to nondilated calyces |
| 3 | Wide splitting of the renal pelvis, dilated outside the renal border, calyces uniformly dilated, normal parenchyma |
| 4 | Large, dilated calyces (may appear convex); thinning of the parenchyma to ≤50% of the ipsilateral (normal) kidney |

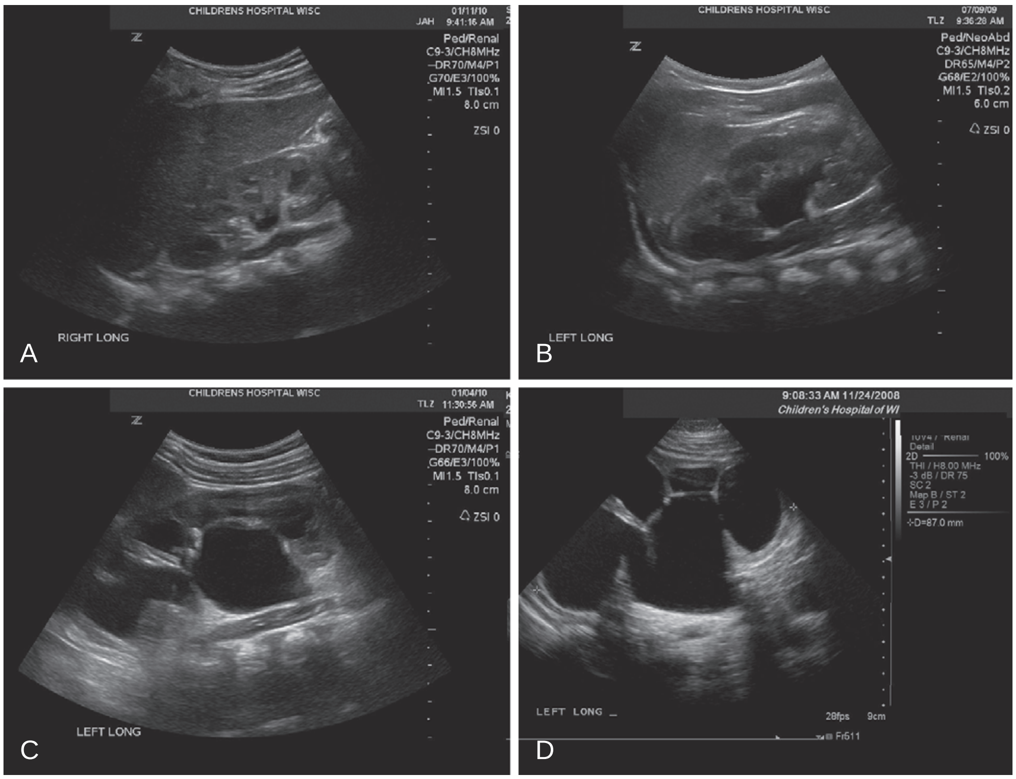

**FIGURE 113-4** Renal ultrasound scans representing the Society for Fetal Urology (SFU) grading schema. **A,** SFU grade 1 hydronephrosis. **B,** SFU grade 2 hydronephrosis. **C,** SFU grade 3 hydronephrosis. **D,** SFU grade 4 hydronephrosis. (Courtesy Children's Hospital of Wisconsin, Milwaukee.)

male fetuses, however, bilateral hydronephrosis should be considered to be a different and more urgent problem relating to bladder outlet obstruction, possibly caused by posterior urethral valves.

### PRENATAL COUNSELING

Parents should be advised of a presumptive diagnosis of hydronephrosis and counseled appropriately. Education and communication are paramount in the process of prenatal counseling. Fortunately, the majority of antenatally detected genitourinary abnormalities are unlikely to require postnatal surgical intervention.[30,31] In fact, only 1% to 25% require surgery at 4 years of follow-up.[32,33] However, referral to a pediatric urologist for prenatal counseling is highly recommended. The survival rate for fetuses found to have unilateral hydronephrosis secondary to obstruction is virtually 100%. Postnatal follow-up is essential to track progression or resolution of hydronephrosis, as well as establish the management principles with the family. For this reason, referral to a pediatric urologist is highly recommended.

### POSTNATAL MANIFESTATIONS

Although often asymptomatic, children with UPJ obstruction may have variable symptoms such as episodic flank, abdominal pain, or less commonly a urinary tract infection. Cyclic abdominal pain, often associated with vomiting, is a classic finding (Dietl crisis*) usually observed in older patients. UPJ obstruction can also be an unsuspected diagnosis made after evaluation for vague and often chronic abdominal symptoms, frequently referred from the pediatric gastroenterologist after an ultrasound had been performed. UPJ obstruction may be associated with renal calculi with an incidence of nephrolithiasis 17 times higher in patients with UPJ obstruction.[34] Hematuria may also be the initial symptom in UPJ obstruction. Trivial trauma can cause friable mucosal vessels in the dilated collecting system to rupture. Left-sided UPJ obstruction can be associated with the insidious manifestation of anorexia and failure to thrive. These children are typically found to have a left UPJ obstruction. The dilated left renal pelvis creates a mass effect on the stomach that results in early satiety, anorexia, and vomiting. Still other children with UPJ obstruction may have profound urosepsis. Snyder and colleagues[6] reported that urinary tract infection is the initial sign in 30% of children with UPJ obstruction beyond the neonatal period (Table 113-2).

## Diagnosis

Because hydronephrosis can be caused by multiple etiologies, it is helpful to try and categorize hydronephrosis into obstructive versus nonobstructive causes. Obstructive causes of hydronephrosis include UPJ obstruction (44% incidence); UVJ obstruction (21% incidence); MCDK, ureterocele, and duplicated collecting systems (12% incidence); posterior urethral valves (9% incidence); and ectopic ureter, urethral atresia, sacrococcygeal teratoma, and hydrometrocolpos. Nonobstructive causes of hydronephrosis include VUR (14% incidence), physiologic dilation, prune-belly syndrome, renal cystic diseases, and megacalicosis (Table 113-3).[35,36]

Although it is easy to diagnose hydronephrosis, it is, unfortunately, difficult to prove obstruction. Furthermore, there has yet to be one diagnostic method that has been able to differentiate significant obstruction from insignificant obstruction in an infant. None of the existing imaging modalities can accurately predict which hydronephrotic kidney is at risk for progressive damage and loss of renal function. With this limitation in mind, sequential radiographic studies can be used to define change that may indicate physiologically significant UPJ obstruction that might require surgical intervention.

### INTRAVENOUS UROGRAPHY

Historically, intravenous urography (IVU) was the radiographic modality of choice for noninvasive assessment of the urinary tract. As an imaging study, it combines anatomic accuracy with qualitative information regarding renal function and obstruction. IVU is now infrequently used in the assessment of a pediatric patient with obstructive uropathy and has been replaced by sonography and scintigraphy. Obstruction, on IVU, of the kidney may be inferred from delay in the appearance of contrast material or a negative nephrogram, a delay in drainage, dilution of contrast medium, or uniform cortical loss.

**TABLE 113-3**
**Differential Diagnosis of Hydronephrosis**

| *Obstructive* | *Nonobstructive* |
|---|---|
| Ureteropelvic junction obstruction | Vesicoureteral reflux |
| Ureterovesical junction obstruction | Physiologic dilatation |
| Multicystic dysplastic kidney | Prune-belly syndrome |
| Ureterocele | Renal cystic diseases |
| Duplicated collecting system | Megacalycosis |
| Posterior urethral valves | |
| Ectopic ureter | |
| Urethral atresia | |
| Sacrococcygeal teratoma | |
| Hydrometrocolpos | |

*Jozef Dietl (1804-1878), a Polish physician, described a syndrome characterized by violent paroxysms of colicky flank pain, nausea, chills, tachycardia, oliguria, transient hematuria or proteinuria, and a palpable enlarged tender kidney that was attributed to acute hydronephrosis caused by kinking or vascular obstruction of the ureter of a floating kidney.

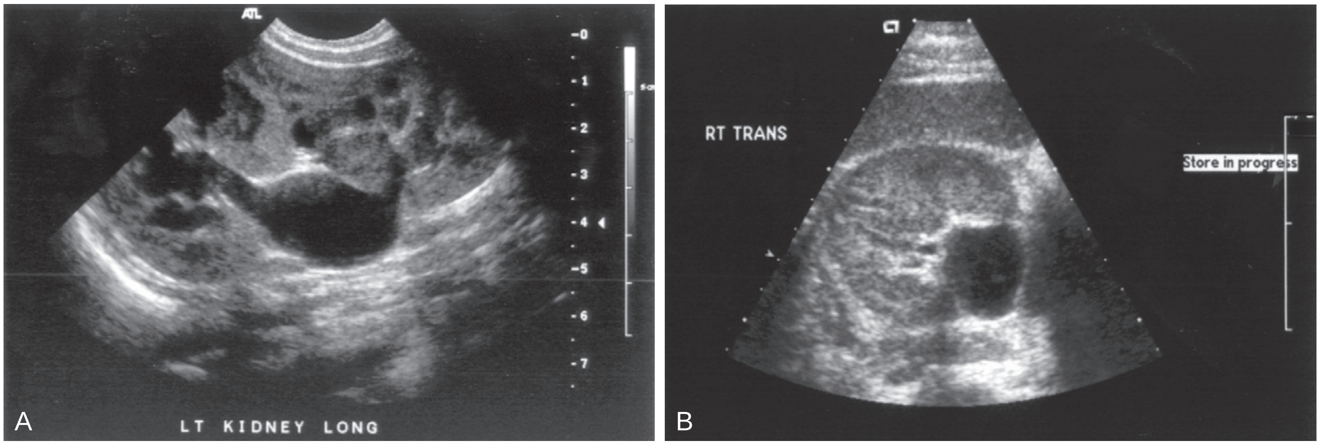

**FIGURE 113-5** **A,** Renal ultrasound representing an obstructed ureteropelvic junction with an intrarenal pelvis. **B,** Renal ultrasound of a nonobstructed extrarenal pelvis. (Courtesy Children's Hospital and Regional Medical Center, Seattle.)

## RENAL ULTRASOUND

Renal ultrasound is a widely available, relatively inexpensive, noninvasive, safe test that provides adequate anatomic visualization without radiation exposure. Given these exceptional qualities, it is widely used both in maternal-fetal sonography and for postnatal imaging. Consequently, renal sonography has resulted in the increased diagnosis of prenatal and postnatal dilation of the upper urinary tract. In fact, renal ultrasound is the most commonly performed initial study for the postnatal evaluation of neonates who have been discovered prenatally to have hydronephrosis. Renal ultrasound is highly accurate in the diagnosis of hydronephrosis. It provides information on findings characteristic of UPJ obstruction including pelviectasis and caliectasis, absence of ureterectasis, normal bladder filling and emptying (cycling), and normal bladder thickness. In unilateral cases of hydronephrosis, ultrasound may delineate parenchymal atrophy on the affected side in comparison with the contralateral side.

Twenty-five years ago, the general consensus among pediatric urologists had been that the amount of hydronephrosis did not correlate with the degree of obstruction. Ransley and colleagues[33] finally established this fact. In their study, progressive hydronephrosis and deterioration in renal function were uncommon in neonates and infants with a maximum anteroposterior renal pelvic diameter of less than 10 mm and no evidence of infundibular or caliceal dilation (SFU grade 1 hydronephrosis). All the patients initially in the nonoperative group who eventually required surgery had a prenatal anteroposterior renal pelvic diameter of greater than 12 mm. However, renal pelvic diameter, alone, was found to be a poor positive predictor of outcome because only 34% of such patients required pyeloplasty. In some of these patients, perhaps, such mild degrees of hydronephrosis are probably physiologic, secondary to the highly compliant nature of the fetal (and neonatal) renal pelvis. An extrarenal pelvis or lucent pyramids of infancy can be mistaken for pathologic hydronephrosis (Fig. 113-5A and B, Fig. 113-6); however, caliceal dilatation is typically *not* present in these patients. An extrarenal pelvis, therefore, is considered to be a variation of normal.

Koff and colleagues[37] proposed the use of serial renal ultrasound to predict progression in unilateral cases of UPJ obstruction. In addition to being able to monitor the temporal behavior of UPJ obstruction, serial renal ultrasound provides

**FIGURE 113-6** Renal ultrasound of normal infant kidney with lucent pyramids, which can be confused with calyceal dilation. (Courtesy Children's Hospital of Wisconsin, Milwaukee.)

the ability to track the axial growth of the kidneys as an indicator of progression of UPJ obstruction. In cases of unilateral UPJ obstruction, the growth rate of the contralateral normal kidney can be used as a comparison standard.[38] With the use of renal growth–function nomograms, compensatory hypertrophy in the contralateral "normal" kidney may be indicative of progressive obstruction in the hydronephrotic kidney. Conversely, a slower than normal growth rate (compensatory hypertrophy) in the normal kidney suggests rapid recovery of function (or even supranormal function) in the unilaterally hydronephrotic kidney and would imply that obstruction is not present. Koff's data, however, have not been corroborated because of operator variability in renal length measurements.

Serial ultrasound studies are important for implementing any protocol for UPJ obstruction, but they can be problematic because they require a waiting period during which progressive renal injury can occur. For example, cortical thinning, an important finding, may develop but is typically a late irreversible finding. Focal cortical loss is easier to detect, though less common than global cortical thinning. Reflecting on Koff and colleagues' study, it is logical to conclude that in patients with unilateral hydronephrosis, contralateral compensatory renal

hypertrophy may indicate a greater risk for continued deterioration of the hydronephrotic kidney.[37] However, reliable sonographic diagnosis of renal hypertrophy requires multiple sequential measurements of renal length or volume, thus limiting its applicability for guiding early intervention.[39]

In summary, renal ultrasound is highly accurate in the diagnosis of hydronephrosis but cannot diagnose obstruction. The degree of hydronephrosis neither specifically indicates the presence or absence of obstruction nor predicts whether the hydronephrosis will improve or progress.[40] A case in point is the neonate, in whom hydronephrosis (by ultrasound) may be transient and is dependent on the degree of hydration and bladder fullness. Most limiting is the fact that ultrasound cannot provide information regarding renal function.

## TECHNETIUM 99m RENAL SCINTIGRAPHY

Differential renal function is one of the most important parameters used in defining significant obstruction and defining the need for surgical correction of congenital UPJ obstruction. It is the present study of choice for estimation of overall and differential renal function. Three radiopharmaceuticals are primarily used in renal scintigraphy, and their characteristics are linked to their biologic activity. Technetium 99m-diethylenetriaminepentaacetic acid ($^{99m}$Tc-DTPA) and technetium 99m-mercaptoacetyltriglycine ($^{99m}$Tc-MAG-3) are preferentially concentrated by the kidney and freely filtered by the glomerulus.[41] **DTPA is neither secreted nor resorbed by the renal tubules, whereas MAG-3 is secreted by the tubules.** Because each is nearly completely excreted, they can be used to estimate differential renal function and urinary drainage. The third agent, technetium 99m-dimercaptosuccinic acid **($^{99m}$Tc-DMSA), is tightly bound to renal tubular cells and is, therefore, useful for the detection of differential renal function and clinically significant cortical lesions such as renal scars.**

At least three consensus statements have been published to decrease the wide clinical variance in protocols: (1) the Society of Nuclear Medicine's Nuclear Medicine *Procedure Guidelines for Pediatric Diuretic Renography,* (2) the *Well Tempered Diuretic Renogram,* and (3) the consensus statement from the Ninth International Meeting of the Society of Radionuclides in Nephrourology, Committee on Diuretic Renography.[42–44] They are all similar in methodology and interpretation. Basically, a collecting system without significant obstruction will have a clearance half-time (i.e., the time for half the radiopharmaceutical to clear) after furosemide administration of less than 10 minutes. Longer than 20 minutes is abnormal and associated with significant obstruction. Clearance half-times between 10 and 20 minutes are considered indeterminate. The half-time should not be the only criterion on which to define obstruction. As in most studies, interpretation requires the use of other available data: curve analysis, differential renal function, and, of course, the clinical context (Fig. 113-7).

Currently, renal scintigraphy is the most popular modality for determining the functional significance of UPJ obstruction, mainly because several investigators have shown that most cases of severe hydronephrosis (SFU grades 3 to 4) demonstrate obstruction on diuretic renography.[28,45] As a result of these studies, the differential renal function of a hydronephrotic kidney, as determined by $^{99m}$Tc-DTPA or $^{99m}$Tc-MAG-3 renal scan, creates an arbitrary threshold for surgical intervention.[46] Thirty-five percent is the pivotal function around which intervention or observation is determined. If the initial ipsilateral differential renal function is greater than

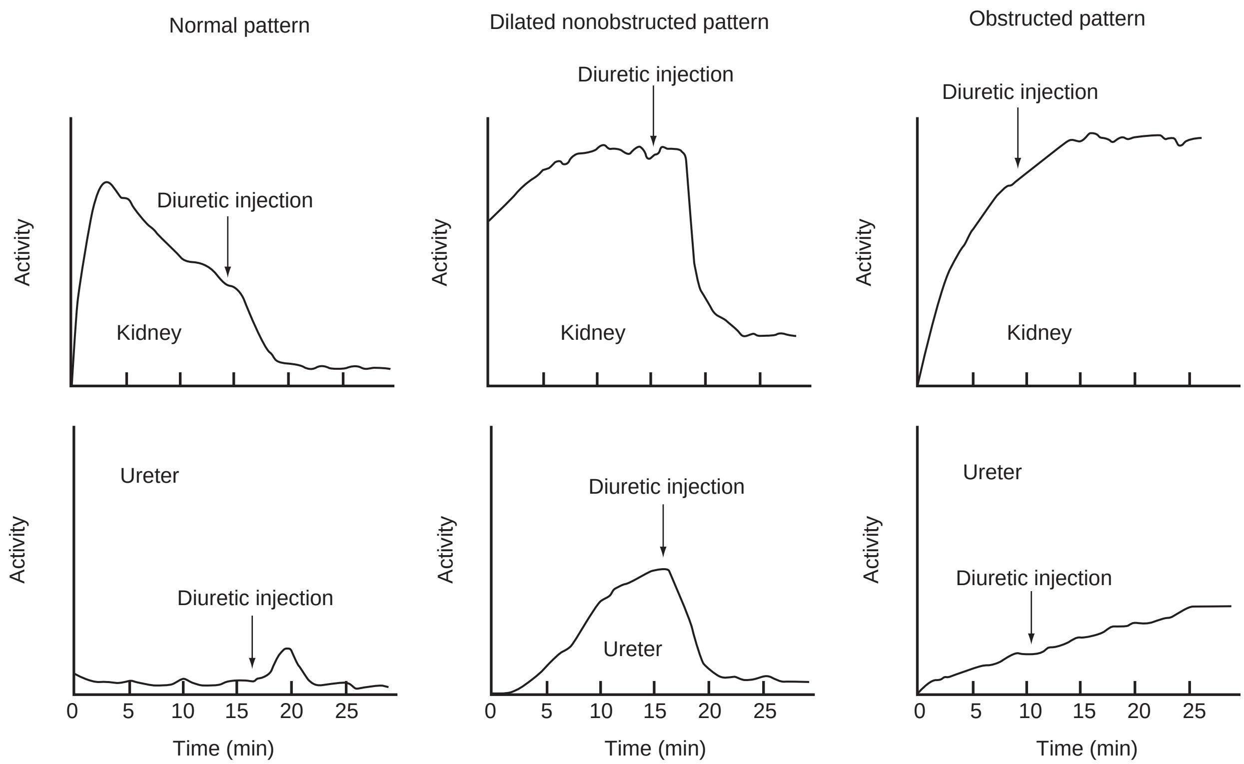

FIGURE 113-7 Lasix renography, classic patterns: normal, dilated nonobstructed, and obstructed. (From Fung LCT, Lakshmanan Y: Anomalies of the renal collecting system: Ureteropelvic junction obstruction [pyelocalyectasis] and infundibular stenosis. In Belman AB, King LR, Kramer SA [eds]: Clinical Pediatric Urology, 4th ed. London, Martin Dunitz, 2002, p 594.)

35%, the neonate may be monitored conservatively by renal ultrasound every 3 months. In contrast, if the differential renal function is less than 35% on the initial study or if there is a decremental change in function of 10% by repeat renal scan, consideration should be given to surgical intervention.[47]

Renal scintigraphy is the study of choice for the estimation of overall and differential renal function, except in patients with poor or immature renal function and those with capacious collecting systems. Other determinates that affect renal scintigraphy include the region of interest, time of measurement, state of hydration, bladder fullness, reservoir effect, type of protocol, renal response to furosemide, and the concept of supranormal function (Fig. 113-8).[42,43,48–51] Supranormal function is defined as greater than 55% of differential renal function in the hydronephrotic kidney in children with unilateral hydronephrosis. It has not been confirmed whether supranormal differential renal function is an artifact or a true finding, nor is there a consensus on how to manage these patients (Fig. 113-9). Oh and colleagues[83] examined supranormal function in human subjects and determined that supranormal function of the ipsilaterally obstructed kidney may not be true hyperfunction but merely a pathologic compensatory mechanism in response to chronic obstruction. For this reason, they warned that interpretation of differential renal function should be made with this caveat in mind. Khan and colleagues[52] believe that supranormal function is an artifact that can be avoided by using MAG-3 and appropriate computer software to account for multiple algorithms.

## VOIDING CYSTOURETHROGRAPHY

It is well known that VUR, the most common problem of the lower urinary tract in children, can coexist with UPJ obstruction, the most common pediatric problem of the upper urinary tract.[53] The exact reason for this association has not yet been established.[54] However, what is known is that approximately 9% to 14% of patients with UPJ obstruction have VUR. Historically, voiding cystourethrography (VCUG) is the standard of practice for the clinical evaluation of all infants with prenatal hydronephrosis, regardless of age or gender.[55,56]

However, several investigators have challenged this standard.[57] In a retrospective review of 106 patients who underwent pyeloplasty for UPJ obstruction, low-grade reflux coexisting with UPJ obstruction spontaneously resolved after pyeloplasty. Additionally, they found that all cases of high-grade VUR coexisting with UPJ obstruction were easily detected by renal ultrasonography. They concluded that VCUG should be limited to children with UPJ obstruction who also have a dilated ureter on ultrasonography. However, patients with a history of febrile UTI and hydronephrosis all should undergo VCUG regardless of dilatated ureter on ultrasonography. Caution should be practiced when evaluating children with this diagnostic dilemma because the approach to management is subtle yet complex.

## MAGNETIC RESONANCE UROGRAPHY

Most recently, dynamic, gadolinium-enhanced magnetic resonance urography (Gd-MRU) has been advocated for its nonionizing radiation and its unparalleled, three-dimensional views of anatomic obstruction. Wen and colleagues[58] used Gd-DTPA-enhanced magnetic resonance imaging in rats and determined that it could distinguish between an obstructed and nonobstructed collecting system. Using a similar technique, Kirsch recently reviewed a cohort of 200 children with hydronephrosis who underwent systematic evaluation

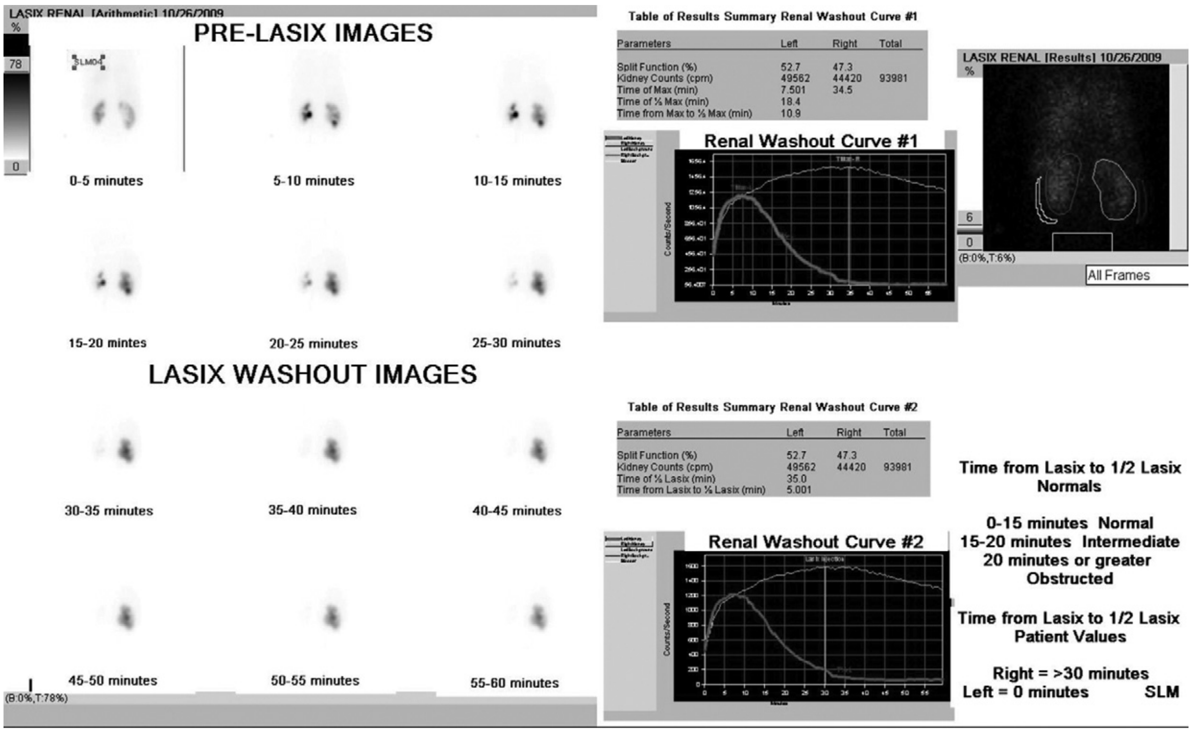

**FIGURE 113-8** MAG-3 lasix renal scintigraphy of a patient with ureteropelvic junction obstruction with delayed washout pattern and excretion of contrast with preserved renal function on the right side. (Courtesy Children's Hospital of Wisconsin, Milwaukee.)

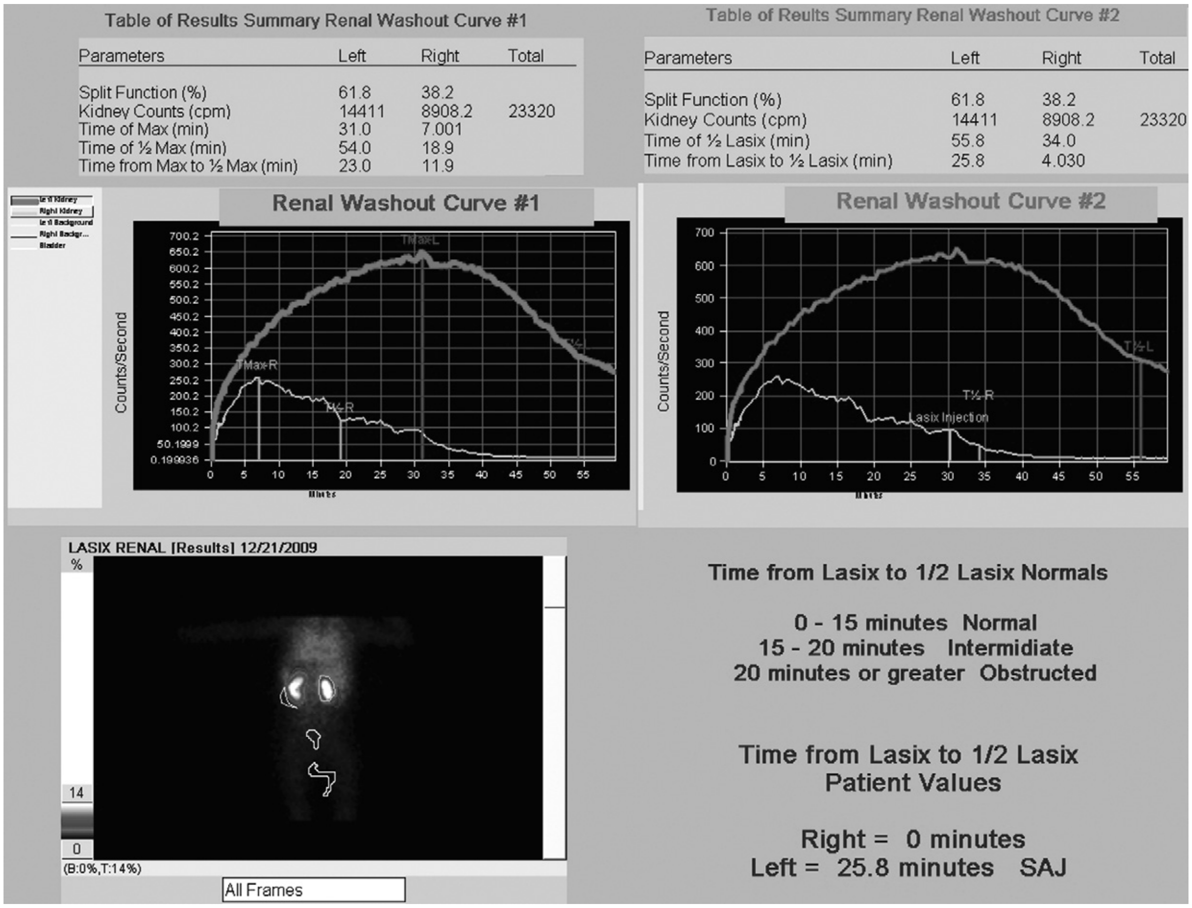

**FIGURE 113-9** MAG-3 lasix renal scintigraphy: Supranormal renal function of a 6-month-old baby who had the SFU grade 3 hydronephrosis, found postnatally to have high-grade left ureteropelvic junction obstruction. (Courtesy Children's Hospital of Wisconsin, Milwaukee.)

**FIGURE 113-10** Three-dimensional maximal intensity projection reconstruction after Gd-DTPA infusion showing classic left ureteropelvic junction obstruction. (From Perez-Brayfield MR, Kirsch AJ, Jones RA, Grattan-Smith JD: A prospective study comparing ultrasound, nuclear scintigraphy and dynamic contrast-enhanced magnetic resonance imaging in the evaluation of hydronephrosis. J Urol 2003;170:1331.)

with Gd-MRU.[59] When compared with sonography and renal scintigraphy, Gd-MRU provided superior anatomic images of the genitourinary system and excellent spatial resolution (Fig. 113-10). The study has been shown to be robust and reproducible with a linear regression coefficient of 0.99. The limitations of the study are that it requires general anesthesia or sedation and involves cumbersome interpretation of the images.[60] Although the technique is not yet widely available, MRU has been considered by some investigators to be a more reliable determinant of renal anatomy and function in cases of UPJ obstruction.

## RETROGRADE PYELOGRAPHY

This radiographic study is rarely necessary to diagnose UPJ obstruction. In a series of 108 children undergoing pyeloplasty, retrograde pyelography (RPG) did not change the surgical approach or planned procedure in any of the cases.[61] However, RPG is still commonly performed before open pyeloplasty. The reason for this is simple. During the diagnostic process, information regarding the exact anatomic location of the UPJ in relation to other anatomic structures is lacking. Therefore to precisely identify the location of obstruction and perhaps exclude the presence of another distal obstruction, RPG is performed (Figs. 113-11 and 113-12).[62]

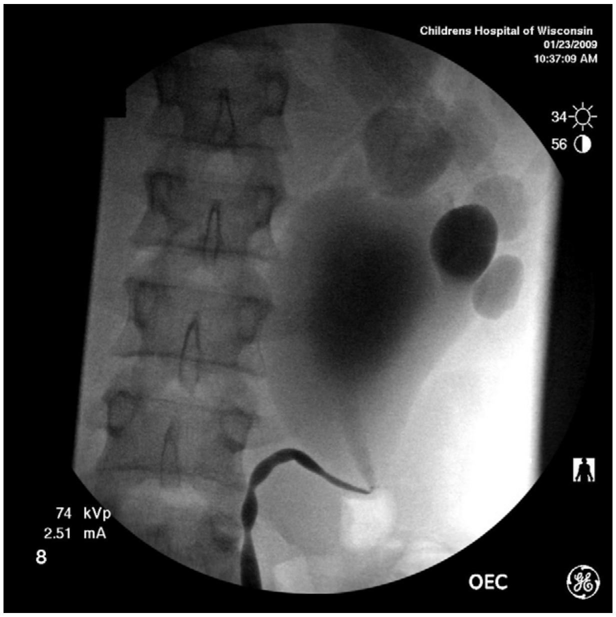

**FIGURE 113-11** Left retrograde pyelogram demonstrating left ureteropelvic junction obstruction. Note the dilation of renal pelvis and small jet of contrast at the ureteropelvic junction. (Courtesy Children's Hospital of Wisconsin, Milwaukee.)

## PRESSURE-FLOW STUDY

The perfusion provocation study, introduced by Bäcklund and colleagues[63] in 1965 and popularized by Whitaker in 1973, is the standard pressure-flow study and is simply referred to as the *Whitaker test* (Fig. 113-13).[64] It detects the resistance of the ureter to a known flow rate by simultaneously measuring manometric pressure between the renal pelvis and bladder. The test is unaffected by the kidney's GRF, and its antegrade pyelography offers excellent anatomic location of the suspected obstructing segment. The study is most useful when

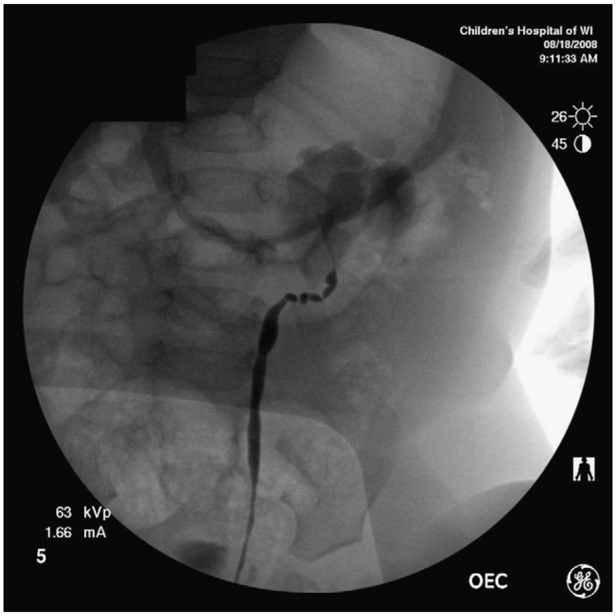

**FIGURE 113-12** Left retrograde pyelogram demonstrating left ureteropelvic junction obstruction along with infantile appearing proximal ureter. (Courtesy Children's Hospital of Wisconsin, Milwaukee.)

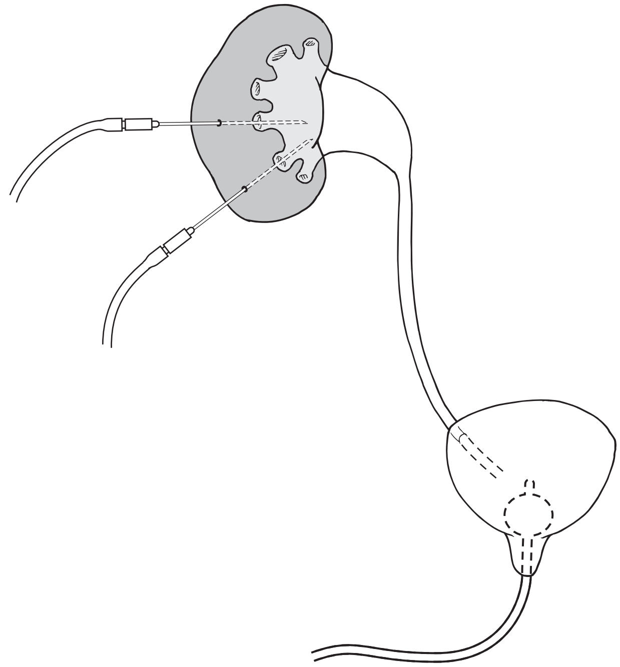

**FIGURE 113-13** Whitaker pressure perfusion study. (From Fung LCT, Lakshmanan Y: Anomalies of the renal collecting system: Ureteropelvic junction obstruction [pyelocalyectasis] and infundibular stenosis. In Belman AB, King LR, Kramer SA [eds]: Clinical Pediatric Urology, 4th ed. London, Martin Dunitz, 2002, p 596.)

there are equivocal studies regarding obstruction in a hydronephrotic kidney. High renal pelvic pressure relative to bladder pressure at a given flow rate confirms the presence of obstruction. According to this test at a flow rate of 10 mL/min, a differential pressure between the renal pelvis and the urinary bladder of less than 13 cm $H_2O$ is considered to be normal. Arbitrary values of 14 to 20 cm $H_2O$ indicate mild obstruction; values in excess of 35 cm $H_2O$ indicate severe obstruction. The Whitaker test requires percutaneous access to the kidney and usually requires general anesthesia in the pediatric population. Consequently, it is undesirable for a routine test. It is typically indicated for equivocal cases of obstruction and is, therefore, rarely performed. In addition, the Whitaker test requires a rigid protocol and exacting measurements to avoid technical errors. The most common error is failure to achieve an equilibrium (what goes in comes out). A physiologic pressure/flow test would be the ideal means of diagnosing "obstruction," but unfortunately one test does not presently exist.

## BIOCHEMICAL MARKERS

A biomarker is something that can be used as an indicator of a disease. Researchers have used proteomics, which is defined as the characterization of protein content within tissue, cells, or fluid, to try to find new biomarkers. It has been well established that ureteral obstruction results in renal injury on a cellular level.[65] Studies have led investigators to surmise that there might be potential biochemical markers detected in the urine that may be predictive of significant postnatal renal injury in patients with elevated hydronephrosis.[66] Prospective markers include urinary sodium, calcium, and $\beta_2$-microglobulin, or appropriate urinary proteins (proteomics) unique to obstruction.

Clearly, it has been demonstrated that persistently elevated collecting system pressure induces renal abnormalities including an increase in tubular pressure, decrease in renal blood flow, decrease in GFR, and renal tubular dysfunction.[67,68]

Recently, there have been several potential biomarkers that have been shown to be increased in the urine of children with UPJ obstruction. These include transforming growth factor β1 (TGF-β1), monocyte chemotactic protein 1 (MCP-1), and endothelin-1.[69–73] Also, urinary epidermal growth factor (EGF) was shown to decrease during obstruction.[72] Fung and Atala, using a nonobstructed porcine model in which urine drained against a predetermined pressure gradient, demonstrated a progressively elevated level of urinary N-acetyl-β-D-glucosaminidase, an indicator of acute renal cell injury.[74] There has yet to be any prospective studies or clinical studies that demonstrate if these biomarkers will be of clinical value. At present, however, because of the lack of standard biochemical or physiologic markers to measure renal obstruction, serial radiographic studies are necessary to evaluate the function and anatomy of a kidney with suspected UPJ obstruction. Proteomics has great potential to help discover new biomarkers that could in theory dramatically change how patients with hydronephrosis are followed and treated. It may be that the profile of a marker of different urinary proteins will reveal a reproducible and dependable measure of ongoing renal injury related to obstruction. Because these markers require vigorous clinical validation, which has been limited to date, and need to be reproducible, their future role in management remains undetermined.

### PREOPERATIVE VASCULAR IMAGING

Once the diagnosis of UPJ obstruction has been determined from the history and basic radiographic studies, there is often a question regarding the possibility of involvement of a crossing polar vessel in the obstructive process. This particular anatomic problem is primarily important in older children or adults with UPJ obstruction because it can influence the surgical approach and require radiographic studies focused on defining the vascular anatomy.

The incidence of crossing vessels in patients with UPJ obstruction is inconsistent in the literature and ranges from 11% to 79%, mainly because of the variable definitions used to describe UPJ obstruction.[7,75] Polar vessels crossing immediately adjacent to the UPJ are designated as "crossing vessels." They are thought to exacerbate rather than initiate the obstructive process, although this remains a controversial issue.[76] Crossing vessels have the potential to cause significant morbidity if not recognized before an endourologic procedure. Several imaging modalities can be used to search for a crossing vessel including digital subtraction intra-arterial angiography, helical computed tomography, contrast-enhanced color Doppler imaging, endoluminal sonography, and magnetic resonance angiography. The anatomic peculiarity of polar crossing vessels makes vascular imaging important, especially when minimally invasive techniques are proposed for the management of UPJ obstruction.[77] An extensive historical review addressing crossing vessels has been published.[78] Among pediatric urologists, the concept of preoperative vascular imaging to verify a crossing vessel is controversial, if not moot. Surgical management of children with UPJ obstruction is open surgery, laparoscopy, or robotic surgery, but not endopyelotomy, which, if used blindly, could inadvertently disrupt an unsuspected crossing vessel. To this date, endourologic procedures are limited in children for several reasons: (1) the available endourologic equipment is not small enough to accommodate children younger than 3 years; (2) most pediatric surgeons are trained to perform an open dismembered pyeloplasty, with the recognition that laparoscopy is an excellent choice in the proper hands; (3) both open and laparoscopic approaches would identify an anterior crossing vessel intraoperatively; and (4) the open surgery, laparoscopy, or robotic surgery for UPJ obstruction success rate is much greater than the reported success rate for endopyelotomy as a primary procedure in children.

## Management

The management of possible UPJ obstruction remains controversial because the natural history of UPJ obstruction still remains unclear in children. Management of unilateral hydronephrosis cannot be based on either the degree of pelvic dilation on ultrasound or obstruction on diuretic renography.[45,79] Several investigators have demonstrated that nearly 50% to 80% of all cases of prenatal hydronephrosis will resolve spontaneously with postnatal follow-up.[80,81] Others, however, have demonstrated progressive hydronephrosis with diminution of function in follow-up 3 years postpartum.[82] These different outcomes are unsettling and, as yet, unanswered. Currently, watchful waiting and early intervention are two main options regarding the management of UPJ obstruction.

### WATCHFUL WAITING

Conservative management of unilateral UPJ obstruction involves sequential radiographic studies and cautious patience. The fact that so many algorithms have been devised for the management of UPJ obstruction is a sure indication that no single algorithm is absolute. In general, however, the typical evaluation of an infant with the prenatal diagnosis of hydronephrosis begins with a directed physical examination and postnatal ultrasound. The physical examination should determine the child's vital signs, general health, and overall appearance. Respiratory distress or vomiting may be associated with a palpable abdominal mass in some cases. In most instances, however, an abdominal mass is not identified.

Postnatal ultrasound should be performed at least 2 days after birth because relative dehydration of the fetus and physiologic oliguria may result in a false-negative study after birth. The one exception to this 2-day rule is a male neonate with bilateral hydronephrosis and a thickened bladder wall, which would be suggestive of a more urgent problem such as bladder outlet obstruction secondary to posterior urethral valves.

Renal sonography suggesting UPJ obstruction should be followed by additional diagnostic studies to confirm or exclude the obstruction. Further radiologic tests should be based on other possible causes of hydronephrosis. Several conditions can produce dilatation of the collecting system with or without urinary tract obstruction such as physiologic pelviectasis, UPJ obstruction, duplication of the collecting system with an ectopic ureter (or an associated ureterocele),

megaureter, MCDK, UVJ obstruction, posterior urethral valves, prune-belly syndrome, renal cystic diseases, parapelvic renal cysts, and megacalicosis. In addition, the diagnosis of hydronephrosis may be falsely diagnosed because of the sonolucent appearance commonly seen in the neonatal renal medullary and pyramids. This curious finding resolves with renal parenchymal maturation, which usually occurs within the first 6 months of life. Follow-up ultrasound reveals no apparent evidence of hydronephrosis (Fig 113-14).

Postnatal renal ultrasound can eliminate several of the aforementioned diagnoses. If a dilated ureter is demonstrated on postnatal ultrasound, the diagnosis of UPJ obstruction is less likely and the differential diagnosis would include ectopic ureter, megaureter, UVJ obstruction, posterior urethral valves, vesicoureteral reflux, or prune-belly syndrome (bilateral). Sonographic evidence of multiple, noncommunicating cysts is typical of parapelvic cysts or MCDK and not UPJ obstruction. Parapelvic cysts are rare in the pediatric population and should not be mistaken for hydronephrosis.[83] MCDK can be confirmed by nuclear scintigraphy, typically a DMSA scan, which reveals no evidence of ipsilateral renal function.

Historically, if the postnatal sonogram confirms characteristic findings consistent with hydronephrosis, the newborn was placed on a once-daily prophylactic dose of oral antibiotics with amoxicillin, 15 mg/kg, but the necessity of this has come into question and frequently these patients will be followed without prophylactic antibiotics, especially in the circumcised male. The use of prophylactic antibiotics in infants with postnatal hydronephrosis in the absence of VUR continues to be controversial.[84–86]

## OPEN SURGERY

The goal of surgery for UPJ obstruction is to preserve renal function by assisting unobstructed drainage of the renal pelvis. Several techniques have been designed for this purpose. The first is the flap techniques, which include Y-V-plasty, spiral flap, or Scardino-Prince vertical flaps. These flaps all use renal pelvic tissue to augment the narrowed UPJ segment (Fig. 113-15). The second type of technique, the dismembered pyeloplasty (Anderson-Hynes pyeloplasty), is the most popular.[8] It involves complete removal of the narrowed (dysfunctional) segment, tailoring of the renal pelvis (if necessary), and reapproximation of the ureter to the renal pelvis in a dependent position. Because neither technique sufficiently treats all the possible anatomic variations, it is imperative to be familiar with all techniques. The anatomy of the renal pelvis, in association with other intraoperative findings, dictates the technique of choice. Dismembered pyeloplasty is appropriate for most repairs of intrinsic and extrinsic obstruction. The flap technique may be useful in the patient with a long narrowed segment. Each technique can provide a solution to UPJ obstruction with success rates in excess of 90% to 95%.[13,87]

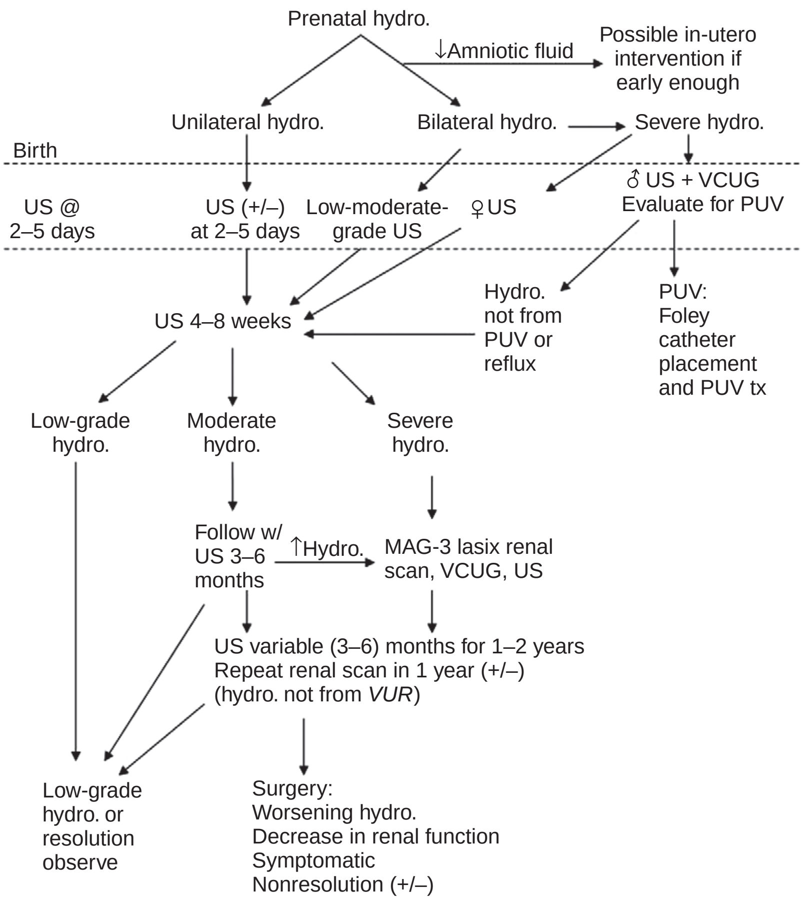

**FIGURE 113-14** A flow chart for workup and management of prenatal-detected hydronephrosis (*hydro.*) without ureteral dilation. *Low-grade hydro.*, SFU grade 1; *moderate hydro.*, SFU grade 2; *PUV*, posterior urethral valves; *renal scan*, MAG-3 lasix renal scan; *severe hydro.*, SFU grades 3-4; *US*, renal and bladder ultrasound; *VCUG*, voiding cystourethrogram; *VUR*, vesicoureteral reflux.

To perform a pyeloplasty, the child is given adequate general anesthesia, with the option of using a regional block. We routinely perform an RPG (retrograde pyelogram) at the onset of the procedure. Although some have challenged the necessity of this, we believe an RPG helps to characterize the lesion and distal ureter and to assist in defining the appropriate site for optimum exposure. After RPG, a Foley catheter is placed in a sterile manner and the child is repositioned for surgery with respect to the particular approach that is planned.

A number of approaches can be used to obtain access to the retroperitoneal space to perform an open pyeloplasty including anterior subcostal, flank, and dorsal lumbotomy. In infants we prefer an anterior subcostal, muscle-splitting approach,

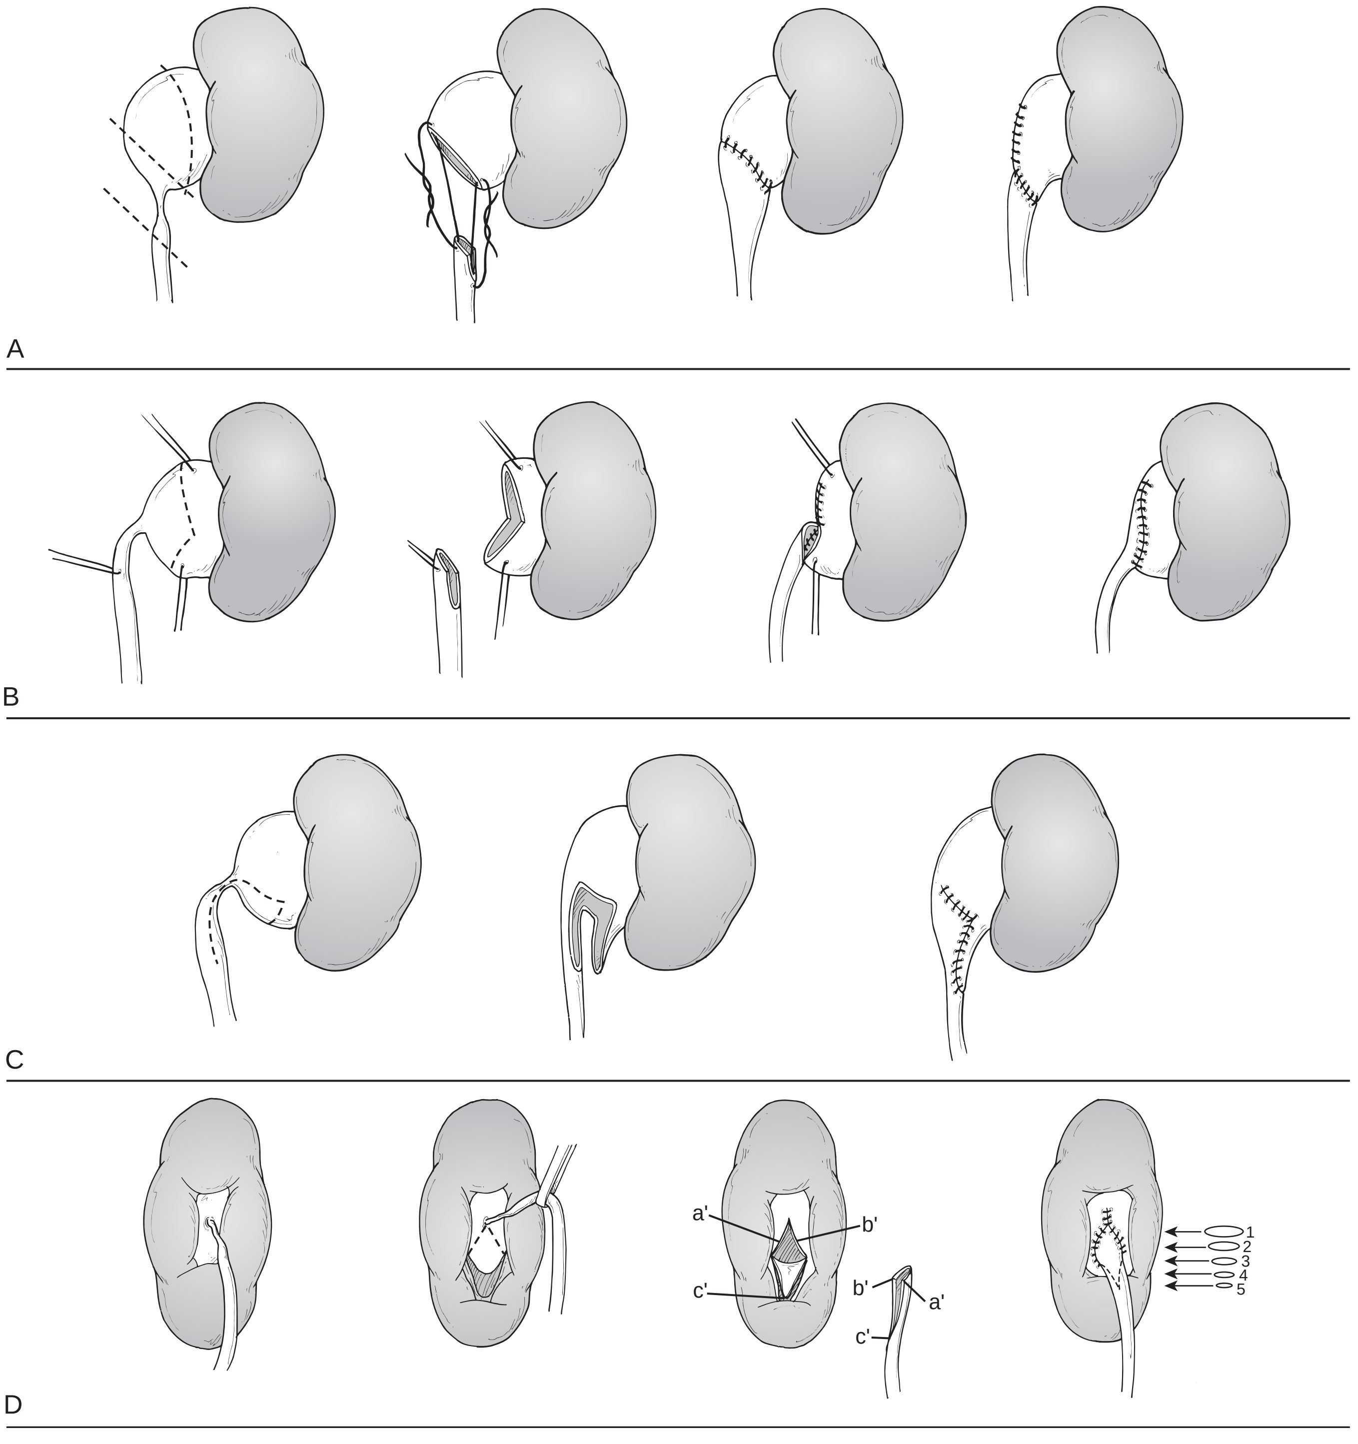

**FIGURE 113-15** **A,** Dismembered pyeloplasty. **B,** Anderson-Hynes pyeloplasty. **C,** Foley Y-V-plasty. **D,** Variation of the Foley Y-V-plasty for proximal ureteral high insertion.

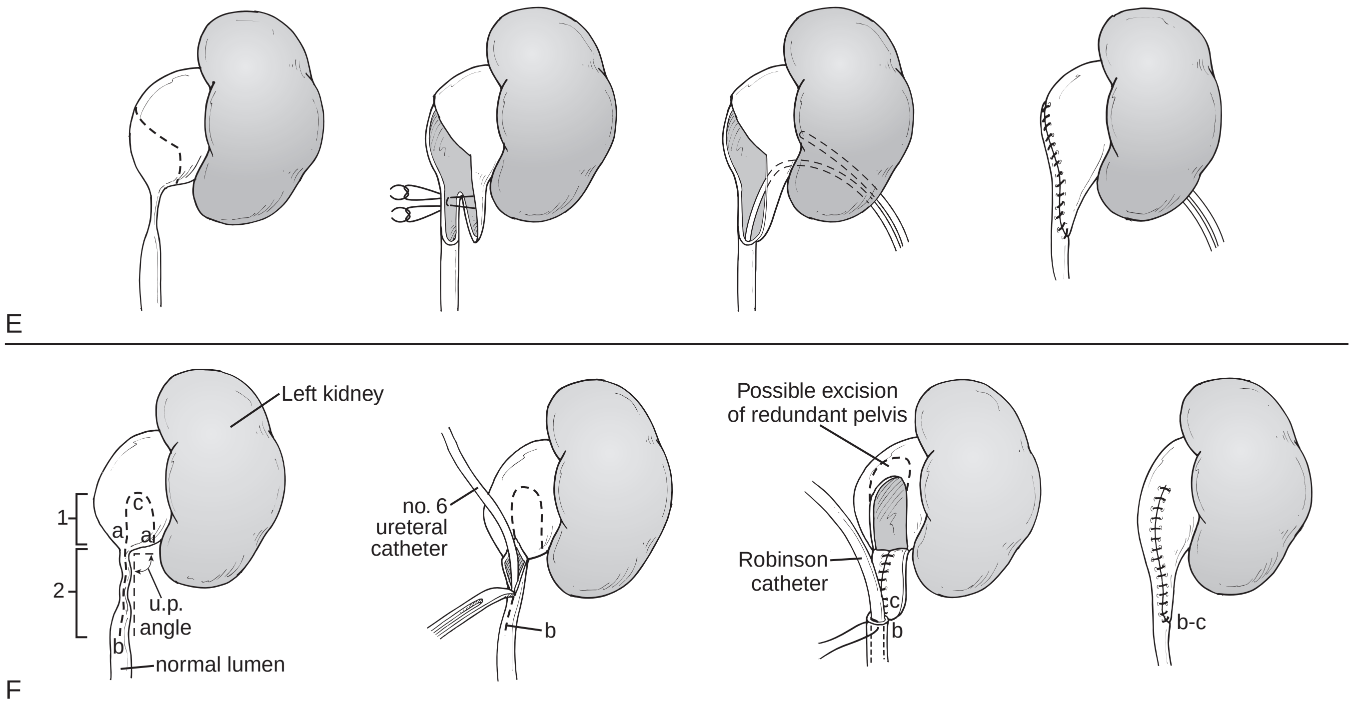

**FIGURE 113-15—CONT'D** **E,** Spiral flap. **F,** Scardino-prince vertical flap pyeloureteroplasty for long proximal ureteral narrowing. (From Fung LCT, Lakshmanan Y: Anomalies of the renal collecting system: Ureteropelvic junction obstruction [pyelocaliectasis] and infundibular stenosis. In Belman AB, King LR, Kramer SA [eds]: Clinical Pediatric Urology, 4th ed. London, Martin Dunitz, 2002, p 612.)

which provides excellent exposure through a small incision. (In older children, a flank incision might be preferential given the lateral displacement of the peritoneum and the frequently thicker muscle bundles.)

The child is then placed in a modified supine position with the ipsilateral side at an approximately 15- to 20-degree angle to the operating table. Small children may have both upper extremities at their sides. The operating table is flexed at the level of the child's anterior superior iliac spine, which exposes the anterior abdominal area and flank. Approximately two fingerbreadths below the subcostal region, a 3- to 4-cm incision is made along Langer's lines. A "muscle-splitting" technique is used to separate the muscle layers without transecting them. This technique provides adequate exposure and reduces postoperative pain. After the fascia is opened, the peritoneum is reflected medially. The Gerota fascia is incised in a plane vertical to the patient. A self-retaining ring retractor provides adequate exposure to the kidney and renal pelvis.

Once the kidney and renal pelvis have been exposed, careful inspection of the anatomy should allow a decision to be made regarding the best technique to use. A dismembered pyeloplasty is performed for most UPJ obstructions. However, there are three anatomic situations that may be treated appropriately with three different flap procedures: Foley Y-V-plasty, spiral flap, or Scardino-Prince vertical flaps. The first situation occurs when the obstructing segment is longer than 1.5 to 2 cm. The second situation occurs in a child with a small extrarenal pelvis, and the renal pelvis does not need to be reduced. The last situation, in which a Foley Y-V-plasty may be the preferred technique, is when the ureter has a high insertion into the renal pelvis. In these cases, the pelvis can be funneled to construct a dependent drainage system.

When a decision is made to perform a dismembered pyeloplasty, the renal pelvis should be evaluated for possible reduction in size. The ureter is transected between stay sutures at the UPJ. Care is taken to not excessively dissect the blood supply from the proximal ureter. Stay sutures are strategically positioned in a "diamond" pattern, and tenotomy scissors are used to excise redundant renal pelvis within the borders of the stay sutures. The narrowed ureteral segment should be incised laterally along the longitudinal axis of the ureter to the point of healthy ureteral tissue of normal caliber. The proximal ureter at the UPJ obstruction level should be excised from and removed before reapproximation. The anastomosis is begun at the inferior apex of renal pelvis and opened ureter, with continuous running 7-0 absorbable monofilament suture used in the infant and 5-0 to 7-0 absorbable sutures used in older patients. During the anastomosis, care should be taken to include adequate adventitial tissue with less mucosal tissue to provide a watertight anastomosis. A temporary ureteral stent may be used when performing the anastomosis to reduce the risk for obstruction as a result of "back-walling." Alternatively, a double-J ureteral stent may be positioned in the distal end of the ureter and bladder with the Seldinger technique. This is typically removed in 4 to 6 weeks.

The dorsal lumbotomy approach provides excellent exposure, especially in the rare case of bilateral UPJ lesions (Fig. 113-16). As in the subcostal approach, a muscle-splitting technique can be used to access the retroperitoneum through a relatively short distance. The dorsal lumbotomy approach requires that the ureteral anatomy be precisely defined before embarking on the technique because it provides limited exposure to the distal part of the ureter.

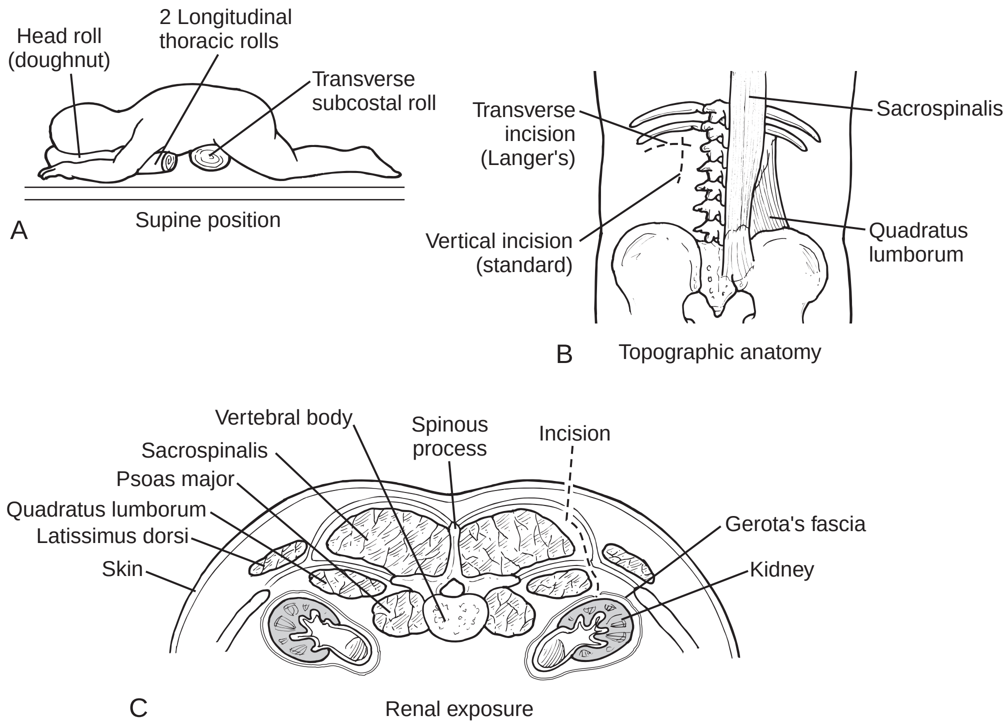

**FIGURE 113-16** Dorsal lumbotomy approach. (From Sheldon CA, Duckett JW: Infant pyeloplasty. AUA Update Series 1988;7[Lesson 37]:293.)

## MINIMALLY INVASIVE SURGERY FOR URETEROPELVIC JUNCTION OBSTRUCTION IN CHILDREN

Unlike in adults, open pyeloplasty is considered the gold standard in the management and treatment of UPJ obstruction. The success rate has been reported to be between 90% and 100%.[88,89] However, open surgery can result in postoperative morbidity because of pain, prolonged length in recovery, and significant scar formation. Minimally invasive surgery evolved to decrease the morbidity of pyeloplasty while maintaining the efficacy of treatment. Minimally invasive techniques to correct UPJ obstruction in adults include balloon dilation, percutaneous antegrade endopyelotomy, retrograde cutting-wire balloon endopyelotomy, ureteroscopic retrograde endopyelotomy, and laparoscopic pyeloplasty.

Techniques such as antegrade and retrograde endopyelotomy, although less invasive, have a significantly decreased success rate when compared with open surgery, with a reported success rate of 61% to 89%. They can also carry a risk of bleeding in patients with crossing vessels.[90,91] The endopyelotomy success rate decreases to 39% to 44% with UPJ obstruction associated with crossing vessels.[92,93] Laparoscopic pyeloplasty was first introduced in adults in 1993 and has a success rate approaching 95%.[94,95] In the adult population, studies have demonstrated decreased pain and decreased length of hospital stay.[96] Laparoscopy in children has shown similar success rates, but the benefit from recovery for the younger patient has been less well established.

Pediatric laparoscopic pyeloplasty faces the same challenges as the other minimally invasive techniques in children.[97] Much of pediatric urologic surgery is reconstructive rather than extirpative, which limits the ability of many practitioners to gain experience in basic laparoscopic skills. Peters reported the first case of pediatric laparoscopic pyeloplasty in 1995.[98] There have been several series demonstrating comparable success rates with laparoscopic dismembered pyeloplasty to open pyeloplasty in the pediatric population.[99–106] Recently, several authors have demonstrated that laparoscopic pyeloplasty is a viable option in infants and children younger than 2 years of age and not solely limited to older children.[107,108]

The two main laparoscopic techniques to pyeloplasty are transperitoneal versus retroperitoneal approaches. The transperitoneal approach is used more frequently in the pediatric patient because it allows for increased working space along with the benefit of easy identification of crossing vessels and readily identifiable anatomic landmarks. The two main procedures used to treat UPJ obstructions laparoscopically include dismembered pyeloplasty and Foley Y-V flap for UPJ obstructions secondary to high inserting ureters. There have been a limited number of reports of higher success rates with a dismembered approach when compared with a nondismembered approach in the laparoscopic setting and thus is the more commonly used.[103]

Various techniques are used to achieve pneumoperitoneum including the Veress needle technique versus the open Hasson technique. The patient is placed at 30 to 45 degrees in a modified flank with the affected side elevated. Peritoneal access is obtained through the umbilicus via Hasson technique. The abdomen is then insufflated to 10 to 12 mm Hg to allow for adequate pneumoperitoneum. The 5- or 10-mm camera port is placed at the umbilicus, and two 5-mm (in infants sometimes 3-mm ports can be used instead) working ports are placed in the midline between the umbilicus and xyphoid and in the midclavicular line 2 cm below the umbilicus on the affected side. Initially, the colon is then mobilized medially by incising the line of Toldt and reflecting the colon to gain

access to the retroperitoneum and kidney. On the left side, a transmesenteric approach can sometimes be undertaken. A ureteral stent is placed either antegrade during laparoscopy or in a retrograde fashion during initial cystoscopy at the start of the procedure depending on surgeon preference. The type of absorbable suture varies between 5-0 and 4-0 depending on the patient's age and surgeon's preference. There is a significant learning curve to laparoscopic pyeloplasty, and it is technically challenging secondary to the intracorporeal suturing and knot tying required. This is why it has been relegated to specialized centers and not universally adopted.

The recent implementation of robotic laparoscopic systems has increased the availability of laparoscopic reconstructive surgery including pyeloplasties. The most commonly used robotic system is the da Vinci robotic system (Intuitive Surgical, Sunnyvale, Calif.). The benefits of robotic laparoscopy include increased magnification, three-dimensional vision, articulating robotic Endowrist with six degrees of articulation, tremor filtering, and an ergonomic surgeon's position. These benefits to robotic laparoscopy assist dissection and suturing, allowing for greater applications with decreased learning curve in reconstructive surgery. The patient is placed at 30 to 45 degrees in modified flank with the affected side elevated. Peritoneal access is obtained similar to conventional laparoscopy through the umbilicus. The 12-mm camera port is placed at the umbilicus, and two robotic working ports (5 mm or 8 mm) are placed in the midline between the umbilicus and xyphoid and in the midclavicular line 2 cm below the umbilicus. The absorbable suture used varies with age but ranges between 7-0 and 4-0 similar to sutures used in an open repair. Robotic surgery has the potential to advance minimally invasive surgery by allowing urologists with limited laparoscopic experience to rapidly master the endocorporeal skills necessary to treat UPJ obstruction.[109,110]

## Outcome

A successful pyeloplasty is most specifically measured by preservation of or improvement of renal function. Several investigators have reported improvement in renal function in children with obstruction detected early and surgery performed before renal impairment occurs.[1,111] Meticulous attention to surgical principles contributes to operative success. The use of proper pediatric instruments is important. Atraumatic tissue handling, careful dissection, and preservation of ureteral blood supply all contribute to a successful anastomosis. The ureteropelvic anastomosis should be watertight and tension free. The retroperitoneal space should have adequate passive drainage.

Finally, the routine use of ureteral stents and percutaneous nephrostomy tubes after an open pyeloplasty remains controversial.[112] The most common reasons to leave a stent in place after pyeloplasty are to ensure proper urinary diversion, maintain ureteral caliber, and ensure anastomotic alignment. The main reasons against leaving a temporary stent in situ are that they are foreign bodies and may be a nidus for infection, they may erode through the anastomotic site, and in children, internalized stents require general anesthesia for removal.

The goal of pediatric pyeloplasty is to reduce hydronephrosis and preserve renal function. This goal is evaluated by radiographic studies and clinical considerations. Renal ultrasound defines a successful pyeloplasty as improvement in SFU-graded hydronephrosis, temporal axial growth of the ipsilateral kidney, and a gradual increase in renal parenchyma. Diuretic renography should demonstrate improved urinary drainage and differential renal function. In older children, successful pyeloplasty is determined by the absence of symptoms.

Depending on the definition, the success rate of pyeloplasty for UPJ obstruction is as high as 98%.[13,113,114] The success rate is so high, in fact, that one investigator suggested that a satisfactory diuretic renogram 3 months after pyeloplasty eliminated the need for further urologic follow-up. Other investigators claim that ideally, follow-up should be extended to 2 years, which would include the period when initial symptoms of recurrence are most likely to take place.[115] Subsequently, renal ultrasound is performed annually for 2 years. Of course, after pyeloplasty, primary care physicians should monitor any patient with renal scars on a preoperative DMSA scan by annual blood pressure reading. We recommend renal ultrasound 3 months after pyeloplasty and diuretic renography if improvement is not obvious by ultrasound.

Complications of pyeloplasty can be categorized as acute and late. Acute complications have a higher incidence in infants.[6] Postoperative pyelonephritis is most commonly seen in children who had a positive intraoperative urine culture. It is treated with intravenous antibiotics. Delayed opening of the ureteropelvic anastomosis typically occurs as a result of edema and may lead to a prolonged leak around the anastomotic site. Interestingly, a transanastomotic ureteral stent does not reduce the frequency of this complication. Patients with persistent hydronephrosis or symptoms after pyeloplasty may be salvaged with placement of a percutaneous nephrostomy tube. In some of these children, a secondary procedure may be necessary such as revision pyeloplasty or nephrectomy. Late complications can be manifested as clinical symptoms or progressively worsening radiographic studies. In either case, evaluation should determine whether optimizing drainage via a nephrostomy tube or ureteral stent improves the clinical symptoms or renal function. Typically, surgery for a failed pyeloplasty should not be considered for at least 2 months. There are five basic approaches to the treatment of secondary UPJ obstruction: revision pyeloplasty, ureterocalicostomy, endopyelotomy, laparoscopy, and nephrectomy.[116]

## Summary

UPJ obstruction is the most common congenital urinary obstruction, and management remains complex because of the variability of the lesion and the unpredictability of the manifestations. In many cases, observation alone is a viable option because the obstruction is not progressive. In other cases, radiographic studies reveal renal deterioration or progressive hydronephrosis, and surgery is required. Unfortunately, the factors that determine which kidneys require surgery have not been clearly defined at this point. However, with future developments in biochemical markers and improvements in radiographic studies, timing of surgical intervention will be defined earlier so that renal deterioration in children with suspected UPJ obstruction might be prevented.

# CHAPTER 114

# Renal Infection, Abscess, Vesicoureteral Reflux, Urinary Lithiasis, and Renal Vein Thrombosis

Leslie T. McQuiston and Anthony A. Caldamone

## Urinary Tract Infection, Renal Abscess, and Vesicoureteral Reflux

The urinary tract is the second most common site of infection in infants and children after the respiratory tract. The true incidence of urinary tract infection (UTI) in children is difficult to determine because of the challenges of diagnosis. Young children may present with only fever or failure to thrive, with no specific urinary symptoms or signs. Diagnosis and treatment of UTI are of particular importance in children, given the long-term complications including renal scarring, hypertension, and decreased renal function. On the basis of several studies, the incidence of renal scarring in young children with febrile UTI may be as high as 40% to 50%.[1] Among infants between the ages of 2 months and 2 years who present with fever, approximately 5% are diagnosed with a UTI.[2,3] Age and gender are significant factors in the incidence of UTI in the pediatric population. The incidence of UTI is greater in girls than in boys; in prepubertal girls, the incidence is reported to be 3%, whereas in prepubertal boys it is only 1%.[1] Some studies have demonstrated that the incidence of UTI in uncircumcised males, particularly boys younger than 1 year, is 5 to 20 times higher than in circumcised males.[4,5] Over the past few years, there have been advances in the understanding of the pathogenesis of UTI and the identification of risk factors that predispose patients to renal damage.

### PATHOGENESIS

There are four major pathways by which bacteria gain access to the urinary tract: ascending, hematogenous, lymphatic, and direct extension. Hematogenous access is most commonly seen in immunocompromised children or in neonates, owing to their immature immune systems. Direct extension can occur in the setting of fistulas from the vagina or the gastrointestinal tract to the genitourinary tract. The ascending route is considered the most common pathway, with bacteria colonizing the periurethral area and then entering via the urethra. Host factors including the ability to resist infection are important elements in the pathogenesis of UTI. There is a higher incidence of UTI in infancy, likely due to the immaturity of the neonatal immune system and the higher periurethral bacterial colonization in the first year of life.[6] Bacteria from the gastrointestinal tract colonize the periurethral mucosa and may ascend into the bladder and then the kidneys (Table 114-1).[7] Certain bacterial traits such as the presence of fimbriae mediate bacterial adherence to uroepithelial cells and increase bacterial virulence.

Differentiation of pyelonephritis from lower UTI is difficult because there is poor correlation between clinical symptoms and localization of bacteria to the upper versus lower tract. In older children, however, the diagnosis of pyelonephritis may be suggested by fever, flank pain, and systemic symptoms. Persistent fever for more than 48 hours after the initiation of appropriate antibiotics may be indicative of upper tract infection. Infants with a febrile UTI should be considered to have pyelonephritis and evaluated and treated accordingly. Alternatively, if one has access to dimercaptosuccinic acid (DMSA) nuclear scanning at the time of the illness, more specific identification of pyelonephritis is possible, which may modify the evaluation and treatment. Studies have demonstrated that 40% to 60% of children with a febrile UTI have a positive DMSA scan.[8,9]

### RISK FACTORS

Although bacterial virulence plays an important role in the development of UTI, a variety of host characteristics may predispose to UTI including age, gender, colonization factors, constipation, genitourinary abnormalities, sexual activity, genetic factors, and iatrogenic factors (Table 114-2).[10] The most important factors influencing prevalence are age and gender. Males are five to eight times more likely than girls to have UTIs during the first 3 months of life.[11] Beyond that age, girls have a

Modified from Handel LN, Caldamone AA: Urinary tract infections in the pediatric population. Lebanese Med J 2000;52:194.

greater incidence of UTIs than boys. Symptomatic infections are 10 to 20 times more likely in preschool girls than boys.[5]

UTI often serves as a marker for anatomic abnormalities of the genitourinary tract. It is important to identify these abnormalities early because, if uncorrected, they may lead to recurrent infection and possible loss of renal parenchyma. Obstructive malformations such as ureteropelvic junction obstruction, posterior urethral valves, ectopic ureters, ureteroceles, and urethral diverticula can increase the risk of UTI. Renal abnormalities such as papillary necrosis, nonfunctioning kidneys, and unilateral medullary sponge kidney also predispose patients to UTI.

Vesicoureteral reflux (VUR), which is the abnormal flow of urine from the bladder to the kidney, allows bacteria from the bladder to gain access to the kidney. By itself, VUR does not cause UTI; bacteriuria must be present in the setting of VUR for UTI to develop. The exception to this rule is a child with massive VUR who may have a significant postvoid residual from refluxed urine. VUR occurs in approximately 1% of the general population and is estimated to occur in 20% to 35% of children evaluated for bacteriuria.[12,13] More than 60% of children younger than 1 year are found to have VUR after their first UTI.[3] This percentage decreases to 30% in 2- to 3-year-olds and is 5% or less in adults.[3] As children grow, the submucosal tunnel elongates and the ratio between the submucosal tunnel length and the ureteral diameter increases. In addition, filling and voiding pressures change over time, which can also improve VUR. These factors, along with changes in bladder dynamics and voiding patterns, account for the spontaneous resolution rate of VUR. VUR is graded I to V on the basis of the International Reflux Grading System. Grades I and II generally resolve or improve over time, whereas grades IV and V typically do not resolve spontaneously and may require intervention.

From American Academy of Pediatrics, Committee on Quality Improvement, Subcommittee on Urinary Tract Infection: Practice parameter: The diagnosis, treatment, and evaluation of the initial urinary tract infection in febrile infants and young children. Pediatrics 1999;103:843.

Functional abnormalities such as a neuropathic bladder predispose to UTI as a result of increased urinary tract pressures, incomplete bladder emptying, and increased frequency of instrumentation. UTI is also more common in patients with bladder and bowel dysfunction (BBD). These children commonly have incomplete bladder emptying, urinary stasis, and abnormally high urinary tract pressures, as well as bladder instability, infrequent voiding, Hinman syndrome, and constipation. Periurethral colonization and preputial colonization also may increase the risk of UTI. Preputial aerobic bacterial colonization is highest during the first month after birth, decreases after 6 months, and is uncommon after 5 years of age.[10,14]

## CLINICAL PRESENTATION

Children with UTIs, especially those younger than 2 years, do not always present with the typical symptoms of dysuria, frequency, or pain, and the physical examination may be of limited value. Thus it is important to maintain a high index of suspicion in infants and young children. In children younger than 2 years, parents may describe nonspecific symptoms such as fever, fussiness, vomiting, or diarrhea; patients may present with failure to thrive or difficulty feeding. In infants, often the only presenting symptom is fever. Children 2 to 5 years of age often present with fever and abdominal pain coincident with upper respiratory infection. After toilet training, children may start to demonstrate more specific symptoms such as fever, dysuria, flank pain, and urgency.

## DIAGNOSIS

Accurate diagnosis of UTI in children is critical. The method of collection can affect the accuracy of diagnosis (Table 114-3). In toilet-trained children, clean-catch specimens have a contamination rate of approximately 30%.[15] The method least likely to be contaminated is suprapubic aspiration; this method, however, is often not favored by parents or by primary practitioners. Suprapubic aspiration may be contraindicated in patients with certain anatomic abnormalities of the genitourinary tract.

Transurethral bladder catheterization is the preferred method, with a lower false-positive rate than perineal bag collection. The sensitivity of positive urine culture is 95%, and the specificity is 99%.[2] In children not yet toilet trained, perineal bag collection is more common but has a high probability of contamination. False-positive results occur in 85% of specimens collected in this manner.[2] Perineal bag collection may be used when there is low suspicion of UTI. Current recommendations are urethral catheterization or suprapubic

**TABLE 114-3**
**Criteria for the Diagnosis of Urinary Tract Infection**

| *Method of Collection* | *Colony Count (Pure Culture)* | *Probability of Infection (%)* |
|---|---|---|
| Suprapubic aspiration | Gram-negative bacilli: any number | >99 |
| | Gram-positive cocci: >a few thousand | |
| Transurethral catheterization | >100,000 | 95 |
| | 10,000-100,000 | Infection likely |
| | 1000-10,000 | Suspicious, repeat |
| | <1000 | Infection unlikely |
| Clean-voided (boy) | >10,000 | Infection likely |
| Clean-voided (girl) | 3 specimens >100,000 | 95 |
| | 2 specimens >100,000 | 90 |
| | 1 specimen >100,000 | 80 |
| | 50,000-100,000 | Suspicious, repeat |
| | 10,000-50,000 | If symptomatic, suspicious, repeat; if asymptomatic, infection unlikely |
| | <10,000 | Infection unlikely |

aspiration following a positive urinalysis or a positive urine culture from a bag specimen to eliminate the possibility of contamination.

On urinalysis, the combination of urine nitrite, leukocyte esterase, bacteria, and white blood cells on microscopy yields a sensitivity of 99.8% and a specificity of 70%.[2,15] However, UTI cannot be ruled out if any of these findings is absent on urinalysis or microscopy. A urine culture is the only way to accurately diagnose a UTI; however, prompt treatment before final culture results are obtained is recommended due to the increased risk of renal scarring in children younger than 5 years, as well as the possibility for rapid clinical deterioration.

## IMAGING

The role of imaging after a UTI is controversial.[10,13,16] The primary goal of imaging is to identify children who are at risk for subsequent UTIs and renal damage. Imaging includes an anatomic evaluation of the kidney and bladder, as well as a functional study to identify the presence of VUR. The current American Academy of Pediatrics guidelines recommend renal and bladder ultrasonography (US) for all children younger than 2 years with a first UTI.[2] The National Institute for Health and Clinical Excellence (NICE) recommends renal and bladder US for all children younger than 3 years of age, but only for those with atypical or recurrent UTI for those older than 3 years of age.[17] The purpose of US in these cases is to assess for the presence of any congenital structural abnormalities of the urinary tract such as hydronephrosis (Fig. 114-1). Additionally, US allows the visualization of any renal parenchymal abnormalities such as cysts and identifies the presence of perinephric fluid collections. Ureteral dilatation, bladder wall thickening (Fig. 114-2), a duplicated collecting system (Fig. 114-3), ureteroceles (Fig. 114-4), bladder diverticula, and calculi are also identifiable with US. In cases of acute pyelonephritis, US may demonstrate focal or diffuse renal enlargement, as well as abnormal cortical echogenicity. Multiple studies have demonstrated obstructive lesions in 5% to 10% of patients and VUR in 20% to 50% following a UTI.[18] Thus imaging should be considered after a first UTI. Imaging for VUR using cystourethrography (VCUG) is the standard of care

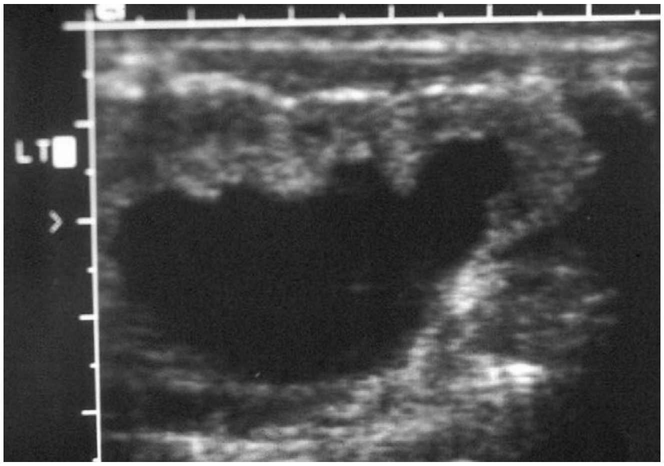

**FIGURE 114-1** Sagittal ultrasonography of a kidney demonstrating hydronephrosis of the renal pelvis and calices. (Modified from Handel LN, Caldamone AA: Urinary tract infections in the pediatric population. Lebanese Med J 2004;52:194.)

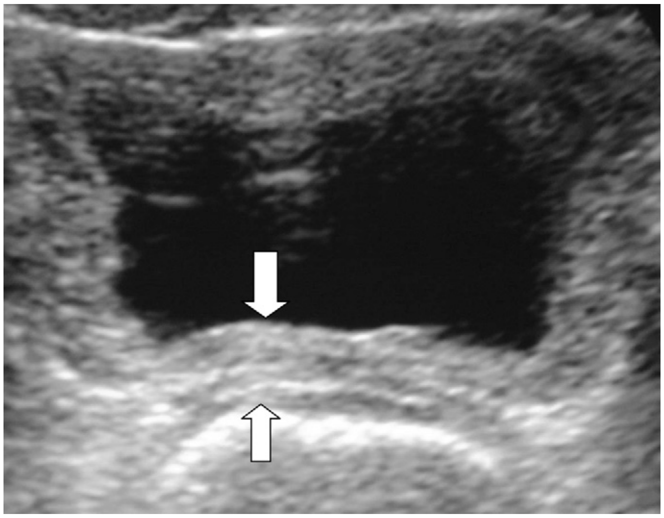

**FIGURE 114-2** Transverse ultrasonography of the bladder demonstrating posterior wall thickening (*arrows*).

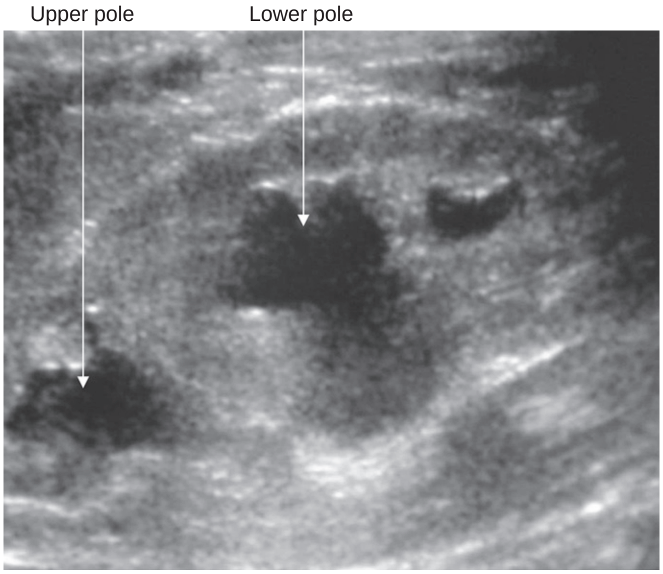

**FIGURE 114-3** Sagittal ultrasonography of a kidney demonstrating a duplicated collecting system.

in infants and children younger than 3 years or not yet toilet trained. In older children, the data to support VCUG are less clear because it is not certain, on the basis of available data, that the treatment of children with VUR provides a clinically significant benefit with respect to reduction in long-term renal damage.[19] The "Top-Down Approach" has suggested that initial DMSA scintigraphy may help to identify children at highest renal risk and therefore those who need further investigation by VCUG.[9] This approach is based on evaluation with DMSA scan as close to the acute episode of febrile UTI as possible, preferably within the first 10 days of diagnosis, and further imaging with VCUG for those with a positive scan. Several studies have shown that a negative DMSA scan decreases the probability that there is high-grade VUR.[8] Children with a negative scan may not require further evaluation unless UTI recurs. Further studies are necessary to clarify the best evaluation strategy to detect children who are at risk of progressive renal damage from UTI. Currently based on age and gender, the recommendation is US and VCUG for all boys with their first UTI regardless of age and for girls younger than 5 years with their first UTI. Additionally, for girls older than 5 years, imaging should be done in those with pyelonephritis or recurrent UTIs (Table 114-4). The type and timing of imaging may depend on the patient's response to initial antibiotic therapy and the availability of DMSA scintigraphy.

The most common anomaly associated with UTI in children is VUR, which is noted in about 20% to 35% of children evaluated after UTI. VCUG is used to detect the presence of VUR (Fig. 114-5). Standard VCUG is performed by instilling iodinated contrast into the bladder and then imaging during filling and voiding. The American Academy of Pediatrics recommends VCUG as the initial study of choice in VUR, especially in male patients to rule out posterior urethral valves (Fig. 114-6).[2] Previous recommendations were that VCUG should be done 4 to 6 weeks after UTI because of possible false-positive results owing to inflammation of the bladder wall causing VUR. More recent studies have shown no difference between early (within 7 days of infection) and late VCUG.[20] VCUG can be performed once the child is afebrile, and cultures are negative to prevent the risk of infected urine being forced in a retrograde fashion during the study.

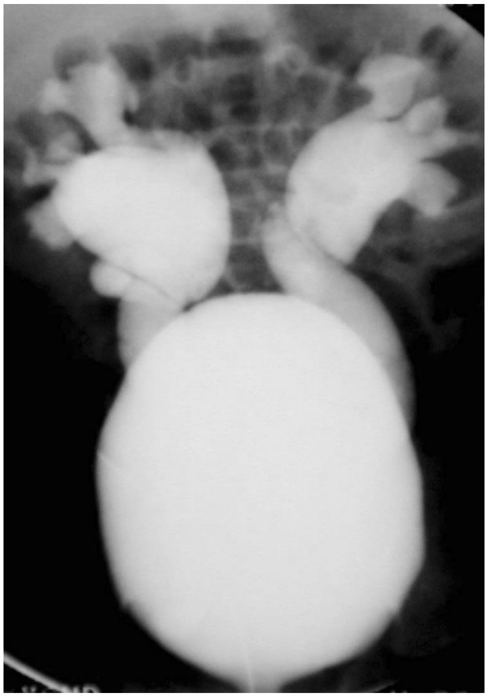

**FIGURE 114-5** Voiding cystourethrogram demonstrating vesicoureteral reflux.

Renal cortical imaging with dimercaptosuccinic acid (DMSA) is both sensitive and specific for the detection of pyelonephritis in children.[18,21] Areas with decreased uptake may represent acute pyelonephritis or renal scarring. Before the availability of DMSA, imaging techniques demonstrated that approximately 17% of children with bacteriuria had renal scarring; current studies using DMSA demonstrate that the percentage is likely twice that.[1] The use of DMSA should be limited to those patients with suspected acute UTI in whom the diagnosis is unclear but there is a high suspicion of pyelonephritis. DMSA can also be used to assess for renal scarring after UTI if the results would change the management of the patient.

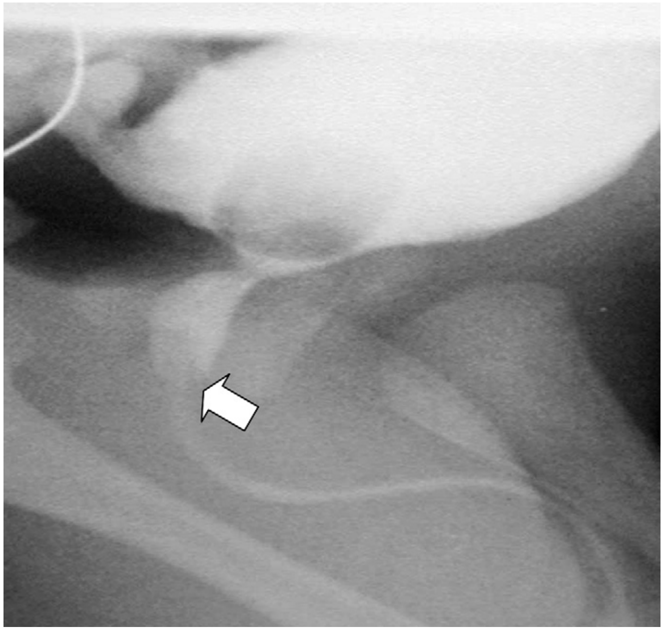

**FIGURE 114-6** Voided cystourethrogram demonstrating posterior urethral valves (*arrow*).

Mercaptoacetyltriglycine (MAG3) or diethylenetriamine pentaacetic acid (DTPA) with a diuretic is used to assess renal function and excretion in patients with hydronephrosis without VUR and to determine the presence or absence of obstruction. Both false-positives and false-negatives are possible, so caution must be used when interpreting the study and clinical correlation is essential.

Renal abscess is a potential complication of pyelonephritis regardless of the underlying cause. Abscess is more common in compromised patients. Gram-positive organisms such as *Staphylococcus aureus* and streptococci may be the causative agents. The diagnosis is best made by US or computed tomography (CT). Treatment may involve long-term antibiotics, percutaneous drainage and antibiotic instillation, or open surgical drainage. Sequential follow-up with radiographic imaging is essential.

## TREATMENT

Because of the risk of renal scarring in children, prompt diagnosis and treatment are critical (Fig. 114-7). The treatment strategy depends on various factors, particularly the child's age and the severity of illness. Children younger than 4 weeks with fever are at increased risk for bacteremia and sepsis and may require hospitalization for parenteral antibiotics. Similarly, any child younger than 5 years with a suspected UTI who appears systemically ill should be hospitalized. The American Academy of Pediatrics recommends that children who are dehydrated, are unable to tolerate oral medication, and appear toxic should receive intravenous antibiotics.[2] Additionally, children who are immunocompromised, are suspected of having urosepsis or bacteremia, or have failed oral therapy should be hospitalized. If the child can tolerate oral antibiotics and has reliable parents who will maintain follow-up and contact with the physician, the child may be managed as an outpatient.

Initial antibiotic treatment needs to be broad spectrum to cover the more common pathogens. Once culture results and sensitivities are complete, treatment can be tailored specifically to cover the identified organism. In patients who have had previous UTIs, the prior culture results should be considered when selecting the initial therapy. For children who are hospitalized, parenteral treatment such as a combination of aminoglycosides and ampicillin or cephalosporins is continued for 48 to 72 hours until the child is afebrile and stable and sensitivities are available. Once the child is stable, oral antibiotics can be initiated on the basis of sensitivity results. Most studies recommend treating febrile UTIs in young children for 7 to 10 days in total,[22,23] although more recent studies suggest that shorter-duration therapy may be equally effective.[24–26] The American Academy of Pediatrics recommends that the treatment duration be 7 to 10 days for uncomplicated UTI and 14 days for children with presumed renal involvement or who are toxic.[2] In infants younger than 6 weeks, ampicillin and gentamicin or ampicillin and a cephalosporin are good initial choices. The exception is ceftriaxone, which can increase the risk of kernicterus in young infants. For children likely to be infected with *Pseudomonas* or *Enterococcus*, ampicillin and gentamicin are the agents of choice because

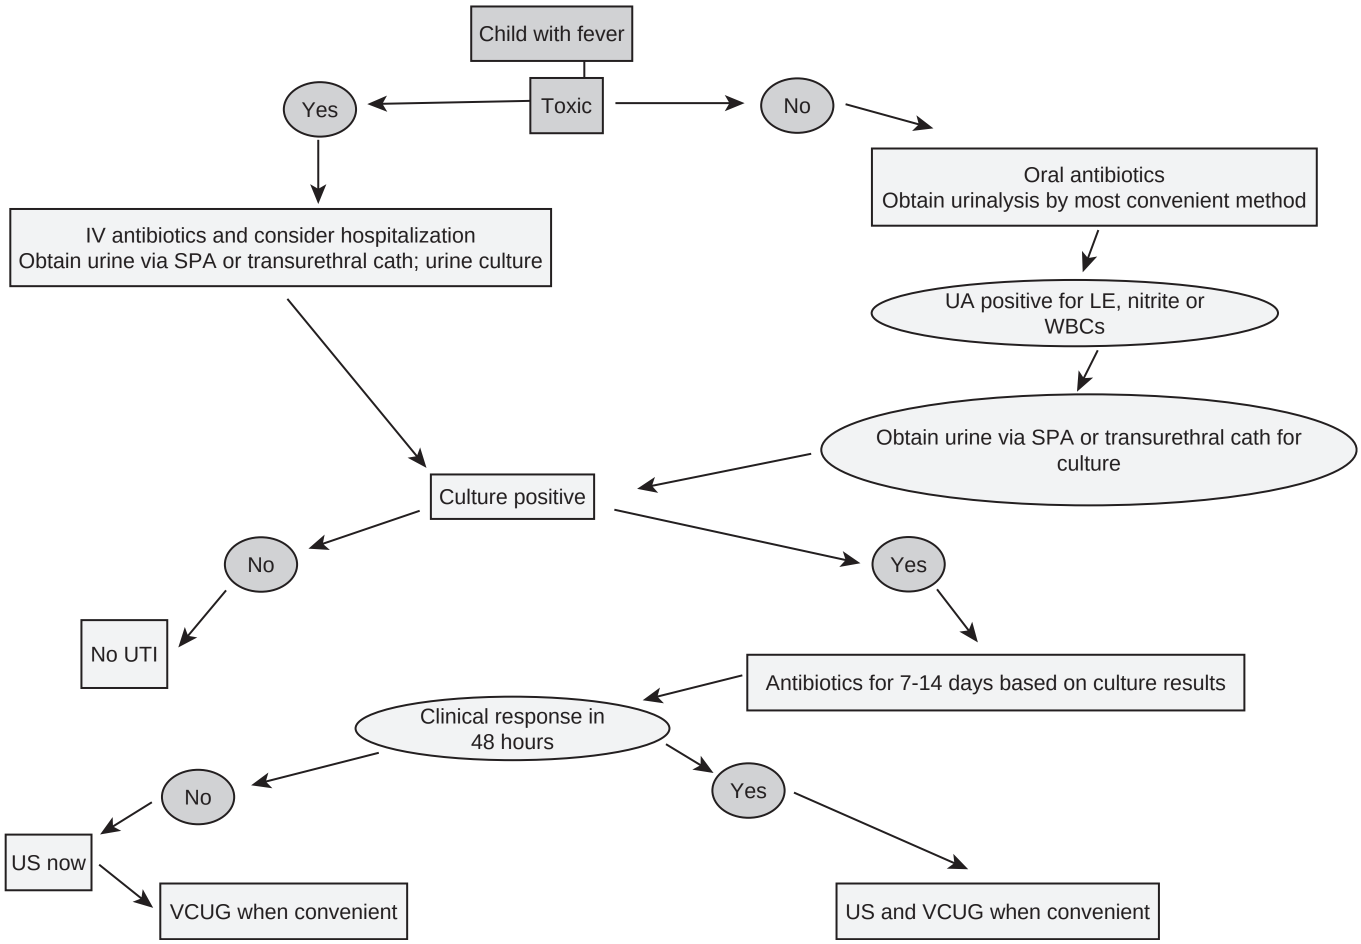

**FIGURE 114-7** Algorithm for management of urinary tract infection (UTI). LE, leukocyte esterase; SPA, suprapubic aspiration; UA, urinalysis; US, ultrasonography; VCUG, voiding cystourethrography; WBC, white blood cell.

cephalosporins have no effect on enterococci. Gentamicin levels should be monitored closely, particularly in children with impaired renal function.

In patients who are clinically stable, a broad-spectrum oral antibiotic is recommended. In a well-appearing child, a cephalosporin, trimethoprim-sulfamethoxazole (TMP-SMZ), or nitrofurantoin is a common choice. TMP-SMZ should not be used in children younger than 2 months because of the increased risk of kernicterus and blood dyscrasias. Nitrofurantoin, which is excreted in the urine and does not achieve therapeutic concentrations in the bloodstream, should not be used in febrile infants with UTI or in children in whom there is concern about renal involvement. The fluoroquinolones have recently been authorized for pediatric use.[11,27] Table 114-5 provides a summary of the commonly used antibiotics.

Low-dose antibiotic prophylaxis should be considered in all children with a febrile UTI awaiting a full evaluation with renal US and VCUG. Children with VUR, recurrent UTIs, or partial obstruction or who are immunocompromised should be considered for prophylactic antibiotics, although the clinical benefit remains in question.[17,19] The ideal prophylactic agent provides high urinary antibiotic excretion with low serum levels. Amoxicillin, nitrofurantoin, and TMP-SMZ are the most commonly prescribed agents. However, *Escherichia coli* has demonstrated increasing resistance to amoxicillin, thus limiting its use in children with symptomatic UTI. Generally, the antibiotic used for prophylaxis should be different from the antibiotic used to treat the acute infection.

In patients with normal studies and recurrent UTIs—defined as three or more infections within a 6-month period—prophylactic antibiotics may be indicated. In these cases, one must consider other factors such as the patient's age, as well as the patient's biologic predisposition for UTIs and voiding pattern. For children started on prophylactic antibiotics, the rate of infection usually decreases; however, the risk of developing another UTI returns to baseline once prophylactic antibiotics are discontinued. These patients should be carefully screened for bladder and bowel dysfunction. In cases of asymptomatic bacteriuria, current recommendations include strict follow-up without antibiotic treatment.

VUR treatment depends on several factors: age at presentation, grade of reflux, presence or absence of voiding dysfunction, comorbidities, family compliance with a treatment protocol, and choice. It is helpful to divide VUR into primary and secondary categories. Primary reflux refers to a congenital abnormality of the vesicoureteral junction resulting in a foreshortened ureteral tunnel and poor detrusor backing of the ureter. The lack of detrusor backing prevents the ureter from being collapsed as the bladder fills (Fig. 114-8). Secondary reflux refers to other anatomic or functional abnormalities that may lead to reflux such as bladder outlet obstruction or an abnormality of the vesicoureteral junction (Table 114-6).

In the majority of patients with VUR, antibiotic prophylaxis, UTI surveillance, a regular voiding pattern, constipation management, and regular follow-up US and VCUG are the mainstays of therapy.[28] Indications for surgical correction are debatable, but most would agree with the following: breakthrough upper UTIs, renal scarring developing on antibiotic prophylaxis, poor renal growth, failure to follow a treatment plan, high-grade VUR (except in young infants), a fixed anatomic defect of the ureterovesical junction, and persistence of VUR followed for 2 years or longer associated with symptoms of BBD or UTI.[28]

VUR in a child with a recognized bladder and bowel dysfunction requires special mention. It is clear that if the bladder and bowel dysfunction (including constipation, if present) is managed well, the incidence of breakthrough UTIs and renal scarring and the need for surgical correction of VUR are significantly reduced.[28–31] Voiding dysfunction is a common cause of failed ureteral reimplantation.[32]

Many surgical techniques exist using intravesical and extravesical approaches. They all require the establishment of an intramural ureter with sufficient muscular backing to provide adequate ureteral wall coaptation with filling and contraction of the bladder such that retrograde flow of urine is prevented (Figs. 114-9 to 114-11). This approach requires an average hospital stay of 48 hours or less and has a complication rate of about 4%, 2% to 2.5% due to ureteral obstruction and 2% to 2.5% due to persistent VUR. The Pediatric Vesicoureteral Reflux Guidelines Panel delineated an open surgical success rate of 98% and a rate of 50% to 92% with endoscopic correction of VUR.[28]

In 1981 Matouschek[33] introduced the concept of endoscopic correction of urinary incontinence and VUR by polytetrafluoroethylene (Teflon) paste injection. This method was developed and popularized by Puri and O'Donnell, initially in a piglet model in 1984 and then applied to children with VUR.[34,35] This procedure causes little postoperative discomfort and can be performed as an outpatient procedure (Figs. 114-12 and 114-13). Owing to the potential risks of particle migration and malignancy induction,[36] Teflon is not in current use.[32] Many other injectable materials have been investigated and applied to animal models and humans for VUR correction. Success rates approach 75% to 80%, depending on the grade of reflux and the number of injections.[37–40] Today, the most commonly used materials worldwide are dextranomer macrospheres (Deflux, Oceana Therapeutics, Edison, N.J.) and polydimethylsiloxane with a water-based biocompatible carrier gel.

# Urinary Lithiasis

## HISTORY AND INCIDENCE

Urinary stones, in both the bladder and the kidney, have been reported in Egyptian mummies dating from 4800 BC,[41] and urolithiasis has long been studied in an effort to understand its pathogenesis and to refine treatment strategies. Although urolithiasis has been recognized in children for centuries, the clinical picture, evaluation, and management continue to evolve.

Approximately 7% of all stones occur in children younger than 16 years.[42] Traditionally, urolithiasis was characterized by bladder calculi in children of developing countries; the

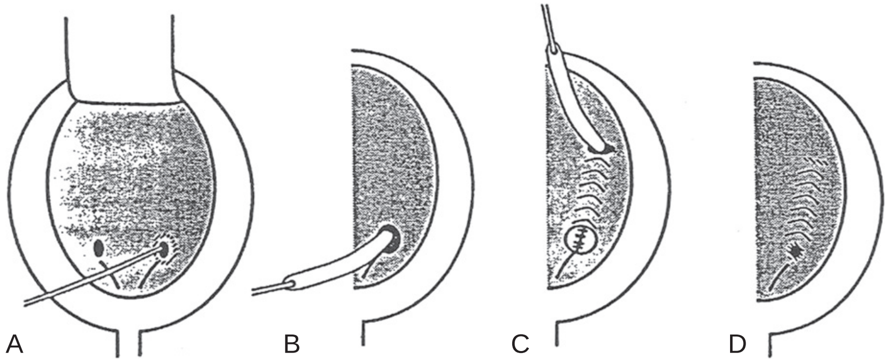

**FIGURE 114-9** Leadbetter-Politano ureteral reimplantation. **A,** The ureter is catheterized through a midline bladder incision. **B,** The ureter is dissected from the surrounding detrusor until it is totally mobilized. **C,** A neohiatus is created by passing a right-angle clamp into the bladder. A subepithelial tunnel is created, and the detrusor defect is closed. **D,** The ureter is then passed through the tunnel, and its orifice is matured. (From Rowe M, O'Neill JA, Grosfeld JL, et al: Essentials of Pediatric Surgery. St Louis, Mosby-Year Book, 1995.)

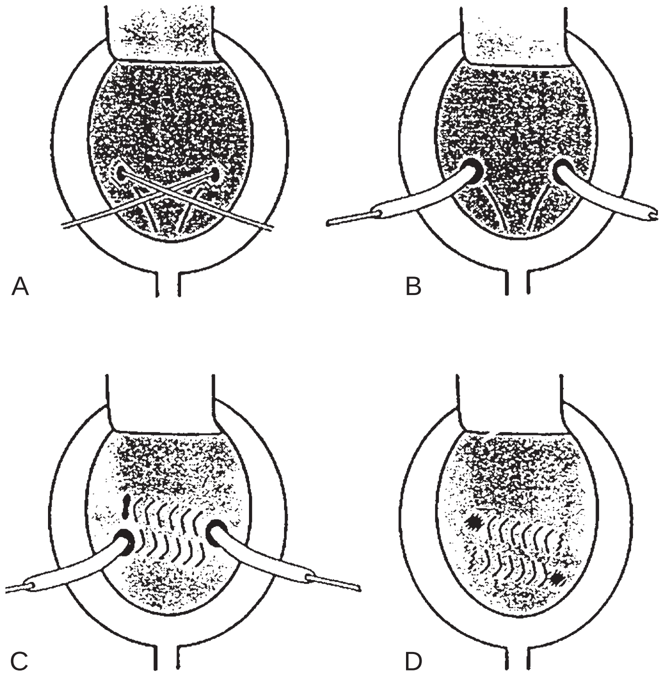

**FIGURE 114-10** Cohen cross-trigonal ureteral reimplantation. **A,** Both ureters are catheterized. **B,** Both ureters are fully mobilized, as in the Leadbetter-Politano procedure. **C,** The detrusor is approximated around the ureter to create a normal neohiatal caliber, and two transtrigonal tunnels are created. **D,** The ureters are then passed through the respective tunnels, and the orifices of the ureters are matured. (From Rowe M, O'Neill JA, Grosfeld JL, et al: Essentials of Pediatric Surgery. St Louis, Mosby-Year Book, 1995.)

incidence of upper tract calculi, occurring mainly in industrialized areas, was much lower in children than in adults. Also, in comparison with adult stone formers, children were more likely to demonstrate risk factors outside the metabolic realm such as UTI, anatomic abnormalities, and surgical alterations in the urinary tract. Currently, the incidence of upper tract calculi in children without these predisposing factors is on the rise worldwide,[43,44] and the paradigms are changing. The importance of metabolic evaluation in children with urolithiasis has been shown, even in countries thought to have primarily endemic bladder stone disease based on diet. With the introduction of smaller endoscopic instruments and the refinement of extracorporeal shock wave lithotripsy (ESWL) technology, treatment of pediatric stone disease now closely parallels stone management in adults.

## SPECTRUM OF DISORDERS

Although there are a number of contributing factors, the central concept in urolithiasis is urinary supersaturation. When a solute is added to a solvent, it dissolves until a certain concentration is reached, at which point the solution is saturated. Beyond this point, the solute may form crystals in the solution, and those crystals may aggregate. Supersaturation occurs when this point is surpassed and crystal precipitation occurs in the urine in the form of nucleation, the basis of urinary stones. Crystallization and aggregation must also occur for stones to form. These processes are influenced by the presence of inhibitors and promoters. Citrate, magnesium, pyrophosphate, glycosaminoglycans, nephrocalcin, and Tamm-Horsfall proteins are inhibitors of crystallization and aggregation. Bacterial infections and anatomic abnormalities such as obstruction or stasis may encourage crystal aggregation and retention, thus increasing the risk of clinically significant urolithiasis.[45,46] Multiple studies of urolithiasis in children have shown metabolic abnormalities in up to 92% of patients, with hypercalciuria and hypocitraturia the most common.[46–52] Interestingly, even in children with urolithiasis and anatomic obstruction, the prevalence of urinary metabolic abnormalities is high.[45,49,53] The prevalence of infection-related stones is especially high in children younger than 6 years.[54] Approximately 12% of children with urolithiasis have no identifiable risk factor.[55] Urinary stone disease can, therefore, be classified as metabolic, anatomic, infectious, or idiopathic, on the basis of underlying factors. The relative contribution of these factors, which may overlap in some cases, is shown in Table 114-7.

Stones can also be classified on the basis of their location in the upper urinary tract (kidneys and ureters) or lower urinary tract (bladder and urethra) and as symptomatic or asymptomatic. These classifications may influence the decision-making process with regard to treatment options.

## CLINICAL PRESENTATION

In adults, upper tract calculi present in a characteristic fashion in the form of renal colic. This severe, intermittent, refractory pain, often accompanied by nausea and vomiting, is a less common presentation in children. Although classic renal colic does occur in children, more commonly, stones involving both the upper and lower tract are detected during the radiologic evaluation for UTI or hematuria. Younger children in

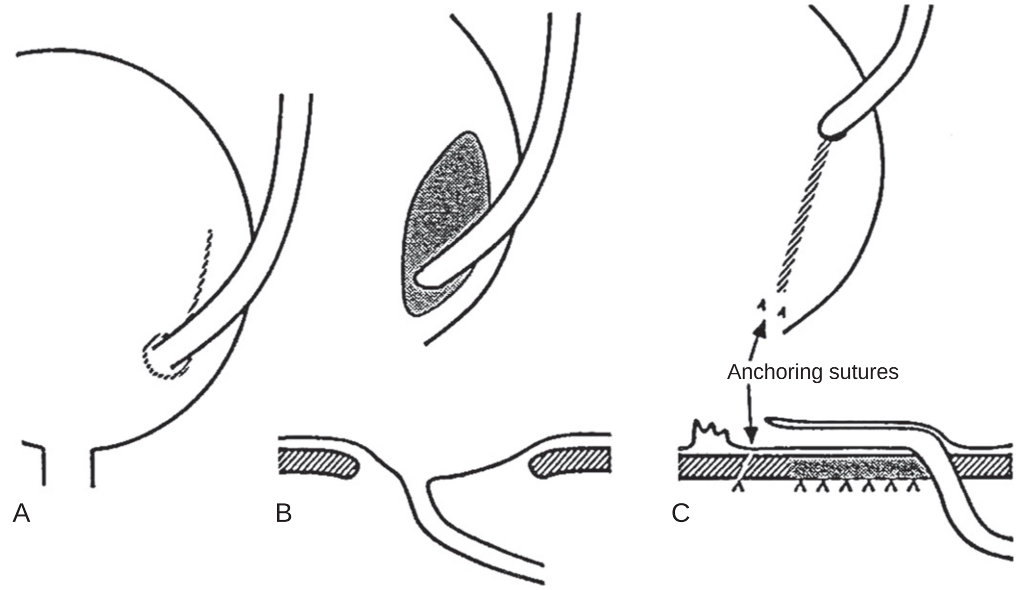

**FIGURE 114-11** Extravesical detrusorrhaphy—a modification of the Lich-Gregoir procedure. **A,** The ureter is mobilized for several centimeters externally. The detrusor is then incised in a caudal direction and carried around the ureteral insertion. **B,** The ureter is left attached only to the underlying bladder mucosa. **C,** The distal ureter is advanced and fixed with two sutures. Then the detrusor is approximated over the ureter to recreate the tunnel, which is now longer than before. (From Rowe M, O'Neill JA, Grosfeld JL, et al: Essentials of Pediatric Surgery. St Louis, Mosby-Year Book, 1995.)

particular may also present with nonspecific abdominal pain accompanied by microscopic hematuria or, less frequently, with outlet obstruction (Fig. 114-14).

## DIAGNOSIS

History and physical examination are key components to rule out other causes of abdominal and back pain. The history should include a dietary and urologic history. One clue to the presence of urolithiasis is a positive family history for kidney stones, which may be present in up to 37% of children with stone disease.[56] Other underlying medical conditions that may predispose children to urolithiasis include hyperparathyroidism, renal tubular acidosis, inflammatory bowel disease, seizure disorders treated with a ketogenic diet,[57] cystic fibrosis, and Dent disease.[58] Urinalysis and urine culture should be obtained to assess for microscopic hematuria, urine pH, crystals in the sediment, and UTI. Baseline serum electrolytes, blood urea nitrogen, creatinine, calcium, uric acid, phosphorus, and magnesium levels should also be obtained. A 24-hour urinalysis for stone risk assessment should be obtained after treatment of the presenting stone.

Radiologic evaluation may include plain abdominal radiography, US, intravenous pyelography, and noncontrast CT. In adults, the standard imaging study is noncontrast CT because of its sensitivity and specificity. In children, however, these studies are limited, although some authors recommend CT as the first-line imaging study.[59,60] Others recommend initial abdominal US because of the varied presentation of urolithiasis in children and because of concerns about radiation exposure.[61,62] Plain abdominal radiography may not be helpful in the initial diagnosis but may assist in planning treatment on the basis of the ability to visualize the stone.

## TREATMENT

Four main factors affect initial treatment decisions: the clinical scenario, stone composition, stone size, and stone location (Table 114-8). In the setting of potential urinary tract obstruction with fever or complete obstruction, urgent relief of the obstruction is warranted, either by placement of a ureteral stent or by percutaneous nephrostomy. The decision between ureteral stent placement and percutaneous nephrostomy is dependent on physician preference, available resources, and patient size and anatomy. In children, nephrostomy drainage may be performed without general anesthesia and may be the procedure of choice. After relief of the obstruction and subsequent treatment of infection, definitive therapy directed at stone clearance can be undertaken.

The most common composition of upper tract calculi is calcium oxalate. The stones are radiopaque and do not respond to dissolution therapy. Calcium oxalate monohydrate stones may be resistant to ESWL, whereas calcium oxalate dihydrate

**TABLE 114-8**
**Factors Affecting the Treatment of Stones**

| *Factor* | *Treatment Consideration* |
|---|---|
| Clinical scenario | |
| Bilateral obstruction | For all scenarios, urgent relief of obstruction via stent or nephrostomy |
| Obstruction of a solitary kidney | |
| Fever/UTI with potential obstruction | |
| Intractable pain | |
| Stone composition | |
| Uric acid | Consider chemodissolution |
| Struvite | Continue antibiotic therapy throughout treatment |
| Cystine | Responds poorly to ESWL |
| Calcium oxalate | Radiopaque; may respond well to ESWL |
| Stone size | |
| <4 mm | Approximately 90% chance of spontaneous passage |
| 4-6 mm | Approximately 50% chance of spontaneous passage |
| >6 mm | Approximately 10%-20% chance of spontaneous passage |
| Stone location | |
| Renal | ESWL or PCNL |
| Proximal ureteral | Ureteroscopic extraction (antegrade) or ESWL |
| Distal ureteral | Ureteroscopic extraction (retrograde) or ESWL |
| Bladder | Cystolithotomy or cystolitholapaxy |

ESWL, extracorporeal shock wave lithotripsy; PCNL, percutaneous nephrostolithotomy; UTI, urinary tract infection.

calculi, which are more common, generally respond well. Uric acid calculi are radiolucent and form at a low urinary pH. They are often identified by their characteristic Hounsfield units on noncontrast CT. Uric acid stones may be dissolved and prevented by alkalinization of the urine (pH $> 6.5$) using sodium bicarbonate or potassium citrate. If symptoms are present, a ureteral stent or nephrostomy tube may be used for temporary relief during dissolution therapy. Struvite stones are usually associated with infection, and antibiotics should be continued throughout treatment. Because struvite stones are generally large or staghorn in shape, percutaneous nephrostolithotomy (PCNL) is often the first-line treatment for these stones. Cystine stones are typically difficult to treat and frequently recur. Small renal cystine stones may be treated by ESWL, whereas larger stones will likely require PCNL or ureteroscopic extraction.[63]

Stone size can be used to predict whether the stone will pass without intervention. In adults, the likelihood of passing a stone less than 4 mm is 90%, a stone between 4 and 6 mm has an approximately 50% rate of spontaneous passage, and one greater than 6 mm has a 10% to 20% rate. Interestingly, small stones and stone fragments after ESWL have shown the same passage rate in the pediatric population, theoretically because of ureteral pliability and peristalsis.[46,64,65] Therefore supportive care in the form of vigorous hydration (oral or intravenous, as needed) and analgesic therapy is a reasonable first step in a child with a small stone in the absence of fever or complete ureteral obstruction. Studies demonstrate that partial obstruction is well tolerated in the short term; thus this treatment may be continued for 3 to 4 weeks on an outpatient basis to allow spontaneous passage of the stone. In the case of an obstructing stone 4 mm or greater in size, the likelihood of spontaneous passage is significantly lower, and intervention may be indicated sooner. Nonobstructing stones can be treated electively. Stones larger than 2 cm have demonstrated a poor stone-free response to ESWL, and a National Institutes of Health Consensus Conference in 1998 recommended that stones larger than 2 cm be approached by PCNL as first-line treatment. "Sandwich therapy," which is a combination of PCNL and ESWL, is an addition to the treatment armamentarium for large calculi.

Calculi are most commonly located within the renal pelvis or calices, proximal ureter, distal ureter, or bladder. Each location lends itself to different treatment approaches. For renal calculi, ESWL or PCNL is suitable. ESWL or ureteroscopic stone extraction is an appropriate choice for ureteral stones, whereas cystolitholapaxy or cystolithotomy is recommended for bladder calculi.

ESWL, first described in the early 1980s,[66] is noninvasive and well-tolerated but requires general anesthesia in many young children and special precautions in infants. Children who weigh as little as 6.8 kg have been successfully treated. This procedure may be suitable for proximal ureteral stones and even some distal ureteral stones; however, treatment of calculi more distal than the midureter is contraindicated in females because of the unknown effects of shock waves on the developing ovary. Stone-free rates after one to two treatments generally range from 70% to 97% (mean 85%).[67–71] Complications of ESWL therapy include incomplete fragmentation of the stone, retained fragments, Steinstrasse, perinephric hematoma, fever, renal colic, and abrasion or ecchymosis at the site of shock wave entry and exit.[72] Although the distant and long-term effects of ESWL are unknown, short-term follow-up studies suggest no demonstrable complications with regard to renal function or hypertension.[42,72–74]

PCNL requires nephrostomy tube placement, general anesthesia, and inpatient hospitalization. Once the nephrostomy tube is placed, the tract is dilated to a size appropriate for the nephroscope and electrohydraulic or ultrasonic lithotriptor.[75] It is a good choice for a large renal stone associated with hydronephrosis or one refractory to ESWL treatment (cystine or calcium oxalate monohydrate). PCNL and ESWL can be combined for optimal treatment in some cases, so-called *sandwich therapy*. Stone-free rates may approach 100%; however, multiple procedures may be required to render a child stone free.[68,76] Complications of PCNL include perforation of the collecting system, bleeding, extravasation of irrigant, pneumothorax, intestinal injury, and retained fragments.

Ureteroscopic stone extraction in children has become feasible with the development of progressively smaller ureteroscopes and working instruments. Ureteroscopic treatment of ureteral calculi may be approached in an antegrade or retrograde fashion, and the stone may be extracted intact or fragmented using a laser, ultrasound, or hydraulic lithotriptor (Swiss Lithoclast). Success rates for ureteroscopic stone extraction may exceed 95%.[68,69,77–80] An indwelling ureteral stent may be left in place for 24 to 72 hours to prevent obstruction secondary to ureteral spasm or edema. Complications include ureteral perforation, ureteral stricture, reflux, proximal migration of the stone, and loss of the stone through a perforated ureter.

Despite the success of minimally invasive treatment for pediatric stone disease, open surgical treatment is still required in up to 17% of patients,[69] which may result in decreased renal function in up to 45%.[81] Anatomic abnormalities such as ureteropelvic junction obstruction or obstructed megaureter may be addressed concurrently with stone treatment and must be dealt with eventually to prevent recurrence and optimize renal function.[82,83]

Cystolitholapaxy, or transurethral lithopexy of bladder stones, has been the preferred approach for all but large bladder calculi. The stone is fragmented using the electrohydraulic lithotriptor, and the fragments are irrigated from the bladder. Bladder calculi are becoming more common in children who have undergone augmentation cystoplasty, and in this population, open removal of the intact calculi may be a more prudent approach to minimize the risk of recurrence due to retained fragments, although this remains controversial.[84–86]

## RECURRENCE

Children who present with urolithiasis are at risk for recurrence for a longer time than adults. Thus the cumulative likelihood of recurrent stone disease is higher in children. Therefore a thorough metabolic evaluation is strongly encouraged in children after their first presentation with urolithiasis. A 24-hour urinalysis for stone risk should be obtained including, at a minimum, urinary volume, pH, and calcium, creatinine, uric acid, citrate, oxalate, and magnesium levels. The cornerstones for preventing stone recurrence as the child enters adulthood are the ability to render the patient stone free, elucidate and treat metabolic abnormalities, control urinary infection, and correct anatomic anomalies.

# Renal Vein Thrombosis

Renal vein thrombosis is a variable clinical disorder related to the acuteness and extent of venous occlusion of the main or intrarenal veins. Rayer[87] first described renal vein thrombosis more than 150 years ago. For many decades, the condition was rarely diagnosed clinically but was discovered at operation or autopsy. Once the condition was clinically recognized, treatment initially consisted of simple nephrectomy; this procedure was advocated until the early 1960s.[88,89] In 1964 Stark[90] reported excellent recovery after conservative management, suggesting that aggressive surgical intervention was unnecessary. The use of anticoagulants or thrombolytic agents still remains controversial because of the limited number of pediatric cases and the absence of controlled trials evaluating the risks and benefits of these therapeutic interventions.

## CAUSE

Renal vein thrombosis is a disease of infancy; approximately 80% of patients present during the first month of life.[91] It results from diminished renal blood flow, increased blood viscosity, and hypercoagulability. The neonatal kidney is particularly vulnerable because of its low renal perfusion pressure and double intrarenal capillary network. Many factors also lead to hemoconcentration, with a sluggish venous flow that predisposes patients to thrombosis. In addition, up to 50% of these patients may have prothrombotic abnormalities.[92,93] The thrombotic process may originate in the main renal vein or in the small intrarenal veins.[94] Thrombosis may be unilateral or bilateral, but thrombosis from the inferior vena cava is rare.[95]

Clinical conditions predisposing neonates to thrombosis include preterm delivery[92]; perinatal asphyxia, polycythemia, and cyanotic congenital heart disease[96]; maternal diabetes[97,98]; septicemia and congenital nephrotic syndrome[99,100]; cytomegalovirus infection[101]; shock, diarrhea, and dehydration[102]; activated protein C resistance[92]; factor V Leiden heterozygosity[93]; and maternal use of diuretics and corticosteroids.[103] Renal vein thrombosis has been noted in association with adrenal hemorrhage and has been recognized on prenatal US.[104–106]

In infants older than 1 month, renal vein thrombosis is usually associated with hypovolemia such as with gastrointestinal fluid losses or burns[99,102,107] or renal disease such as nephrotic syndrome.[108,109] Renal vein thrombosis may occur secondary to prolonged inferior vena cava catheterization, with thrombus extending into the renal vasculature.[108]

## CLINICAL PRESENTATION

Clinical presentation varies, depending on the age, extent, and acuity of the thrombosis. In the neonatal period, males are affected predominantly (62%) and most cases are unilateral (70%) and on the left side (63.6%).[110] Renal vein thrombosis may present prenatally or in a healthy newborn with no predisposing illness. In neonates, classic features include a palpable mass and gross hematuria; however, these signs may be found in only 13% of patients at the time of diagnosis.[101] Caval thrombosis may be suspected when the lower extremities are swollen and the superficial abdominal veins are dilated. Renal vein thrombosis may also present in infancy after a predisposing illness, or it may develop in an older child who has preexisting renal disease (nephrotic syndrome). Presentation in older children generally includes acute flank pain, hematuria, and a palpable mass.

## DIAGNOSIS

Renal vein thrombosis is frequently associated with thrombocytopenia (platelet count $< 75{,}000$ cells/mm$^3$) as a result of platelet entrapment in the renal thrombus. A consumptive coagulopathy characterized by a prolonged prothrombin time and increased fibrin degradation products may also be present. Leukocytosis is often present, and the presence of anemia varies. Serum electrolyte levels vary, depending on predisposing illness and renal function. Urinalysis usually shows blood and protein. Screening for prothrombotic abnormalities should be considered.

## IMAGING

An abdominal radiograph may show an enlarged renal shadow or have a lacelike pattern, similar to the renal vascular tree, but it is usually normal.[111] Renal Doppler US is the test of choice to evaluate the renal mass and image the renal vein and inferior vena cava. Diagnostic features include thrombus in the vein and renal enlargement.[112] Renal function can be monitored initially and during recovery with radionuclide scintigraphy using technetium 99m DMSA or technetium 99m MAG3. CT, magnetic resonance imaging, or inferior venacavography may be indicated to determine the extent of a thrombus (with inferior vena cava involvement) or to rule out rare causes of thrombus or thrombosis (e.g., external venous compression or thrombus from a renal tumor).

## TREATMENT

Because of the relative infrequency of renal vein thrombosis and the lack of controlled trials, no general consensus on optimal treatment exists. Although nephrectomy and thrombectomy were previously performed during the acute phase, this was rarely necessary on an emergent basis and is now limited to patients with anatomic obstruction of the inferior vena cava.[90] Management of renal vein thrombosis should include a multidisciplinary team including neonatologist or pediatrician, radiologist, hematologist, and nephrologist. Initial treatment should include correction of and therapy for all predisposing conditions, aggressive fluid and electrolyte repletion, and prevention of propagation of the venous thrombus. The use of anticoagulants or thrombolytic agents is controversial because of the absence of controlled trials. In a retrospective study of 16 patients with renal vein thrombosis, renal function was normal in 6 of 9 patients treated with heparin or enoxaparin or both, compared with 0 of 7 patients who did not receive anticoagulation therapy.[93,113] In a review of the English-language literature from 1992-2006, no difference in the rate of significant renal atrophy (70.6% overall) was seen between groups treated with supportive care only (72.5%) and heparin (75.3%).[110] A reasonable approach includes aggressive supportive measures in cases of unilateral renal vein thrombosis without caval extension, especially for those at increased risk of hemorrhagic complications.

For unilateral renal vein thrombosis with caval extension or bilateral renal vein thrombosis, heparin therapy may be considered because of the risk of pulmonary emboli or renal failure.[91] Thrombolytic therapy may be considered for bilateral renal vein thrombosis and renal failure. Although heparin has been used successfully, hemorrhagic complications have been reported in neonates.[114,115] Low-molecular-weight heparin may be a safer alternative, with careful attention to special dosing requirements in preterm and full-term newborns.[93,116] Thrombolytic therapy with streptokinase and urokinase by systemic and regional routes has been reported.[95,99,114] Potential complications with the systemic use of streptokinase include hemorrhage and allergic reactions; these occur less often with selective regional use. Route, rate, and length of infusion of thrombolytic agents differ among various reports; thus standardized protocols are difficult to establish.

## OUTCOME

With improved recognition and management of renal vein thrombosis and the various predisposing conditions, the overall survival rates have improved to about 80% to 85% or higher.[91,110] Most deaths are due to underlying disease rather than renal infarction. Long-term morbidity including conditions such as hypertension, renal atrophy, and chronic UTI has not been systematically assessed. In terms of renal function, the outcome can vary from full recovery to nonfunction. Periodic monitoring with radionuclide scintigraphy permits detailed follow-up evaluation of renal recovery. Renin-mediated hypertension in association with a small, atrophic kidney or recurrent UTIs localized to the shrunken renal unit are reasonable indications for nephrectomy.

CHAPTER 115

# Ureteral Duplication and Ureteroceles

Ramnath Subramaniam

A duplex (duplicated) system is a kidney with two pelvicaliceal systems. Complete duplication refers to a kidney with two ureters that drain separately into or below the bladder. Incomplete duplication refers to a kidney with two ureters that fuse into a unit proximal to the bladder and then drains into the bladder through a single orifice. A bifid system is a form of incomplete duplication with two renal pelves that join into a single ureter.

The upper or lower pole ureter refers to the ureter draining the upper or lower pole (moiety) of the kidney, respectively. The upper or lower pole orifice refers to the ureteral orifice associated with the upper or lower pole ureter, respectively. An ectopic ureter refers to a ureter that drains into an abnormal site.

The greater majority of duplicated systems are incomplete, and these forms rarely give rise to clinical problems. In contrast, complete duplication anomalies are rare, affecting less than 0.1% of individuals (most females), and are more commonly of clinical significance.[1] Patients with urinary symptoms such as those associated with urinary tract infection (UTI), have about a 4% incidence of ureteral duplication.[2] Two thirds of children with duplex systems who present with UTI have vesicoureteric reflux (VUR).[3] This is particularly true of complete duplex systems, which are associated with higher grades of reflux and renal dysplasia with poor renal function in the affected moieties.[4] A significant familial predisposition exists—between 12.5% and 30% of siblings of affected patients have duplications.[5–7] It has been suggested that the mode of inheritance is autosomal dominant with incomplete penetrance.[5,8]

Less common types of ureteral duplications are (1) the “inverted Y” ureter, consisting of a single pelvis and a proximal ureter that bifurcates distally into two ureters ending with two separate orifices, one of them being frequently ectopic; and (2) the “blind-ending” duplication of the ureter, which occurs when one limb of a bifid ureter does not drain a portion of renal parenchyma.[9,10]

A ureterocele is a cystic dilatation of the lower end of the ureter where it joins the epithelium of the lower urinary tract. An intravesical ureterocele lies entirely within the bladder, whereas an ectopic ureterocele has a portion that lies below the bladder neck.

## Embryology

Ureteral duplication is the consequence of the abnormal development of the ureteral bud from the mesonephric (wolffian) duct. Premature branching of the bud causes incompletely duplicated ureters. Complete ureteral duplication occurs when two separate ureteral buds arise independently from the mesonephric bud and induce the development of a duplex kidney.

The cloaca is divided into the urogenital sinus anteriorly and the alimentary tract behind. Around the eighth week of gestation, the distal end of the mesonephric duct plus a short segment of this duct above the ureteric bud expands and, by differential growth, is incorporated into the lower end of the posterior wall of the developing bladder and urogenital sinus. At this stage the mesonephric duct lies below and medial to the ureteral orifice and is referred to as the wolffian duct. As a result of this “migration,” the normal ureteral orifice is situated at the superolateral angle of the bladder trigone (Fig. 115-1, *A*).[11]

In the male the mesonephric duct becomes the epididymis, vas deferens, and seminal vesicle and enters the posterior urethra above the external urethral sphincter at the verumontanum. The associated ureteric bud must, therefore, also join the developing bladder and urethra above the external sphincter. The testis that initially arises from a region medial to the developing kidney becomes attached to the mesonephric duct. As it descends to the deep inguinal ring, the vas deferens (mesonephric duct) crosses the origin of the ureter superiorly as it arches medially and inferiorly to the seminal vesicle at the level of the verumontanum.[11]

In the female the mesonephric duct becomes the Gartner duct, which lies close to the lateral wall of the vagina. The paramesonephric ducts (müllerian ducts) develop medial to the mesonephric duct. At the caudad end of the embryo, these incorporate the distal end of the remnants of the mesonephric duct where they penetrate the cloaca near the midline. Thus owing to differential growth, the ureteric bud may migrate

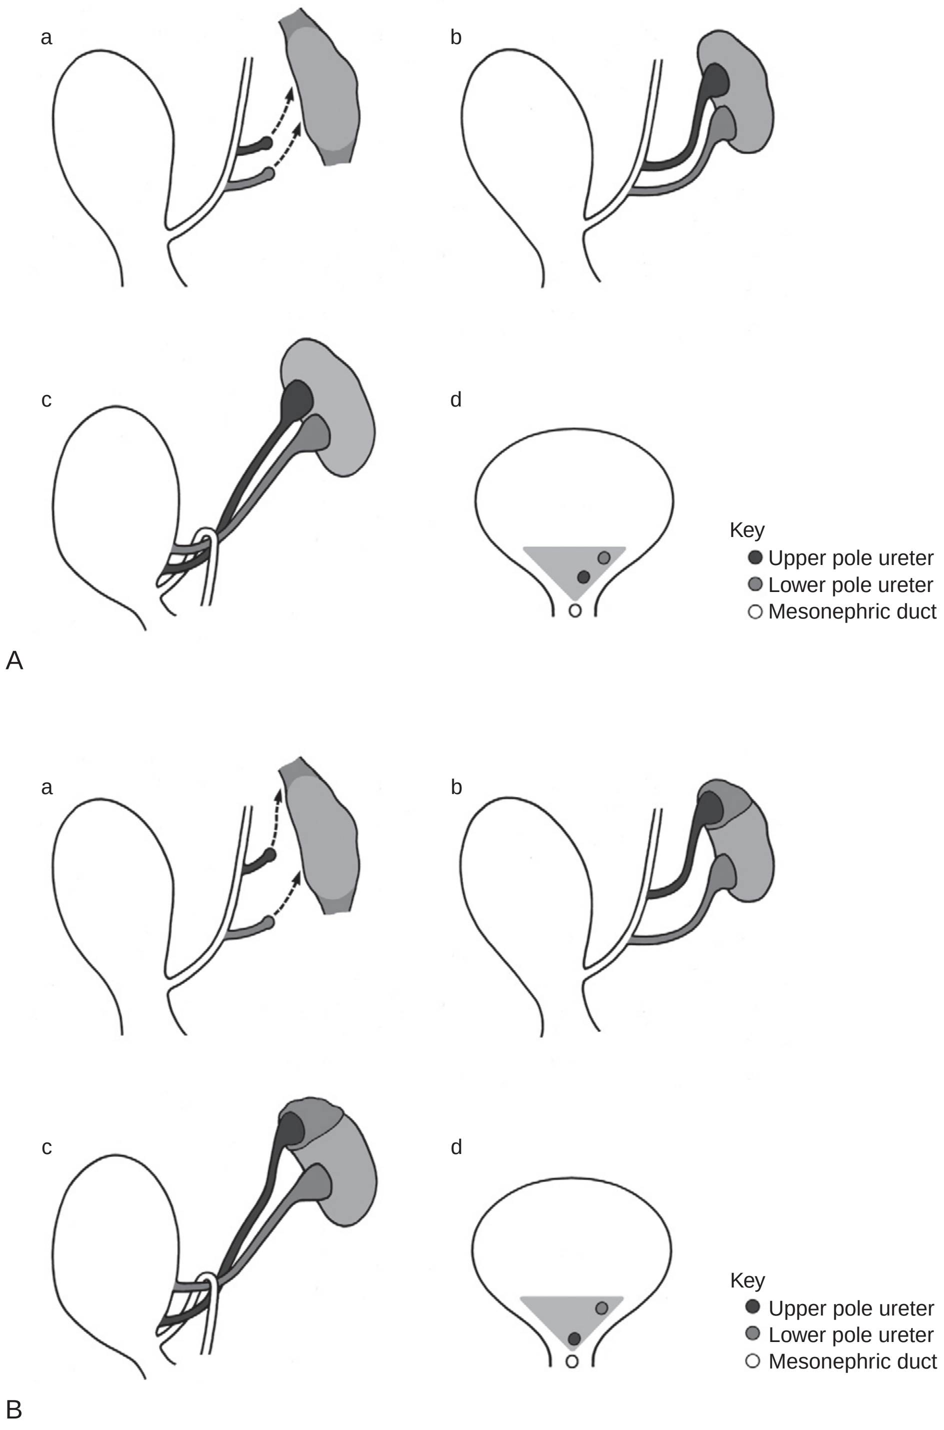

**FIGURE 115-1** **A,** The normal relationship between the mesonephric duct and the ureteric buds and the subsequent positions of their orifices within the bladder (Weigert Meyer law). Also note the area where the buds come in contact with the renal blastema. **B,** Compare with **A** and you will notice that the upper ureteric bud reaches the renal blastema late and into the periphery, thus inducing dysplasia of the upper renal moiety (shaded); also note the position of the upper ureteric orifice in this scenario is caudal in comparison with the situation in **A.**

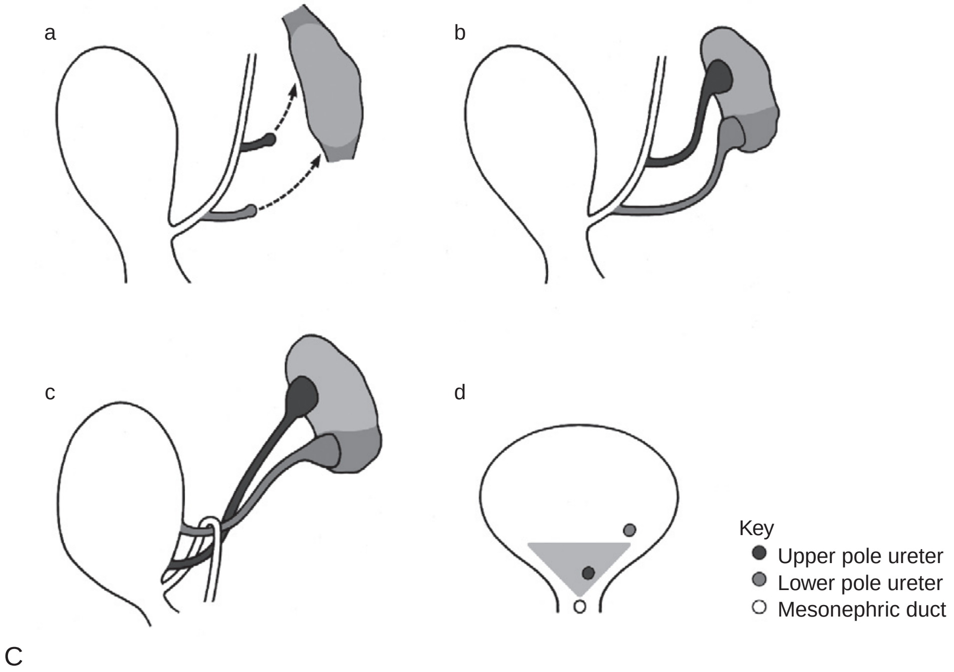

**FIGURE 115-1—CONT'D.** **C,** Compare with **A** and you will notice the lower ureteric bud reaches the renal blastema in the periphery and thus induces abnormal dysplastic development of the lower renal moiety; also note that the position of the lower ureteric orifice in this case is superolateral in comparison with the situation in **A.** Here the submucosal tunnel of the lower pole ureter is relatively short and therefore more prone to reflux.

with the associated paramesonephric duct structures to sites such as the vestibule, vagina, cervix, uterus, and rectum.[11]

The induction of the metanephric blastema by the ureteral bud in a central position is critical to normal renal development. If the ureteral bud meets the metanephric blastema either too caudal or too cranial along the metanephric blastema, renal dysplasia will result.[12] The more superior of the two ureteric buds may make contact with the blastema of the upper pole of the kidney too late to induce normal development. In clinical practice, renal dysplasia affecting the upper pole of the kidney is often encountered in duplex systems (see Fig. 115-1, *A* and *B*).

During development of the trigone, the most cranial ureter that drains the upper moiety of the duplex kidney rotates inward on its long axis and crosses the lower pole ureter. Therefore the upper pole ureter opens in the urogenital sinus in a more distal and medial position than the lower pole ureter that opens more proximally. This relationship between the two ureteral orifices is constant and is called the Weigert-Meyer rule (Fig. 115-1, *A*).

When the two ureters originate close to each other and in a near normal position, both ureteral orifices open in the trigone (see Fig. 115-1, *A*). Conversely, when the two ureteral buds originate at widely separate positions on the mesonephric duct, the upper pole ureter, which is located at a more cranial position on the mesonephric duct, is incorporated into the urogenital sinus at a later stage of development. As a result, the ureteral orifice is situated in an ectopic position, inferior to the trigone (see Fig. 115-1, *B*). In the male in this situation, the location of the ureteral orifices can be anywhere along the lower mesonephric duct or its derivatives below the bladder neck in the posterior urethra but always above the external urethral sphincter. Therefore urinary incontinence due to duplex systems with ectopia of the upper pole ureter does not occur in boys. In girls, however, the situation is different. During development, the mesonephric duct derivatives can open anywhere caudally from the developing bladder, commonly into the vault of the vagina.

The lower pole ureter, which joins the mesonephric duct closer to the urogenital sinus, is incorporated into the developing trigone at an early stage and consequently migrates laterally and cranially, leaving a relatively short intravesical tunnel (Fig. 115-1, *C*). VUR into the lower pole ureter may be present because of the short length of the intramural tunnel.

Occasionally, in either complete or incomplete duplication, one of the ureters fails to meet the developing blastema of the metanephros. In this case, a blind-ending ureter occurs, with no attachment to the kidney.[10] Rarely, an inverted Y abnormality is encountered. It is presumed to be caused by double ureteric buds arising from the mesonephric duct caudally and fusing cranially before merging above with the blastema of the metanephros.[9]

Recently, there has been a shift from classic theories to the cell biology view of congenital anomalies of the kidney and urinary tract (CAKUT).[13] The process of ureteral budding and metanephric differentiation into the final kidney is under the control of the renin-angiotensin system through the Agtr-2 receptor, which is intensely expressed in the mesenchymal cells surrounding the wolffian duct at the time of the initial budding of the ureter. Most recently it has been shown that ectopic budding and ureteral duplication may occur in Agtr2 null mice.[14] The formation of a double collecting system has also been observed in another group of experimental animals that are heterozygous mutants for the bone morphogenetic protein 4 (BMP4). BMP4 is a member of the transforming

growth factor-beta (TGF-β) superfamily and is credited to be part of the navigating system that allows the budding of the ureter from the mesonephric duct at a precise site.[13] Abnormalities in the number and site of the initial ureteral buds preceding a duplex collecting system and ectopic ureteral orifice with concurrent renal abnormalities are constantly observed in mice that are homozygous mutants for the *FOXC1* gene, which encodes for a transcription factor playing an essential role in embryonic development.[13]

# Incomplete Duplicated Systems

Uncomplicated duplex kidneys may be detected incidentally on ultrasound scans done for unrelated reasons. Bifid pelvis is never responsible for any symptoms. Incompletely duplicated ureters are also often completely asymptomatic but in rare cases are associated with distinct clinical problems.

Three clinical problems may affect an incompletely duplicated ureter: (1) VUR, (2) ureteropelvic junction obstruction, and (3) retrograde ureteral peristalsis (yo-yo phenomenon).

Treatment depends on the function of the affected renal moiety and on the length of the lower limb. If the function is poor, a partial lower pole nephroureterectomy is the appropriate choice, removing the lower moiety and its ureter down to the junction with the upper pole ureter. If the lower moiety is worth saving, the type of repair depends on the length of the ureter. If the ureter is very short, the upper and lower pelvis may be joined side by side (pyelopyelostomy) to create a single pelvis drained by the upper ureter. Conversely, if the lower ureter is long, a conventional dismembered pyeloplasty can be done, but, if the junction between the two limbs is close to the bladder, a ureteroureterostomy with excision of the distal ureter is a better solution in order to avoid the possibility of uretero-ureteral reflux.

Even when uretero-ureteral reflux (yo-yo reflux) is demonstrated, it is difficult to relate the frequently vague complaints of the patient to the peristaltic disorder. Clinical judgment is required before proceeding to a surgical repair, which may consist of a proximal pyelo-ureteral anastomosis with removal of one ureter or, if the ureteral junction is close to bladder wall, excision of the common limb and reimplantation of the two ureters into the bladder side by side.

## COMPLETE DUPLICATION ANOMALIES

### Vesicoureteric Reflux

The most frequent anomaly detected in completely duplicated ureters is VUR. As a rule, it always affects the lower pole ureter either independently or with VUR into the upper pole ureter because it opens in the trigone in a more cranial and lateral position with a shorter submucosal tunnel, causing incompetence of the ureterovesical junction. When VUR rarely occurs into both moieties, the ureteral orifices are usually close together and in a lateral ectopic location.

The most common presentation is UTI, with more than 60% of children with UTIs and a duplex kidney having vesicoureteral reflux.[15] Therefore when ultrasound reveals a duplex kidney in a child with a history of a UTI, a micturating cystourethrogram is mandatory.

**FIGURE 115-2** Drooping lily appearance of a refluxing right lower pole ureter. Note that the contralateral ureter is also refluxing with all its calyces intact, but the calyces are missing on the right, giving it a characteristic lower pole appearance.

Cystourethrogram often reveals the pelvis in a lower than normal position with an abnormal renal axis. The upper calyces are missing, and the lower ones often show signs of chronic reflux nephropathy, resulting in the appearance of a drooping lily (Fig. 115-2).

The affected lower pole on dimercaptosuccinic acid (DMSA) renal scan may be nonfunctioning or poorly functioning, indicating severe dysplastic changes or parenchymal scarring due to repeated episodes of UTI. In this relatively rare case, the treatment of choice is lower pole partial nephrectomy and ureterectomy (Fig. 115-3). It is recommended that the lower pole ureter be removed completely down to the bladder wall in order to avoid leaving a refluxing stump. In most cases, however, the lower pole is worth saving and several options are available for treatment.

Contrary to popular belief, a significant proportion of refluxing units associated with duplex systems resolve spontaneously with time. This is more likely with grade 1 and 2 VUR (up to 85%) than with higher grades.[16–19]

Provided the child remains asymptomatic (as with primary VUR), antibiotic prophylaxis is justified initially. These patients must be followed carefully to assess the kidneys for scarring and its progression. VUR can be assessed using either indirect MAG3 cystography or a micturating cystourethrogram (MCUG). If progressive renal scarring with deteriorating renal function is identified, or if symptomatic upper renal UTIs cannot be controlled by antibiotic prophylaxis, operative intervention is indicated.[20,21]

Endoscopic treatment of VUR in a duplicated system is not as successful as with a single-unit VUR, with a permanent resolution rate of only 46%.[22] However, it is still worthwhile to

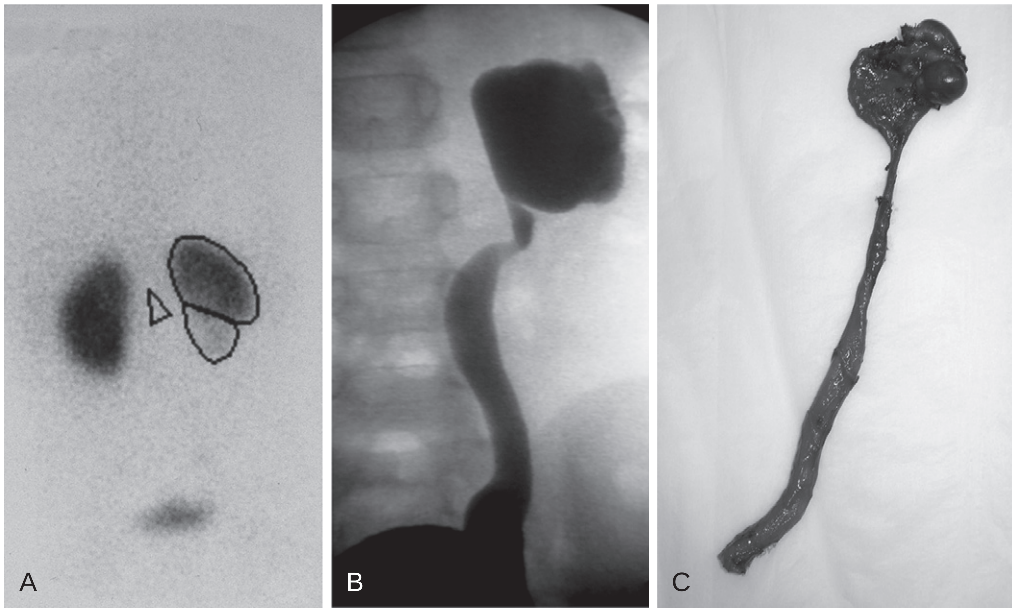

**FIGURE 115-3** A case of poorly functioning lower pole **(A)** on dimercaptosuccinic acid scan and refluxing on micturating cystourethrogram **(B).** The specimen after lower pole heminephroureterectomy **(C);** note that the refluxing ureter has been removed as low as possible to avoid a refluxing stump.

consider it as an effective option in selected cases.[17,23] In duplex systems in which the ureteral orifices are close together, the implant is injected under the upper pole moiety orifice (inferomedial). The needle is advanced below both orifices, and the injection is commenced under direct vision until both moiety orifices are compressed. When the ureteral orifices are separated by more than a few millimeters, they can be individually injected; however, caution is required when placing the injection under the lower pole orifice because the upper pole ureteral lumen may be entered in error.

The procedure of choice, when the refluxing ureter is not excessively dilated, is "double barrelled" or common sheath ureteroneocystostomy. When the ureteral orifices are situated relatively normally on the trigone, both should be mobilized from the bladder base together, even if only the lower pole ureter is refluxing. This is necessary because the ureters share the same adventitial sheath and blood supply.[24] Attempts to mobilize only the affected ureter will result in ischemia of one or both ureters. Alternatively, both ureters can be mobilized to a level above the common sheath. The ureters can then be rerouted through the bladder wall using either an intravesical cross-trigonal technique or an extravesical approach. The objective in both instances is to create a sufficiently long submucosal tunnel for the ureters (preferably three times their diameter), in order to create a satisfactory "flap valve" antireflux mechanism.

When one or both ureters are massively dilated, they can be safely reduced in size, plicating or excising the side away from the common wall.[25] When both ureters need to be reduced in size, excisional tapering is a better choice in order to avoid an excessive bulk of tissue that may make subsequent ureteroneocystostomy difficult.

Other surgical options, when only one ureter needs to be addressed, include uretero-ureterostomy. Recent literature indicates it is effective and has a low incidence of complications.[26–28] The size of the ureter does not seem to be a problem with this technique, which has also been performed via an inguinal incision with good results.[29] It is important to make sure there is no reflux in the ureter draining into the bladder. There is a theoretical risk of inducing yo-yo reflux. Such a risk can be avoided with pyelo-ureterostomy, which is a highly successful procedure, but a second lower abdominal incision is required to completely remove the refluxing stump or the stump can be dealt with by endoscopic correction.

### Ectopia of the Upper Pole Ureter

Another common anomaly in complete duplications is ectopia of the upper pole ureter.

Approximately 80% of all ectopic ureters occur in duplicated systems. The upper pole drained by an ectopic ureter commonly has severe dysplasia. In addition, findings consistent with obstructive changes are the rule in the male, where ectopic ureters are always obstructed. In females, obstruction affects only ureters ending inside the urinary tract.

Ureters ending on the bladder neck or in the posterior urethra are obstructed when the bladder neck is closed but may occasionally reflux during micturition; in such cases UTI is common. In the male, ectopic ureters generally cause infections and are identified during the evaluation for UTI. Epididymo-orchitis is a frequent presentation when the ureter opens in the genital tract in association with the vas or seminal vesicle.[30–32]

Many infant girls with ureters opening inside the urinary tract and, as a consequence, obstructed, present with UTI. Conversely, an ectopic ureter opening in the müllerian derivatives, having its orifices outside the realm of the urinary sphincter, causes urinary pseudo incontinence. A constant dribbling of urine in the interval between normal micturition is frequently observed.[33] This symptom is generally overlooked until the girl is fully toilet trained and has normal voiding habits. If the ectopic upper pole function is poor and little urine is produced, dribbling may not be observed and the patient may present with constant vaginal discharge. When the urine pools in a dilated ureter, especially at night when the patient is in a recumbent position, urinary losses may assume different features and mimic stress or urge incontinence.

Physical examination is often completely normal. Rarely, close and careful scrutiny of the external female genitalia reveals that the ectopic ureter is located in the urethro-vaginal septum. In addition, a dilated ureter is occasionally palpated during rectal examination.

Diagnosis of a suspected ureteral ectopia is straightforward when the ectopic ureter is massively dilated and may be easily identified on an abdominal ultrasound or when the upper pole functions sufficiently to excrete contrast material on intravenous urography (IVU).

Difficulties arise when the upper pole function is so poor that contrast is not excreted and the ureter is not dilated or when the ectopic ureter is associated with other malformations like massive reflux in the ipsilateral lower pole ureter or contralateral pathology that confuses the picture.

Ultrasound, the first-line investigation, may reveal a dilated duplex ureter and upper pole or, when the ureter is not dilated, show changes in the echogenicity of an otherwise normal upper pole that help in defining the correct diagnosis. MCUG should be included in the diagnostic workup. Associated reflux either in the ipsilateral lower pole ureter or in the ectopic upper pole ureter may be demonstrated; in the latter case MCUG delineates the anatomy of the ureter, making more sophisticated imaging studies unnecessary. An ectopic ureter should always be suspected in cases of isolated reflux into the upper pole of a duplicated system, which most commonly occurs on the voiding phase of the MCUG. Excretory urography is useful for defining the anatomy in a ureter associated with a functioning renal unit.[34] However, when the affected moiety is nonfunctioning, the findings are more subtle and changes on ultrasonography, DMSA scans, and excretory urography are easily missed.[19,34] Magnetic resonance imaging (MRI) scanning is particularly useful in these circumstances and provides both anatomic detail and functional analysis (Fig. 115-4)[35–38]; however, anesthesia is required in children.

The choice between the different treatment options largely depends on the function of the affected segment, on the coexistence of associated malformations, and, to a lesser degree, on the size of the affected ureter.

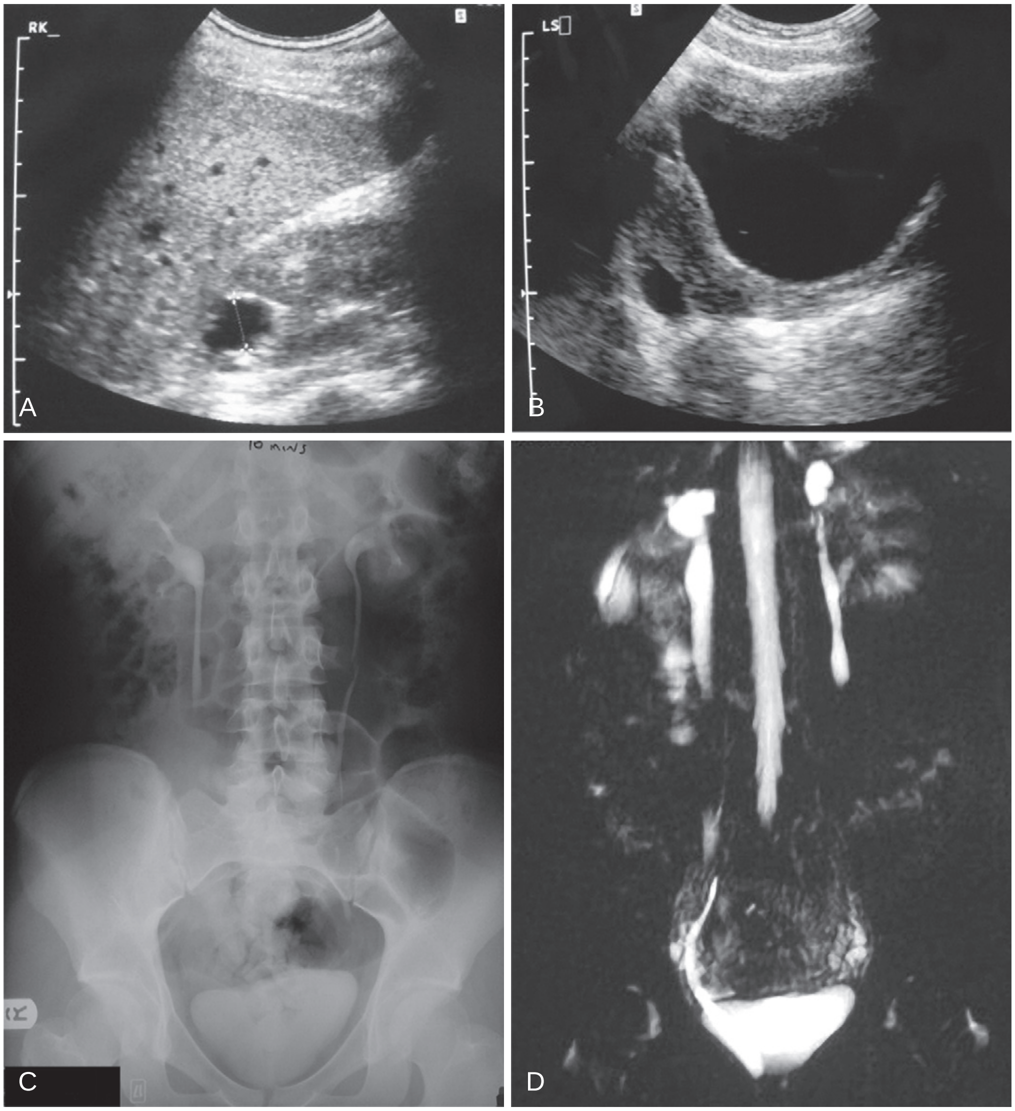

FIGURE 115-4 A case of ectopic ureter causing incontinence in a young girl. The ultrasound shows a dysplastic upper pole **(A)** with a dilated ureter behind the bladder **(B).** Excretory urogram is unremarkable **(C),** but magnetic resonance imaging (MRI) shows the ureter opening well below the bladder **(D).** This girl had bilateral ectopic upper pole ureters as diagnosed on the MRI.

In the great majority of cases when the involved upper pole contributes to less than 5% total function, open surgical, laparoscopic, or, even better, retroperitoneoscopic removal of the upper pole along with its ureteral segment is the treatment of choice.

Partial nephrectomy involves identifying the demarcation between the normal lower pole and the nonfunctioning upper pole and excising the ureter of the affected renal unit inferiorly as near the bladder as possible without compromising the lower pole ureter. The potential problems of excising the lower end of the affected ureter are well recognized and are discussed in more detail later.

The operation may be undertaken by either open or endoscopic techniques. The important steps are to clearly identify the ureter and pelvis of the affected upper pole moiety. After dividing the blood supply to the upper pole of the kidney, it is then possible to identify the limit of the affected upper pole, and a relatively bloodless plane can be developed between the abnormal and normal renal tissue without entering the caliceal system of the lower pole.[39] The ureter can then be excised down to the pelvic brim.

This upper tract approach lends itself well to minimally invasive surgery because access to the kidney and ease of defining the vascular anatomy, particularly with the retroperitoneoscopic approach, are excellent.[40–43] Secondary surgery at the bladder level to remove the stump or to reimplant the refluxing lower pole ureter is necessary only in a small number of cases.[44,45]

If the upper pole retains some function and is considered worth saving, then proximal ureteropyelostomy or distal uretero-ureterostomy is advisable. In a series of 11 infants who underwent ureteropyelostomy for obstructed duplicated ureters with satisfactory results, only 3 children needed secondary surgery at the bladder level for persisting reflux in the lower pole ureter.[46] When ipsilateral lower pole reflux is present, a "double-barrelled" ureteroneocystostomy may allow resolving both obstruction and reflux with a single operation. It requires a meticulous and tedious extravesical dissection in order to isolate enough length of both ureters and perform a safe reimplantation. Moreover, both ureters are usually markedly dilated and need tapering before ureteroneocystostomy. A possible, easier alternative is to perform a distal end-to-side anastomosis of the obstructed ureter to the refluxing one and to reimplant the lower pole ureter into the bladder.

However, in the great majority of cases an upper tract approach is strongly recommended, either by an upper pole partial nephrectomy or a ureteropyelostomy. If VUR is present preoperatively or develops postoperatively, it can be safely managed conservatively with antibiotic prophylaxis or treated endoscopically at a later stage. With such an approach the number of surgical procedures and complications can be substantially reduced, allowing, when possible, the preservation of a functioning upper pole.

### Ureteropelvic Obstruction

In duplex systems, the obstruction usually affects the lower pole and is more common in boys.[47,48] The decision to operate is guided by the size and function of the renal unit involved. An increase in hydronephrosis or decreased function of the affected part of the kidney on isotope study is an indication to intervene. However, these parameters are sometimes difficult to assess objectively in a growing child. Loin pain in older children, typically preadolescents, associated with objective evidence of ureteropelvic junction obstruction on MAG3 isotope scan, is a common indication for operation. The surgical options are pyeloplasty or pyeloureterostomy to the unaffected upper pole ureter, with excision of the distal ureter of the affected lower pole.[47–49] Partial nephroureterectomy is undertaken when the function of the affected renal unit is severely impaired.

# Ureteroceles

The term *ureterocele* describes the cystic dilatation of distal intravesical portion of the ureter. A single-system ureterocele is associated with a kidney with only one ureter, whereas a duplex system ureterocele is associated with the upper pole of a kidney with a complete ureteral duplication.

Most frequently the pelvicaliceal system drained by the ureterocele is also obstructed. The malformation may be further complicated by VUR into the ipsilateral lower pole or into the contralateral ureter or by ureteral obstruction.

The incidence of ureteroceles is approximately 0.02% of individuals with 80% occurring in females.[50,51] A slight majority are left sided and bilateral in 10%.[52] Some 80% of ureteroceles are associated with the upper pole of a complete duplication,[53] and in most series 60% to 80% are ectopic.[54] Bilateral ureteroceles or those associated with contralateral duplicity occur in 15% of cases.[55] Single-system ureteroceles are uncommon, occur most often in males, and can be associated with other anomalies including abnormalities of the kidneys such as fusion, ectopia,[56] or multicystic dysplasia.[57]

## CLASSIFICATION

The Committee on Terminology of the Urologic section of the American Academy of Pediatrics, proposed a simple and widely adopted classification, whereby ureteroceles contained entirely within the bladder are named *orthotopic* or *intravesical* and a ureterocele that has a portion permanently located outside the bladder is called *ectopic*.[58] In 1971 Douglas Stephens classified the ureteroceles associated with ureteral duplication according to the position and/or presence of intrinsic obstruction of the ureteral orifice as shown in Table 115-1.[59]

Stenotic ureteroceles are completely located inside the bladder and have a small, stenotic, often pinpoint orifice; they are usually tense and show a well muscularized wall with predominantly longitudinal muscle fibers. The nonobstructed variety is rather rare; in such cases the ureterocele is visible only when a peristaltic wave fills it.

**TABLE 115-1**

| Douglas Stephens Classification Ureteroceles |
|---|
| Intravesical |
| Extravesical |
| Stenotic 40% |
| Sphincteric 40% |
| Nonobstructed 5% |
| Sphinctero-stenotic 5% |
| Cecoureterocele 5% |
| Blind ureterocele 5% |

In the sphincteric subtypes the ureteral orifice is wide and often gaping, but it is located inside the bladder neck or urethra and is obstructed by the contraction of sphincteric muscle. These ureteroceles decompress during voiding. Sphinctero-stenotic ureterocele is similar to the previous one, but the orifice is both ectopic and stenotic. Because a sphinctero-stenotic ureterocele does not decompress during micturition, it may ball valve and obstruct the bladder outlet. The meatus of the cecoureterocele is in the bladder, but a tongue of the ureterocele extends down in the urethra. Ureteroceles are described as blind when no kidney or upper pole associated with ureterocele can be demonstrated.

In duplex kidneys the upper pole drained by the ureterocele is affected by some degree of dysplasia in 43% to 73% of cases. In 20% the dysplasia is severe, affecting more than 25% of the upper pole.[60,61] The contribution of the affected upper pole to the global renal function ranges from 4% to 8%. Measurable loss after upper pole partial nephrectomy is, on average, around 1% while functional gain after endoscopic incision is around 2%.[62]

## CLINICAL PRESENTATION

Prenatal diagnosis of ureterocele represents approximately 15% of all antenatal diagnosis of duplex kidneys as the number of neonates with prenatally detected ureteroceles has increased from 2% to 28% in the past 20 years.[63] Prenatal ultrasound screening of the kidneys often identifies some degree of hydronephrosis, which is most pronounced with ureteroceles.[64] Although there is no evidence that treatment of these prenatally diagnosed children affects the prognosis for the kidney, symptomatic UTIs can be reduced in frequency.[65–67]

In the postnatal period, infection is the most common presentation for ureteroceles in both sexes; in infants symptoms may vary from a life-threatening gram-negative sepsis to a febrile illness with gastrointestinal symptoms or failure to thrive. In older boys and girls symptoms are more specific and point to a urinary tract infection: fever, malaise, dysuria, foul-smelling urine, and back pain.

Other presenting symptoms in both girls and boys may be hematuria after minimal trauma or a palpable abdominal mass representing the bladder or the obstructed urinary tract.

In girls an interlabial mass or acute urethral obstruction due to the ball valve effect of a ureterocele prolapsing in the urethra is another possible presentation. Rarely, the most distal portion of a cecoureterocele can protrude from the urethra as a pink, interlabial mass without obvious urethral obstruction or retention and, consequently, such cases do not need emergency treatment.

Prolapsing ureteroceles are the most common cause of acute urethral obstruction in girls,[68] but this event has been also reported in males,[69] even if much less frequently. Patients present in obvious pain with an acute urinary retention and a palpable bladder. A purple red or frankly necrotic round mass may be seen protruding from the labia. In such cases emergency treatment to decompress the ureterocele and remove the bladder outlet obstruction is warranted. In extreme cases, when the ureterocele prolapses and obstructs the urethra, it may affect the function of all the renal units.[69,70]

## DIAGNOSIS

The diagnostic workup relies on the use of ultrasound, MCUG, and renal isotope scans.

Excretory urography, the mainstay of ureterocele diagnosis until a decade ago, is much less commonly used now. Computed tomography scan and magnetic resonance urography may be useful, especially the latter, when the urinary tract anatomy is not clear.

Ultrasound of the urinary tract is the first investigation and generally depicts clearly the ureterocele as a sonolucent round image that sits on the bladder base and occupies a portion of the bladder. One or more dilated ureters can be seen behind the bladder (Fig. 115-5). Ultrasound gives valuable information on the presence of unilateral or bilateral renal duplicity and on the dilatation of the collecting systems, and it helps in identifying which kidney is drained by the ureterocele. Cortical cysts and severe parenchymal thinning, but not increased echogenicity, suggest renal dysplasia that is confirmed by isotope scan.[71]

An MCUG is an essential part of a ureterocele evaluation. The ureterocele is seen in the first films as a negative shadow in the bladder, with a rim of contrast around it. If the ureterocele is not tense, it may be obscured with the progressive filling of the bladder because it may be compressed or, if it is small, may be obscured by the contrast medium around it. MCUG may also reveal VUR in the lower pole ureter (50%) or in the contralateral ureter (25%).[53,72,73] In less than 10% of cases, reflux can be identified in the ureterocele if it is ruptured or if it has a large open meatus placed on the bladder neck that allows

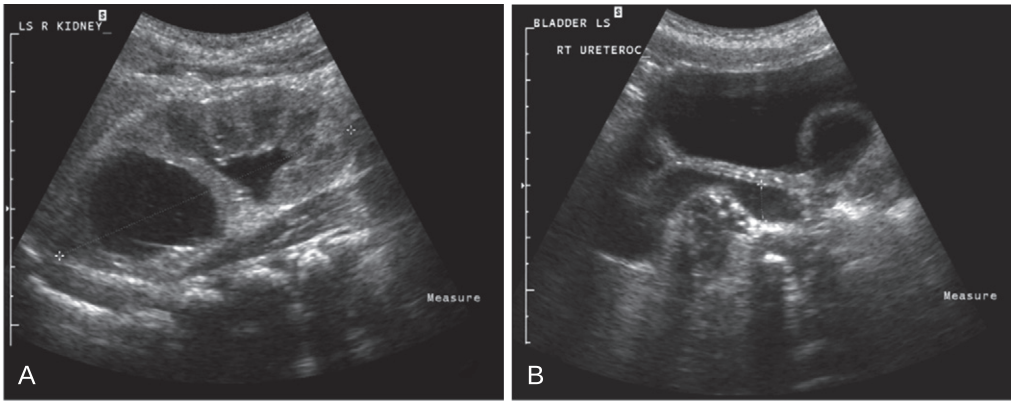

FIGURE 115-5 Ultrasound images of a dysplastic dilated upper pole **(A)** with corresponding dilated ureter and ureterocele in the bladder **(B).**

**FIGURE 115-6** Voiding cystourethrogram demonstrating retrograde prolapse of a ureterocele into the upper pole ureter and vesicoureteral reflux into the lower pole ureter on the left side in a complete duplex system. This appearance may be confused with a bladder diverticulum.

reflux during voiding.[33,73] The MCUG is also useful to ascertain the degree of the detrusor backing for the ureterocele. If the detrusor support is poor, the ureterocele may evert during micturition, mimicking a bladder diverticulum (Fig. 115-6). During voiding, the ureterocele may also be seen prolapsing through the urethra and obstructing the urinary flow.

IVU was the most important diagnostic step in the past. More recently, however, the progress of ultrasonography, DMSA, and MRI has made this examination obsolete in most cases. Nevertheless, when the anatomy is confusing, excretory urography may still play a role.

If the renal parenchyma associated with the ureterocele retains some function, which most commonly occurs in single systems, a characteristic "cobra head" or "spring onion" deformity of the intravesical ureter is produced due to opacified urine in the ureterocele being surrounded by a radiolucent halo that represents the wall of the ureter. More commonly, when the ureterocele is associated with the upper pole of a duplex kidney, function is absent or minimal in 90% of cases; therefore the radiographic signs are mainly negative, reflecting the displacement of the lower pole renal unit by the hydronephrotic upper pole ureter. The lower pole pelvis is often laterally and downward displaced, producing the characteristic "drooping lily" appearance; the number of calices is reduced; and the upper calices are missing (Fig. 115-7).

At the bladder level a negative shadow may be seen, suggesting the presence of a ureterocele (see Fig. 115-7). The shadow may vary from a large, tense, round shadow occupying most of the bladder to a minor irregularity in the base of the bladder.

Excretory urogram also shows the condition of the contralateral kidney collecting system that may be duplex (see Fig. 115-7) or may be obstructed at the bladder level by a large and tense ureterocele compressing the ureteral orifice.

**FIGURE 115-7** Excretory urogram appearances of a ureterocele in the bladder as a negative shadow. Please note bilateral duplex with nonfunctioning right upper pole corresponding to the ureterocele. The lower pole of the right and both the poles on the left are functioning. The lower pole on the right is dilated and possibly refluxing (back flow of contrast during the study).

The function of the pole or of the kidney associated with the ureterocele is best assessed by a DMSA renal scan that shows the quality and quantifies the amount of functioning renal tissue (Fig. 115-8).

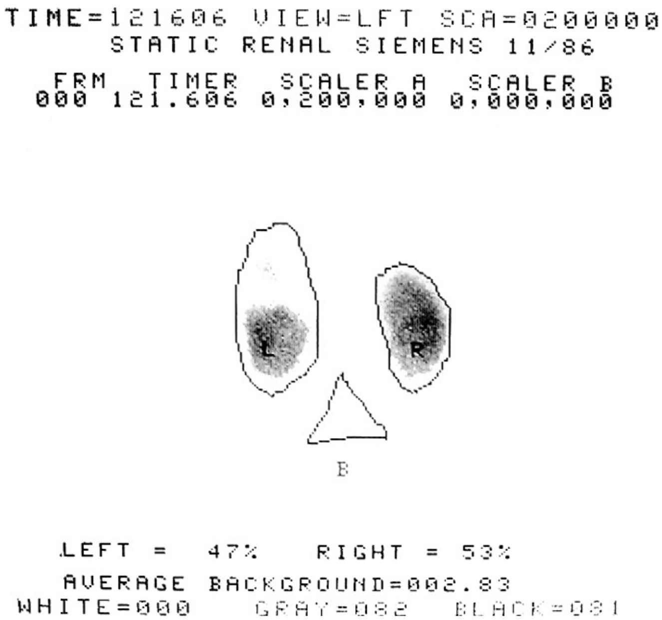

**FIGURE 115-8** Dimercaptosuccinic acid isotope scan demonstrating poorly functioning upper pole moiety in a left-sided complete duplex system. The upper pole ureter was associated with a ureterocele.

## PRINCIPLES OF TREATMENT

The goals of the ureterocele treatment are to preserve renal function by providing unobstructed drainage of all functioning renal tissue, removing any potential source of infection and treating VUR; prevent bladder outlet obstruction and/or urinary incontinence; and prevent and treat any bladder wall deficiency (e.g., diverticula, poor detrusor backing).

The surgical strategy should be optimized in order to attain these goals with minimal surgical morbidity. Few cases of prenatal treatment of a prolapsing obstructing ureterocele with anhydramnios have been recently reported with a view to restore amniotic volume.[74–76] In a small number of prenatally detected cases of ureteroceles with no obstruction or reflux, a nonoperative watchful waiting approach has been attempted successfully.[65,77,78]

Postnatally, the treatment options are endoscopic incision, upper pole partial nephrectomy (upper tract approach), complete reconstruction at the bladder level, or nonoperative (conservative) treatment. These methods cannot be compared easily, and the choice must be appropriately applied to patients with different clinical presentations. Skill in all methods of management is important, and an understanding of when to apply these methods is critical because the management of each patient with a ureterocele must be individualized.[79]

The factors that influence treatment choice are type of presentation (prenatally diagnosed or symptomatic), age of the patient, type of ureterocele (intravesical versus ectopic), differential function of the renal moieties, and presence of VUR and UTI.

## ENDOSCOPIC DECOMPRESSION

Wide, open deroofing of the ureterocele was performed in the past. The problem with this technique is that if the ureterocele arises from the urethra, epithelial remnants that have not been completely excised may result in urethral obstruction owing to the valvelike nature of these folds.[80] In addition, with this type of operation, postoperative VUR is almost inevitable. Therefore deroofing usually requires a subsequent antireflux procedure that is normally best undertaken as part of the initial surgery. This more aggressive approach is potentially difficult and is associated with increased morbidity, especially in the very young child with a small bladder.[81]

Endoscopic techniques have been used for some time to simply incise the ureterocele. At any age endoscopic incision has the advantage of being a simple, quick, and minimally invasive procedure that can be performed with a minimal hospital stay.

This can take the form of either diathermy incision or simple puncture of the cyst.[82–84] During this procedure it is important not to overfill the bladder; otherwise, the ureterocele may be compressed, making it difficult to identify. If this occurs, loin compression on the affected side may assist in refilling the ureterocele. The planned decompression point on the ureterocele is important and, if possible, should not overlie the ureteral lumen where it is attached to the bladder base. Recently a novel technique of fulgurating the internal layer of the ureterocele has been described to achieve and maintain collapse of the ureterocele.[85] This technique is challenging and tedious, especially when the postoperative outcomes following endoscopic incision depend on anatomic and functional characteristics rather than the technique used.[86]

Simple decompression obviates obstruction and allows a better evaluation of the function of the kidney or pole involved by the ureterocele. It often reduces the size of the ureter so that secondary procedures (such as excision of the ureterocele and ureteroneocystostomy), if required, are less difficult and may reduce the need for ureteral tapering. In addition, associated VUR into the lower pole ureter may subside spontaneously.[72]

Endoscopic incision of intravesical ureterocele is the definitive treatment in 77% to 93% of cases; therefore it can be considered to be the initial treatment for this type of ureterocele.[79] A recent meta-analysis looking at endoscopic management of ureteroceles confirmed what others have suggested that the risk of reoperation after endoscopic incision of ectopic ureteroceles was significantly higher than with intravesical ureteroceles.[73,87]

There is no consensus about the effectiveness of endoscopic incision in ectopic ureteroceles because it rarely represents the definitive treatment modality[88,89]; seldom ameliorates the function of the involved upper renal pole; and, if an iatrogenic reflux is created in the ureterocele, it may unnecessarily commit the patient to future lower tract surgery. Alternative treatment options are represented by the upper tract approach, which includes either an open or retroperitoneoscopic upper pole partial nephrectomy and ureterectomy, leaving the upper ureteral stump open in order to decompress the ureterocele, or, if the upper pole is considered worth being kept, a uretero-pyelostomy or uretero-ureterostomy, joining the upper pole ureter to the lower one.

The preservation of the upper pole affected by an ectopic ureterocele is rarely warranted because its function is often minimal, the severity of renal dysplasia being directly proportional to the degree of ectopia of the ureterocele.[62] There is little hope of recovery of function after relief of obstruction in most cases because the upper pole is often dysplastic with irreversible changes, neither progressive nor amenable to any type of treatment.

The upper tract approach may be recommended when there is no associated VUR and the choice between removing and keeping the upper pole is dictated by its relative function.

With this approach, the rate of secondary procedures on the bladder ranges from 15% to 20% if preoperative VUR was absent.[90,91]

When VUR is associated with an extravesical ureterocele, no matter which approach is used first, a second stage at the bladder level to remove the ureterocele and reimplant the ureters is necessary in the majority of cases. As the number of renal units affected by VUR in a duplex system with an ectopic ureterocele increases, the higher the incidence of surgery at the bladder level.[61,92]

The reoperation rate in patients with duplex system ectopic ureterocele and VUR varies from approximately 50% to 100% after endoscopic incision[93] and from 84% to 90% after upper pole partial nephrectomy.[90]

## BLADDER BASE RECONSTRUCTION

As mentioned earlier, bladder base reconstruction including excision of ureterocele and ureteroneocystostomy may be required. This usually produces a significant defect that necessitates a precise anatomic reconstruction; otherwise, disruption of the bladder neck and posterior urethra could lead to incontinence. Fortunately, it is unusual for the ureter to open directly into the urethra; this most often occurs at a

level at or just above the bladder neck. Recently, it has been suggested that the ureterocele can be excised or marsupialized without much effect on clinical outcome.[94] The ureterocele, however, often involves the urethra, requiring that the epithelial edges of the cyst be excised completely and then meticulously repaired. Otherwise, obstruction of the urethra may result from either the residual "valvular" remnants of the ureterocele or stricturing due to excessive scarring.[80] Therefore it is usually necessary to mobilize the unaffected lower pole ureter with that associated with the ureterocele. If the upper pole ureter is to be excised, mobilization of both ureters should be extended above the common adventitial sheath. Alternatively, the two ureters can be separated by preferentially taking the adventitia of the affected ureter, thus preserving the blood supply to the "normal" ureter. In any case the defect in the bladder base and outlet must be repaired without narrowing the outlet. The remaining lower pole ureter can then be reimplanted using either a cross-trigonal or an extravesical method as described earlier.

Proponents of complete primary lower urinary tract reconstruction early in the neonatal period or infancy argue that the need for secondary surgery in patients affected by duplex system ectopic ureteroceles with preoperative VUR ranges from 0% to 32%.[95–97] They have reported that this approach in patients with ectopic ureterocele with VUR appears to have better results than a staged approach with initial endoscopic treatment. Moreover, they conclude and have been supported by others that extensive reconstructive bladder surgery in neonates and infants does not lead to bladder function deterioration at a later age.[98] However, severe bladder dysfunction was observed in 7 of 10 girls who underwent bilateral ureterocele repair in their first 2 years of life,[81] suggesting that due to the gross abnormality of the bladder base in duplex systems, there is a significant risk of damaging the bladder outlet in the course of mobilizing the ureters. The difficulty is in determining whether these children's problems are a primary abnormality of bladder function or congenital and unrelated to surgical intervention.[99,100]

# Summary

Ureteral duplications and ureteroceles represent a spectrum of often overlapping embryologic and anatomic abnormalities. Most unobstructed or nonrefluxing duplications are of no clinical significance along with incomplete duplications; others are associated with significant morbidity. Complete duplications are often asymptomatic but can be associated with VUR or ureteroceles with a predominance in girls.

VUR is the most common anomaly of duplications, occurring in about 65% of those with symptomatic UTIs; the reflux is usually into the lower pole ureter. Ectopia of the ureter is not uncommon, and a detailed history is often useful in pointing toward the cause of incontinence. Specialized imaging techniques are often required, however, to identify the precise anatomic abnormality; these include ultrasonography, isotope scanning, MCUG, excretory urography, and MRI.

On the basis of these data, a planned, individualized approach to each case can be taken, with an emphasis on preventing deterioration in renal function, controlling symptoms, and avoiding surgical interventions that could risk bladder function.

### *Acknowledgments*

I would like to acknowledge the contribution of Dr. Victor Boston, the previous author of this chapter, because parts of the previous version and some figures are retained. I would also like to thank my friend and colleague Dr. Emilio Merlini for allowing me to refer to previous educational materials on duplication anomalies that we produced together.

CHAPTER 116

# Disorders of Bladder Function

Martin Kaefer

Disorders of bladder function can range from the most mundane problem of dysfunctional voiding to complex disorders involving neuropathic bladder dysfunction. The typical symptom with which the patient presents is that of wetting. Although of great concern to parents and child alike, this relatively benign-appearing outward sign of bladder dysfunction may in the extreme case reflect a far more insidious and occult problem involving injury to the lower and upper urinary tracts. This chapter begins with the physician's initial assessment of the child with voiding symptoms. Radiographic and dynamic studies relevant to bladder dysfunction are covered next. Finally, specific disorders and their treatment are discussed.

## History and Physical Examination

The evaluation of the child with bladder dysfunction should begin with establishing both day and nighttime voiding patterns. Voiding symptoms have classically been divided into irritative and obstructive, examples of which can be found in Figure 116-1. It should be noted that nearly every disorder discussed in this chapter can have a combination of these symptoms. For example, parents of a boy with obstructing posterior urethral valves may not report that their child is suffering from urinary retention but rather that he is experiencing urinary frequency and urgency (secondary to increased bladder irritability from overdistention). It should be established whether the child has had a urinary tract infection (UTI) and, if so, whether there has been associated fever. This latter symptom will help distinguish an episode of cystitis from the more significant episode of pyelonephritis. The physician should inquire as to whether the child suffers from constipation in that it may reflect a form of retentive behavior (as in the case of dysfunctional elimination) or neuropathic bowel dysfunction (as in the various forms of spinal dysraphism). As pertains to the latter diagnosis, it is also important to record any symptoms of lower extremity weakness or change in sensation.

The physical examination of the child with bladder complaints should include evaluation of the abdomen, back, genitalia, and lower extremities. In examining the abdomen, special note should be made of palpable feces and whether the bladder is palpable and/or percussible, especially if the child has just voided. What has become a common pediatric urology office procedure and an extension of the physical examination is a postvoid bladder scan to check for residual urine.

Examination of the back is critical. Cutaneous findings of a hair patch or nevus overlying the lumbar spine reflect abnormal migration of the neuroectoderm, which can often signal abnormal formation of the lumbosacral spinal cord. A dimple over the lumbosacral spine may likewise signal such an abnormality (Fig. 116-2). An asymmetric gluteal crease is a further sign of potential problems of the spinal cord. This asymmetry reflects differing degrees of impaired innervation to the two groups of gluteal muscles. For example, if the right gluteal nerves are affected to a greater degree than those on the left, then a greater degree of atrophy may ensue and the crease would deviate to the right. With respect to this last outward sign of occult spinal cord dysraphism, it is critical to note that gluteal asymmetry may be an acquired finding as the child matures and grows in axial length. Therefore the back should be examined not only on the initial patient evaluation but during return visits in children with continued voiding complaints. Figure 116-3, *A* and *B*, demonstrates the concept of spinal cord tethering. Patients who possess any of these cutaneous findings should undergo a magnetic resonance imaging (MRI) of the lumbosacral spine.

Examination of the male genitalia should include palpation along the entire urethra. Induration may be a sign of urethral inflammation and stricture. Position of the testicles should be noted because there is an increased incidence of cryptorchidism in children with myelodysplasia.[1,2] The anus should be examined to ensure that there is good tone and proper location on the perineum. Finally, any deficits in lower extremity reflexes or motor strength should be noted in that they are outward signs of neuromuscular disorders, especially disorders of the lumbosacral spinal cord.

A urinalysis should be obtained in every child with voiding symptoms. The presence of red cells, white cells, glucose, and protein should be noted. A low specific gravity may reflect poor concentrating ability secondary to renal dysfunction.

Voiding Symptoms

Irritative

- Dysuria
- Urgency
- Frequency

Obstructive

- Retention
- Hesitancy
- Staccato voiding (starting and stopping)
- Straining to void
- Feeling of incomplete emptying

**FIGURE 116-1** Irritative and obstructive voiding symptoms.

**FIGURE 116-2** Cutaneous findings suggestive of occult spinal cord tethering: picture of a 10-year-old child with neuropathic bladder who was found on physical examination to have a cutaneous lumbar birthmark, a lumbar dimple and asymmetry of the gluteal cleft. Magnetic resonance imaging of the lumbosacral spinal cord revealed an intraspinal lipoma responsible for cord tethering.

# Radiographic and Dynamic Assessment of Bladder Dysfunction

## BLADDER ULTRASOUND

Although it is the most basic of radiographic imaging modalities, the bladder ultrasound can provide many clues about whether there is significant bladder pathology. In the absence of infection, a thickened bladder wall may reflect a compensatory response on the part of the bladder to either an anatomic (e.g., posterior urethral valves) or functional (e.g., detrusor sphincter dyssynergy) form of bladder outlet obstruction (Fig. 116-4).[3] Calculation of postvoid residual urine volume is an excellent means of assessing whether the patient can efficiently empty the bladder.

## VOIDING CYSTOURETHROGRAPHY

The instillation of radiographic contrast into the bladder provides information regarding bladder, bladder neck, and urethral anatomy. Figure 116-5 demonstrates the classic radiographic findings seen in neuropathic bladder dysfunction. Because of chronic high-pressure urine storage, the bladder wall becomes thick and multiple diverticuli may form. In many conditions the voiding phase provides the most useful information because it is only during this time that the bladder neck and urethra can be properly evaluated. The importance of obtaining oblique imaging during voiding cannot be overemphasized because this may be the only image that reveals urethral pathology. A classic example of this is the patient with posterior urethral valves. The bladder neck and urethra proximal to the site of obstruction are markedly dilated, and the bladder itself can demonstrate findings of trabeculation and diverticuli formation. Vesicoureteral reflux is a common finding in both anatomic and functional causes of bladder dysfunction.

## URODYNAMIC EVALUATION

The urodynamic evaluation is the one test that provides in-depth functional information regarding the bladder. It establishes bladder capacity, bladder filling pressures, the patient's perception of bladder filling, and the ability of the bladder neck to empty efficiently and in proper coordination with external sphincter relaxation.

Normal values for various urodynamic parameters have been published. Two parameters are especially useful to mention. Early formulas for calculating expected bladder volume gave reasonable estimates of bladder capacity. One of the most commonly used is Age (years) $+ 2 =$ Capacity (in ounces).[4] However, data in the studies were obtained in large part from patients undergoing evaluation for functional bladder pathology.[5] More recently, Kaefer and colleagues, in measuring the bladder capacity of 2000 healthy children without bladder pathology, demonstrated that bladder capacity was not a linear function of age.[6] The curvilinear relationship $4.5 \times \text{age}^{0.4} =$ capacity (ounces) is similar to the relationship between age and other morphometric parameters (e.g., height and weight). This nonlinear relationship can be approximated by two practical linear formulas that have excellent predictive value when applied prospectively ($2 \times$ Age [years] $+ 2 =$ capacity [ounces] for children younger than 2 years old, and Age [years] $\div 2 + 6 =$ capacity [ounces] for those older than 2 years old).

Neurologic modulation combined with the viscoelastic properties of the healthy detrusor muscle allow the bladder to maintain fairly constant pressure throughout the filling phase. As a result, intravesical pressures in the healthy bladder remain at or below 5 to 10 cm $H_2O$ pressure until capacity is achieved. When various pathologic processes alter the composition of the bladder wall (e.g., collagen deposition following mechanical outlet obstruction) or affect neurologic control of the bladder (e.g., loss of upper or lower motor neuron function in myelomeningocele) compliance can be adversely affected, resulting in increased intravesical storage pressures.

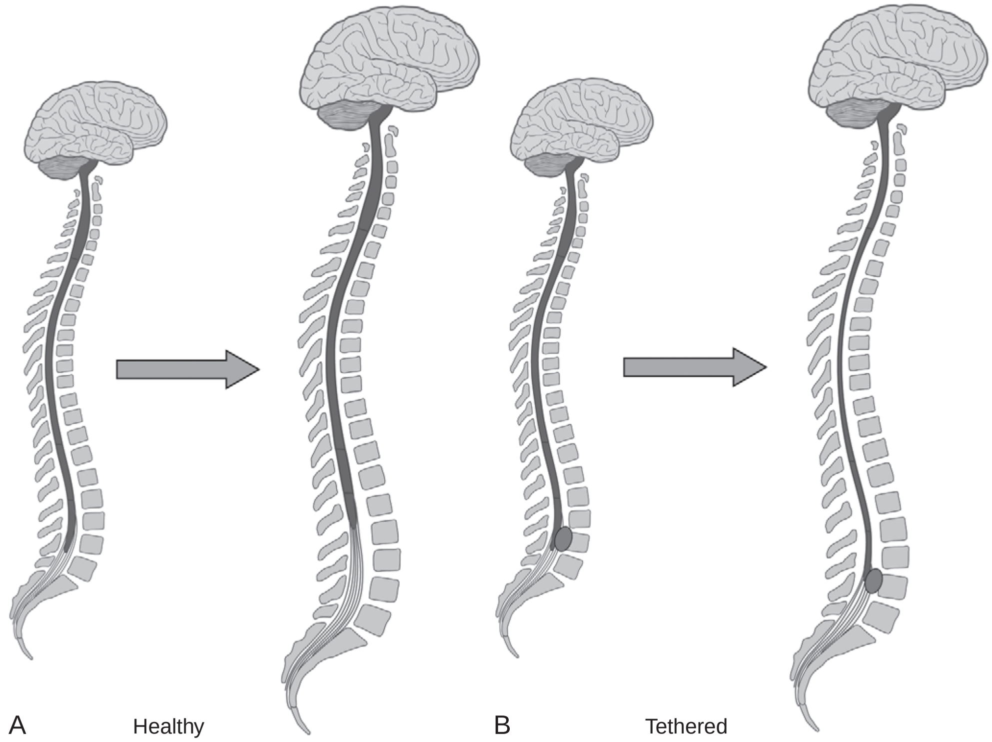

**FIGURE 116-3** **A,** Normal spinal cord. Spinal column increases in axial length at a greater rate than does the spinal cord. As a result, the spinal cord rises to a higher position. **B,** Abnormal spinal cord anatomy with spinal cord lipoma. As the spine grows, the spinal cord is unable to float upward and the cord is stretched. This stretching results in a relative state of hypoxia in the area of the distal cord and subsequent nerve injury to the distal spinal cord segments.

If intravesical storage pressures reach levels higher than 40 cm $H_2O$, renal injury is likely to ensue.[7]

Before undergoing placement of the urodynamic catheter, the child is asked to void into a toilet that measures urinary flow rate. The catheter is then placed through the urethra (or alternatively through a suprapubic site if one is available), and the intravesical pressure is measured. The bladder is then emptied and residual urine determined, yielding a pressure at residual volume.[8] This measurement may prove useful in determining whether the bladder is experiencing high resting

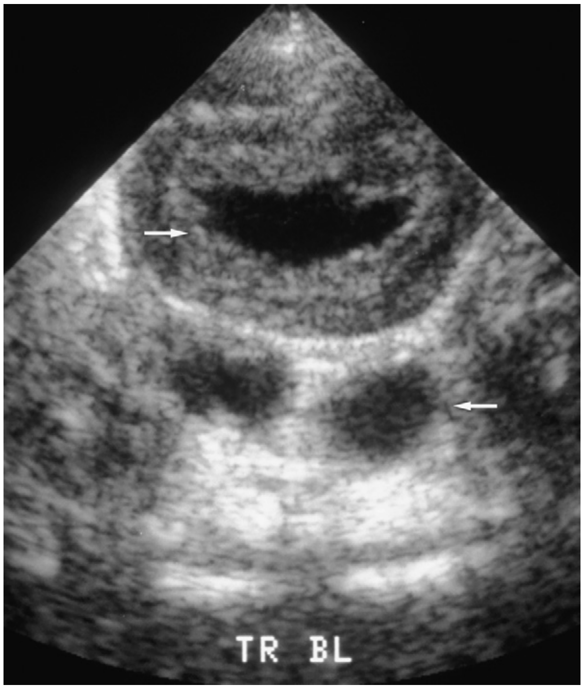

**FIGURE 116-4** Bladder ultrasound from a child with posterior urethral valves. Note the markedly thickened bladder wall *(left arrow)* and the dilatation of the distal ureters *(right arrow)*.

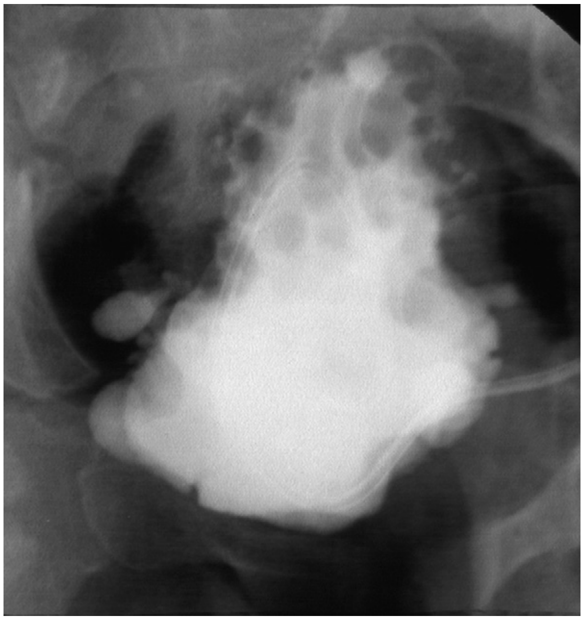

**FIGURE 116-5** Typical voiding cystourethrogram from a child with neuropathic bladder dysfunction secondary to myelomeningocele. The "Christmas tree" appearance is a result of greater bladder wall thickening at the dome relative to the bladder base.

pressures. Next, electromyographic (EMG) electrodes are placed on the perineum either in the form of patch surface sensors or needle sensors, the latter of which is placed directly into the external sphincter complex. These electrodes record the electrical activity of the muscle in order to determine the function of the external sphincter during bladder filling and emptying. Under normal conditions the external sphincter is active during periods of urine storage. Just before voiding there should be silencing of external sphincter activity as the bladder neck relaxes (Fig. 116-6, *A*). Failure of the sphincter to relax before a voiding contraction is termed *detrusor sphincter dyssynergy* (DSD) and is commonly noted in patients with neuropathic bladder dysfunction (Fig. 116-6, *B*), as well as in patients with functional urinary incontinence.

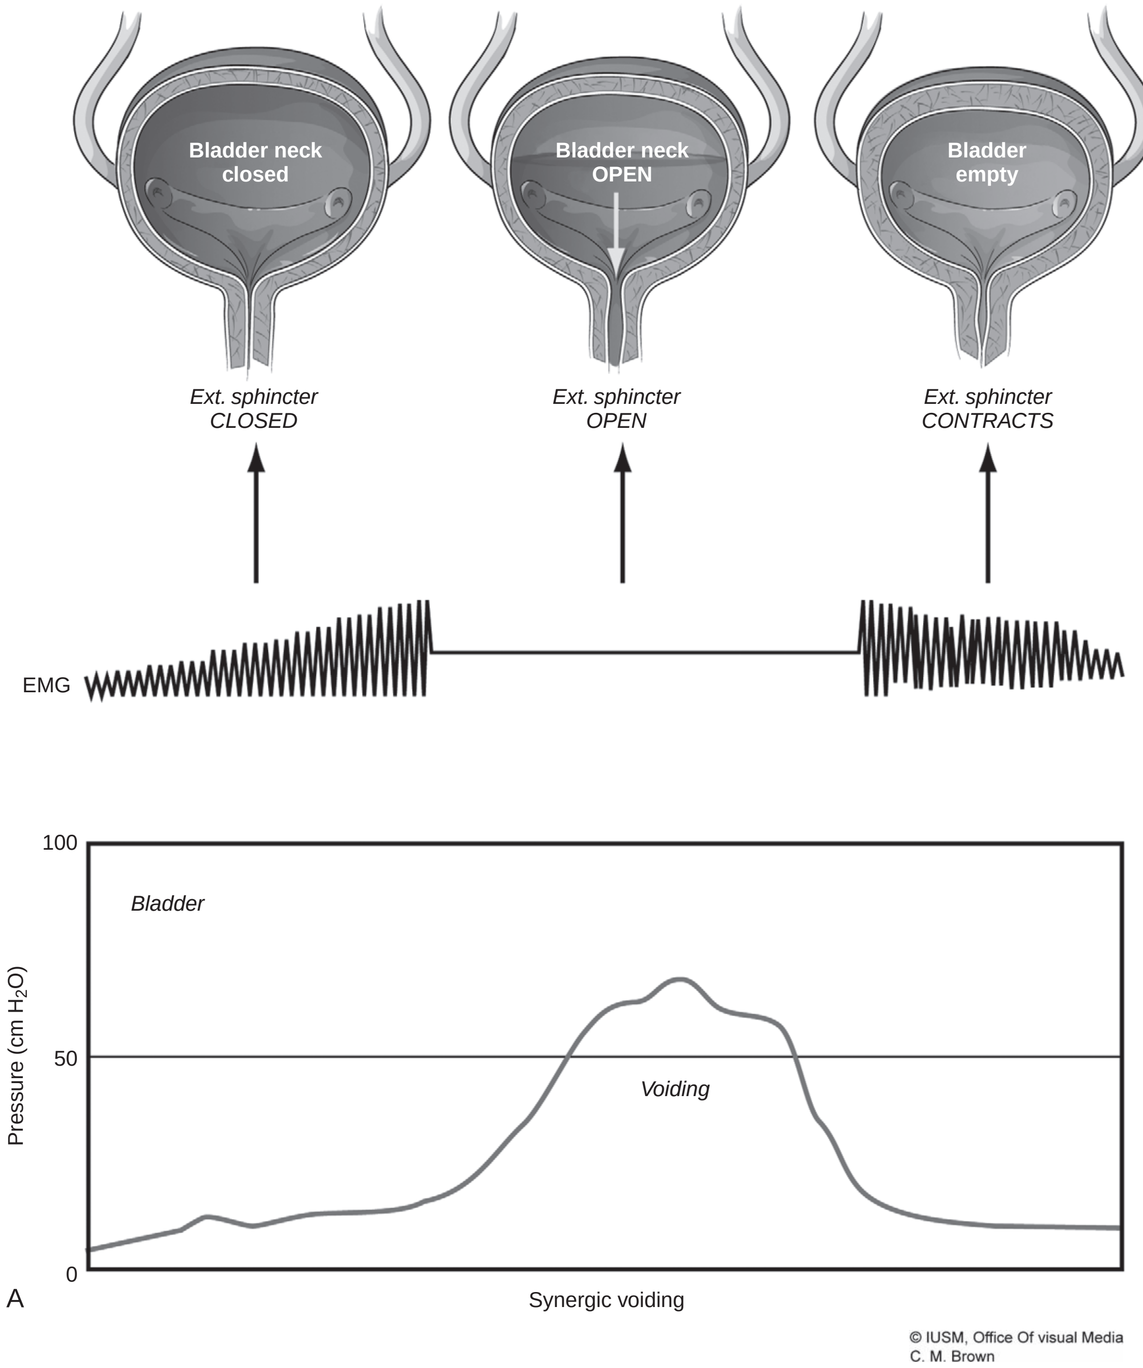

**FIGURE 116-6** **A,** Coordinated synergic voiding: Electrical activity of the external urethral sphincter is chronically active. Just before experiencing a detrusor contraction, the activity of the external sphincter is silenced, providing a marked decrease in urethral resistance and thereby facilitating emptying. Intravesical pressure is shown in the bottom panel.

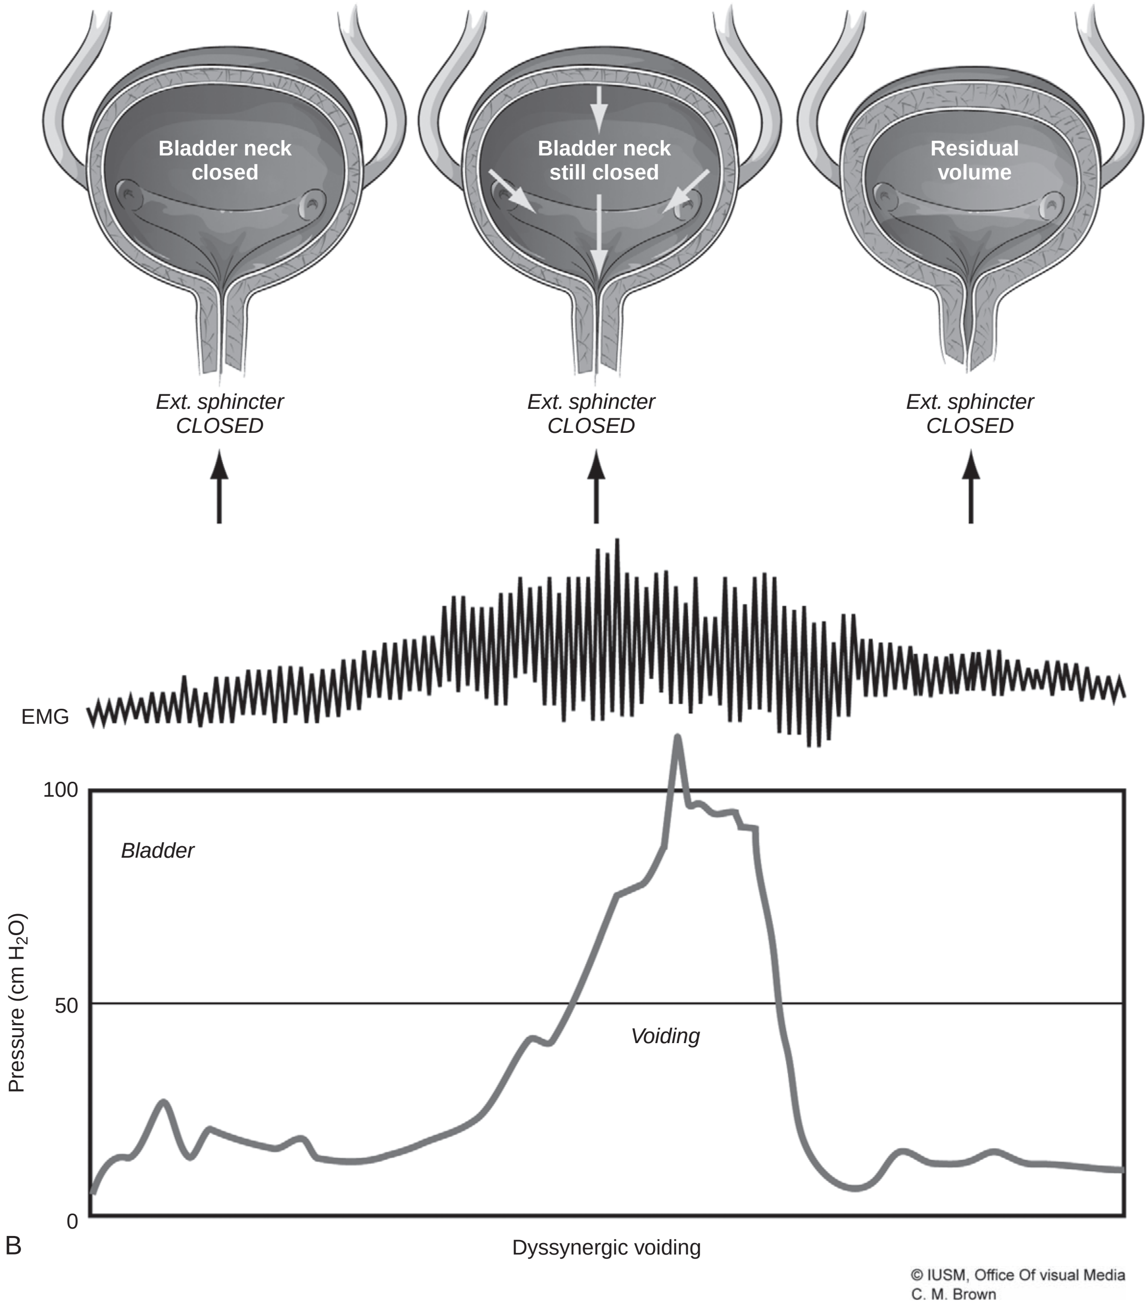

**FIGURE 116-6—CONT'D** **B,** Dyssynergic voiding: In cases of neuropathic bladder dysfunction discoordination between bladder and sphincter activity can often be appreciated. As the bladder begins to contract the activity of the external sphincter actually increases resulting in high outlet pressures and ineffective voiding. Intravesical pressure shown in bottom panel.

The bladder is next filled slowly with normal saline to determine bladder capacity, and the pressure-volume relationship is measured in order to establish bladder wall compliance. Percent expected bladder capacity is calculated by dividing the patient's actual capacity by the expected normal bladder capacity for age.[9] During the filling phase, any uninhibited contractions should be noted because they are a reflection of bladder irritability. Figure 116-7 shows a comparison between pressure tracings from a compliant bladder with those of a poorly compliant, irritable bladder. During the filling phase, the leak point pressure is also noted.

# Neuropathic Causes of Bladder Dysfunction

## NEUROPATHIC BLADDER SECONDARY TO MYELODYSPLASIA

Myelodysplasia, defined as abnormal development of the spinal canal and spinal cord, is the most common etiology of neuropathic bladder dysfunction in children. A genetic component appears to be partially responsible for this

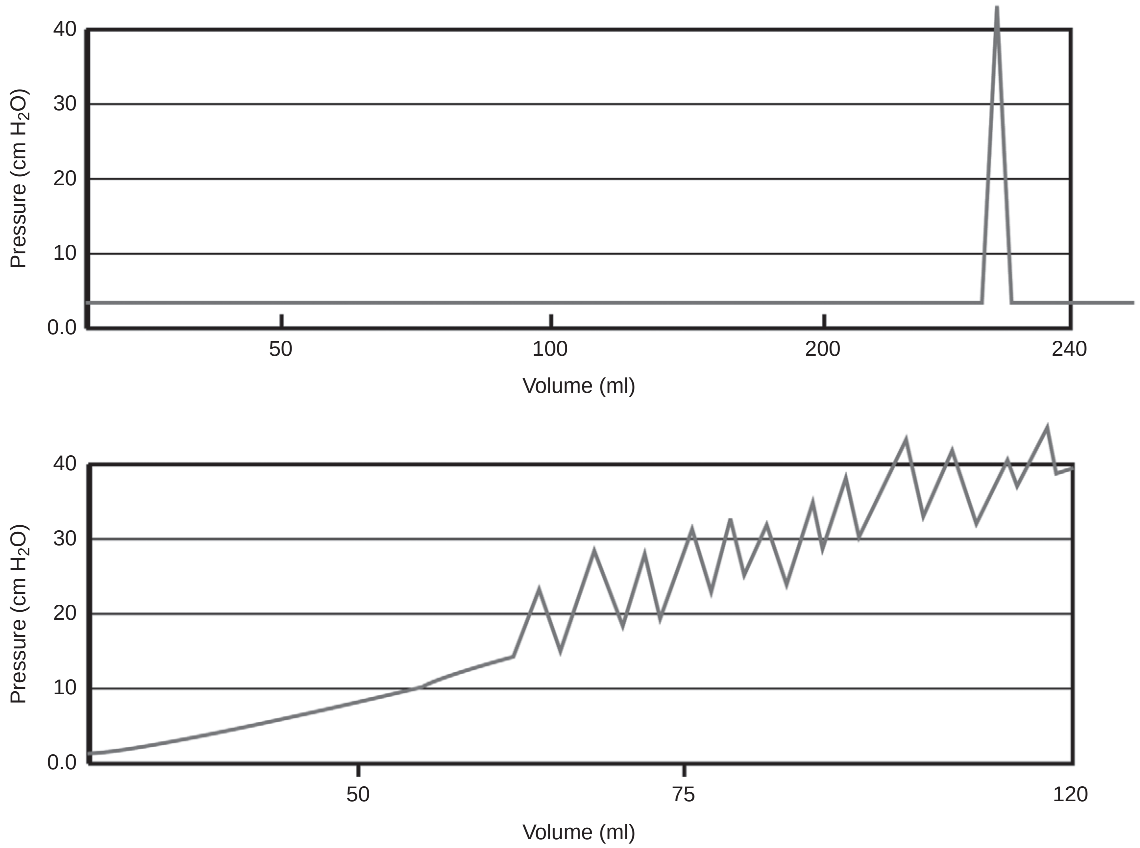

**FIGURE 116-7** Representation of typical urodynamic tracings from a compliant bladder and a poorly compliant bladder. Upper tracing demonstrates a compliant bladder: As the bladder fills, numerous factors serve to maintain low intravesical pressure until a voiding contraction is initiated. Lower tracing demonstrates a poorly compliant bladder with detrusor hyperreflexia. As the bladder fills, intravesical pressure rises precipitously. Irritability of the dysfunctional detrusor muscle is reflected in numerous small pressure spikes (i.e., uninhibited contractions).

**FIGURE 116-8** Photograph of spinal dysraphism.

disorder. In a family with one child with myelodysplasia, there exists a 2% to 5% chance that each subsequent sibling will suffer from the same condition. Early studies reported the incidence at 1 in 1000 live births.[10] However, over the past 20 years there has been a steady decrease in this rate. Reasons cited for this decrease include the widespread perinatal supplementation of folic acid (a metabolite important for proper spinal cord formation) and pregnancy termination.[11,12] Dietary supplementation with folic acid can reduce the incidence of myelodysplasia by approximately 50%.

The most common forms of myelodysplasia consist of prolapse of the meninges (meningocele) and in many cases neural tissue (myelomeningocele) beyond the confines of the bony vertebral canal. Initial urologic evaluation of the child found to have spinal dysraphism (Fig. 116-8) should include a renal ultrasound, voiding cystourethrogram, and determination of postvoid residuals by clean intermittent catheterization (CIC). The renal ultrasound will detect the presence of hydronephrosis. Up to 15% of newborns will be found to have an abnormal urinary tract; 3% have hydroureteronephrosis secondary to spinal shock from the closure procedure; and 10% have abnormalities that developed in utero as a result of abnormal lower urinary tract function in the form of outlet obstruction, thus resulting in high intravesical pressures.[13,14] The renal ultrasound serves the additional purpose of evaluating for renal fusion anomalies, which are known to be more common in patients with myelodysplasia.[15]

The voiding cystourethrogram serves the purpose of detecting vesicoureteral reflux, which is present in 3% to 5% of newborns with myelodysplasia.[16] Reflux is typically seen in children with detrusor hypertonicity or detrusor sphincter dyssynergy. New reflux will develop in approximately 30% of children with unfavorably high-pressure bladder dynamics if proper treatment is not taken to lower intravesical pressures. As mentioned earlier, several postvoid residuals (PVRs) are obtained in order to determine the efficiency of emptying. If the postvoid residuals average greater than 10 mL, the parents are taught CIC to be performed three times daily after discharge to home. Alternatively, because it may be difficult to obtain exact PVRs in newborns, random catheterized volumes can be measured. Random catheterized volumes consistently below expected bladder capacity imply efficient bladder emptying.

Follow-up urologic evaluation consists of a urodynamic evaluation at 3 months of life. Performing urodynamics at an earlier time point is often discouraged due to the fact that the infant may experience a degree of spinal shock from spinal closure that may last for up to 2 months. The urodynamic evaluation serves two purposes. First, it serves as a baseline against which all future urodynamic evaluations can be compared. Changes in the urodynamic profile may be the first indication (often before lower extremity function changes) that postmyelomeningocele closure spinal cord tethering is occurring and that surgical intervention may be required.

The second purpose of the urodynamic evaluation is to determine the overall storage characteristics of the bladder and sphincteric function. Three specific combinations of bladder contractility and external sphincter activity are seen. Bauer demonstrated that 19% of patients will demonstrate synergic voiding, 45% will have dyssynergic voiding, and the remaining 36% will suffer from complete denervation.[17] This system of classification is of great importance in predicting long-term renal and bladder function and thereby determining who will benefit from aggressive measures to minimize progressive urinary tract injury. Bauer has shown that within the first 3 years of life, patients with a dyssynergic voiding pattern have a much higher incidence of urinary tract deterioration. He found that 71% of newborns with DSD had urinary tract deterioration on initial assessment or subsequent studies, whereas only 17% of synergic children and 23% of completely denervated individuals developed similar changes. Notably, the small percentages of children with synergic or denervated voiding patterns that did go on to demonstrate urinary tract deterioration all had subsequent conversion to a high outlet resistance.

Frequent follow-up of patients with neuropathic bladder dysfunction secondary to myelomeningocele is mandatory because bladder dynamics (and thereby the effect on the upper urinary tract and continence) can change with time. Many reasons for a change in bladder dynamics exist, the most important being spinal cord tethering.[18]

The primary goal of treatment of the neuropathic bladder is the preservation of renal and bladder function. An additional goal of achieving urinary continence is addressed once the child reaches the age at which his or her peers are achieving this developmental milestone. CIC and the use of anticholinergic medications are the cornerstones of medical therapy to provide a low-pressure storage environment for urine. Edelstein and colleagues[19] demonstrated that if one aggressively and proactively treated high-risk patients who are defined as having either high outlet resistance, detrusor sphincter dyssynergy, and/or bladder hypercontractility (so-called *hostile bladder dynamics*) with CIC and anticholinergic medications that the rate of upper urinary tract injury could be substantially reduced. Kaefer and colleagues[20] subsequently demonstrated that long-term bladder function is similarly preserved in a greater number of patients if such measures are taken (Fig. 116-9). In this later study the incidence of long-term bladder deterioration requiring surgical bladder augmentation was reduced 2.5-fold. If these medical measures do not adequately reduce intravesical pressures and progressive hydronephrosis is noted in the first few years of life, then surgical intervention in the form of a cutaneous vesicostomy is indicated.

Urinary incontinence is likewise treated initially with conservative measures (i.e., CIC and anticholinergic medications) to decrease intravesical pressures. If such measures do not result in adequate improvement in bladder capacity and compliance, it may become necessary to enlarge the bladder by means of enterocystoplasty.[21,22] Additional surgical maneuvers may be required to provide adequate outlet resistance in order to achieve a state of urinary continence.[23]

## OCCULT SPINAL CORD TETHERING

A number of congenital defects affect the formation of the spinal column yet do not result in an open vertebral canal. These conditions occur in approximately 1 of every 4000 live births.[24] These lesions may result in no obvious outward neurologic signs, but in many there is a cutaneous abnormality overlying the lower spine (see earlier section on physical examination). There is an increased incidence (up to 50%) of these conditions in individuals with anorectal malformations,[25,26] with earlier reports demonstrating that the incidence varied proportionately in relation to the height of the

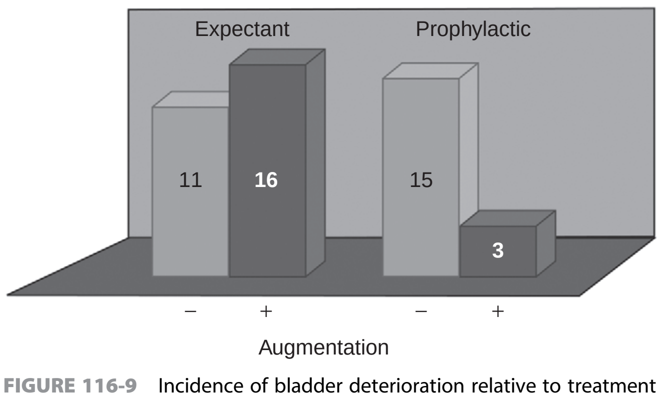

FIGURE 116-9 Incidence of bladder deterioration relative to treatment regiment in myelomeningocele patients. The expectant group comprised patients with hostile bladder dynamics noted at birth who were started on clean intermittent catheterization and anticholinergic medications to lower bladder pressure only after signs of upper tract deterioration or worsening incontinence became evident. On average treatment was initiated at age 4.1 years in this group. The prophylactic group comprised patients with hostile bladder dynamics noted at birth who were treated with measures to lower intravesical pressures beginning in the first 3 months of life. The greater than twofold higher incidence of bladder augmentation in the expectant group is highly statistically significant (41% vs. 17%). (From Kaefer M, Pabby A, Kelly M, et al: Improved bladder function after prophylactic treatment of the high risk neurogenic bladder in newborns with myelomeningocele. J Urol 1999;162(3 Pt 2):1068-1071.)

rectal lesion.[27] However, one recent study suggests that the incidence may not differ significantly between patients with supralevator and infralevator lesions.[25] All patients with a cutaneous abnormality overlying the lower spine or an anorectal malformation should undergo an MRI to evaluate for an intraspinal lesion.[28] In the first 6 months of life it is also possible to evaluate for spinal cord tethering with a spinal ultrasound.[29] When using ultrasound, one expects to see the conus medullaris at the level of the L2 vertebrate. In addition, the nontethered spinal cord should move with respiration. After 6 months of life, ossification of the vertebral segments limits the ability of ultrasound to penetrate to the level of the spinal cord and achieve adequate visualization of the distal spinal cord.

Urologic symptoms of occult spinal cord tethering may include difficulty with toilet training, urinary incontinence after an initial period of dryness (especially during the pubertal growth spurt when the most stress is put on the tethered cord), recurrent urinary infections, and/or fecal soiling.

Although the majority of newborns evaluated for occult spinal cord tethering have a perfectly normal physical examination, urodynamic testing will reveal abnormal lower urinary tract function in about one third of babies younger than 18 months of age.[30] In contrast, practically all individuals older than 3 years of age who have not been operated on or in whom an occult dysraphism has been belatedly diagnosed have abnormal urodynamic profiles.

Once it has been shown on MRI that there are signs of spinal cord tethering (e.g., the conus medullaris lies below the second lumbar vertebrae or there is a significant intraspinal lipoma), then a judgment is made as to the need for neurosurgical intervention. Often, the first sign of neurologic impairment is an abnormal urodynamic profile. Therefore urodynamics are performed on all patients with positive MRI findings. If a decision is made not to perform spinal cord tether release, then follow-up with biannual renal ultrasound and yearly urodynamic evaluations is indicated so that any future neurologic deficits can be identified early and appropriate intervention can be instituted in a timely fashion before irreversible nerve injury occurs.

## SACRAL AGENESIS

Patients with sacral agenesis frequently suffer from neuropathic bladder dysfunction. The etiology of sacral agenesis is still uncertain. It is, however, known that insulin-dependent mothers have a 1% chance of giving birth to a child with this disorder and that 16% of children with sacral agenesis have a diabetic mother.[31,32] Because these children have normal sensation and little or no orthopedic deformity in the lower extremities, the underlying lesion is often overlooked. Up to 20% of children with this condition escape detection until the age of 3 or 4 years.[33] Typically, the only outward sign of this condition is flattened buttocks and a low, short gluteal cleft (Fig. 116-10, *A*). The diagnosis is confirmed with a lateral film of the lower spine, which reveals the missing sacral vertebrae. MRI of the lumbosacral spine, which is recommended in all patients, consistently reveals a sharp cutoff of the conus at T12[34] (Fig. 116-10, *B*). Urodynamic testing shows that an almost equal number of individuals manifest a primarily upper (i.e., hypertonic, hyperreflexic) or lower (i.e., atonic) motor neuron type lesion (35% vs. 40%, respectively), while 25%

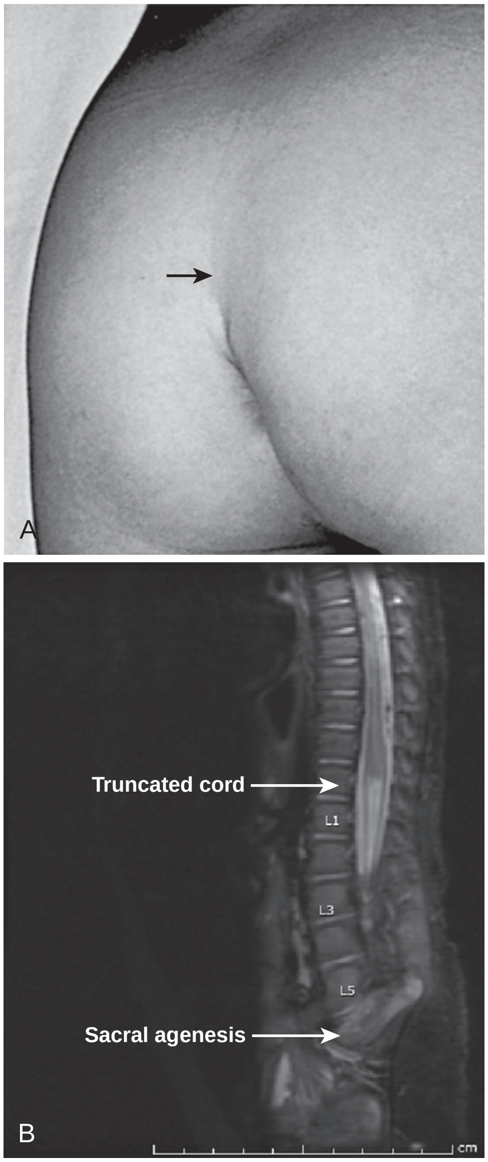

**FIGURE 116-10** **A,** Photograph of buttocks of patient with sacral agenesis. Note flattened buttocks and a low, short gluteal cleft. **B,** Magnetic resonance imaging of the lumbosacral spine in patient with sacral agenesis. Note sharp cutoff of the conus at T12 *(arrow)*.

have no sign of bladder dysfunction.[35] The number of affected vertebrae does not correlate with the type of motor neuron lesion. In contrast to the lesions noted in myelodysplasia or occult spinal cord anomalies, the injury is most frequently found to be stable. Although it is rare to see signs of progressive denervation such as a changing urodynamic pattern in these children as they grow, there can occasionally be a progressive renal impairment.[36,37] Anticholinergic agents are used to treat uninhibited contractions and/or relax the hypertonic detrusor, whereas CIC is used in patients with impaired bladder emptying.

## CEREBRAL PALSY

*Cerebral palsy* is the term used to describe a nonprogressive injury of the brain (e.g., hypoxic) occurring in the perinatal period that frequently produces a neuromuscular disability.[38]

Its incidence is approximately 1 in 1000 births. However, the incidence of cerebral palsy appears to be increasing as smaller premature infants survive in intensive care units. Although a high percentage of children will be found to have uninhibited contractions on urodynamic evaluation, the majority of children with this diagnosis have the capacity to develop total urinary control.[39] Incontinence is most commonly related to the physical handicap, making it difficult for the child to get to the bathroom in time. For this reason continence is often achieved at a later than expected age, once the child has become adept at transferring. Properly addressing the issue of adequate access to handicapped facilities may be extremely helpful in many of these children.

As a result of the many physical issues facing the child with cerebral palsy, urodynamic evaluation is typically reserved for those children who appear to be trainable, do not seem to be hampered too much by their physical impairment, and have not achieved continence by late childhood. For similar reasons, upper and lower urinary tract imaging is not recommended unless UTI has occurred.

Treatment focuses on providing an appropriate setting to allow the patient to easily access a toilet where they can properly relax while voiding. Individualized orthotics and upper body stabilization can help in this regard. If urodynamic data reveal uninhibited bladder activity, one can use anticholinergic medications but residual urine must be monitored closely to ensure complete evacuation with each void. CIC may be required for those who cannot empty their bladder. These children are also prone to severe constipation largely due to their poor fluid intake and limited physical activity. Insofar as constipation can adversely affect bladder stability and emptying, treatment to improve fecal elimination can prove beneficial in treating incontinence in these children. In a small subset of patients who do not respond to conservative measures, selective dorsal rhizotomy has improved bladder capacity, reduced the number of uninhibited contractions, and increased compliance.[40]

# Anatomic Causes of Bladder Dysfunction

## POSTERIOR URETHRAL VALVES

The most common form of anatomic bladder outlet obstruction in the pediatric population is posterior urethral valves (PUVs) in boys. Other etiologies of bladder outlet obstruction include urethral stricture, anterior urethral diverticulum, and an obstructing ureterocele situated at the bladder outlet.[41–43]

The incidence of posterior urethral valves is between 1 in 5000 and 1 in 8000 male births. Children present in a variety of ways depending on the degree of obstruction. Newborn children with severe outlet obstruction from posterior urethral valves typically present with a palpable midline abdominal mass (a distended bladder) and/or ascites (from urinary leak at the level of the kidney). In the most extreme cases children may experience respiratory distress from pulmonary hypoplasia due to the lack of adequate amniotic fluid volumes during lung development. Children who are identified later in life as having PUVs generally do not suffer from as severe an obstruction. These children typically present with voiding dysfunction, UTI, and on rare occasion with signs of renal failure (e.g., short stature). Today, with the widespread use of prenatal sonography, the majority of boys with bladder outlet obstruction are identified before delivery.[44]

Anatomic obstruction of the urethra results in pathologic changes at both the level of the kidney and the bladder. The bladder wall hypertrophies, diverticuli can form, and the posterior urethra becomes variably dilated (Fig. 116-11). Vesicoureteral reflux is seen in between 30% and 50% of patients. In approximately one third of these cases the reflux resolves once the obstruction has been relieved.[45] However, even in the absence of vesicoureteral reflux the upper urinary tract may still suffer injury due to lower urinary tract dysfunction that arises as a result of bladder wall thickening.

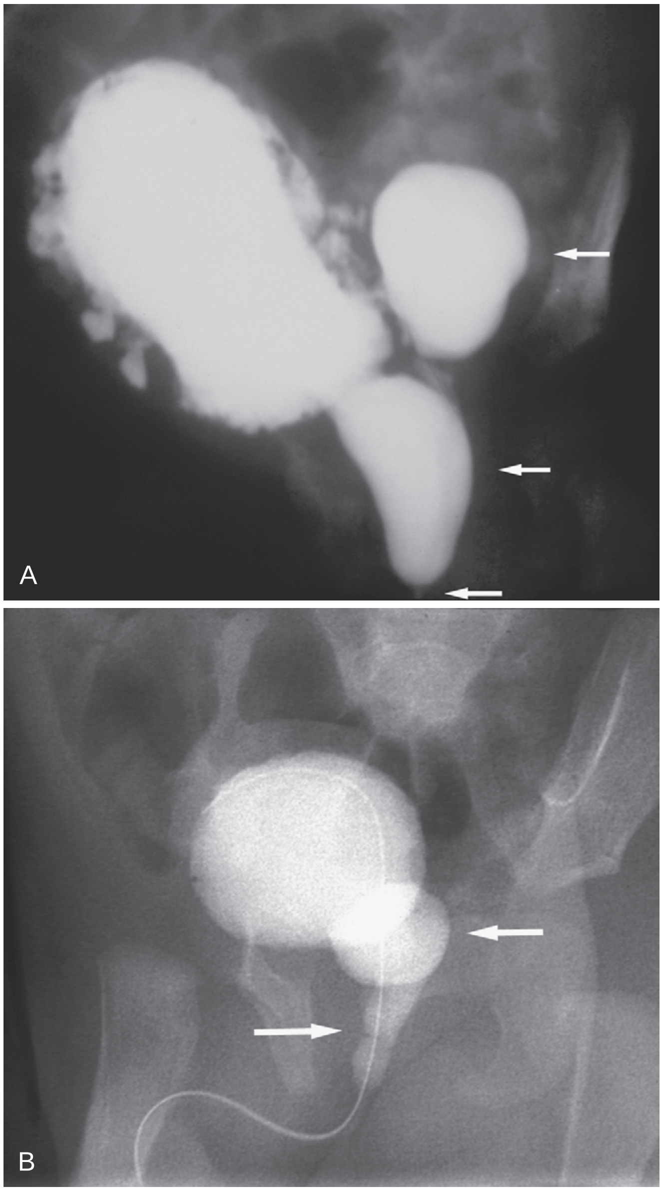

**FIGURE 116-11** Voiding cystourethrograms in children with posterior urethral valves. **A,** Severe case in which there is dramatic bladder decompensation with multiple small and large diverticuli *(uppermost arrow)* and dilated posterior urethra *(middle arrow)*. The site of valvular obstruction is shown by the inferior arrow. **B,** Mild case in which there is little evidence of bladder deterioration. *Upper arrow* points to the distended posterior urethra. *Lower arrow* points to the negative impression resulting from the posterior urethral valve itself.

Both cellular hypertrophy and the increased deposition of extracellular matrix are seen histologically in a bladder that is of lower capacity and decreased compliance.

Endoscopic destruction of the valve leaflets can be performed safely in nearly all term infants. An antegrade approach to valve destruction has been used in patients whose urethra is too small to accept a cystoscope.[46] Although cautery electrodes are the most frequently used device for disrupting the obstructing leaflets, cautery hooks, the neodymium: yttrium laser, and the antegrade withdrawal of a balloon catheter have also been used effectively for this purpose.[47–49]

Once the urethral obstruction has been relieved, bladder dysfunction may persist. Most often the bladder dysfunction manifests itself as daytime urinary incontinence that persists after the child has reached school age. Initially it was felt that persistent incontinence was due to injury to the urethral sphincter during endoscopic ablation of the valves and/or abnormal bladder sphincter development as a result of the initial obstruction. However, urodynamic assessment of these children has clearly shown that persistent bladder dysfunction is frequently seen well after the valves have been ablated. Several investigators have demonstrated that there are three primary abnormalities of detrusor function: bladder hypertonia, detrusor hyperreflexia, and myogenic failure.[50–53] Furthermore, evidence suggests that urodynamic patterns can change as the child matures. A study by Holmdahl and colleagues[54,55] has demonstrated that many children who are initially shown to have a hypercontractile, poorly compliant bladder as newborns will later have a urodynamic pattern that is more consistent with myogenic failure. Many children with bladder dysfunction secondary to posterior urethral valves also appear to have abnormal bladder sensation and an inability to sense when their bladder is full.[56] Adding to the problem of persistent bladder dysfunction is the common finding of renal injury and associated poor urinary concentrating ability. The large volumes of urine that result put a further stress on the dysfunctional lower urinary tract.

The treatment of bladder dysfunction in children with posterior urethral valves depends on the severity and form of bladder dysfunction, as well as the efficiency of bladder emptying. Patients with high-pressure voiding dynamics often benefit from the use of anticholinergic medications to improve compliance. In younger patients with an impaired ability to empty the bladder spontaneously, CIC may be required. Daytime catheterization can often be avoided in older children if they can adhere to a strict schedule of timed voiding. Recently Koff and colleagues have advocated the use of a nighttime indwelling catheter to provide optimal bladder drainage. By improving nighttime drainage, the authors have documented significant improvement in hydronephrosis and bladder compliance.[56,57] Although conservative measures are usually effective in modifying bladder dynamics (i.e., keeping bladder volumes sufficiently low to maintain acceptable bladder pressures), a small number of patients may still require bladder augmentation to improve bladder volume and compliance.[52] Patients with posterior urethral valves do not have altered urethral sensation, and many of these children will find catheterization through the penis painful. Creation of a continent catheterizable channel to the anterior abdominal wall can therefore improve the quality of life and result in improved compliance with catheterization in these children.[58]

# Nonneuropathic, Nonanatomic Causes of Bladder Dysfunction

## DYSFUNCTIONAL ELIMINATION SYNDROMES

Bladder dysfunction in the absence of anatomic bladder outlet obstruction or neurologic disease is frequently termed *dysfunctional voiding*. This term encompasses children who fit along a spectrum of relative urinary retention. At the most severe end of this spectrum are children who retain urine to such a great degree that they demonstrate altered bladder anatomy, upper urinary tract dilatation, and scarring, which is virtually indistinguishable from that seen in neuropathic bladder dysfunction (the so-called *non-neurogenic neurogenic bladder*) (Fig. 116-12).[59,60] The severity of the radiographic findings leads the physician to obtain an MRI of the lumbosacral spine, which by definition shows no abnormalities suggestive of spinal cord tethering. Urodynamic evaluation classically demonstrates a low-capacity, high-pressure bladder. Treatment of Hinman syndrome parallels that used in true neuropathic bladder dysfunction. An attempt should be made to lower intravesical pressures with the combined use of anticholinergic medication and CIC. If conservative measures fail to adequately reduce storage pressures, bladder augmentation is performed. Unlike patients with true neurologic lesions, many of these children will find catheterization painful and will benefit from creation of a continent catheterizable channel to the anterior abdominal wall.

At the opposite end of the spectrum is a large population of otherwise healthy children who, as a result of relative urinary retention experience, increased irritative voiding symptoms and a higher propensity toward developing UTIs. In the past decade it has become clear that constipation can be seen in many of these individuals and that a large fecal burden can have a significant impact on bladder function. As a result, the more encompassing term *dysfunctional elimination syndrome* (DES) has largely supplanted the term *dysfunctional voiding*.

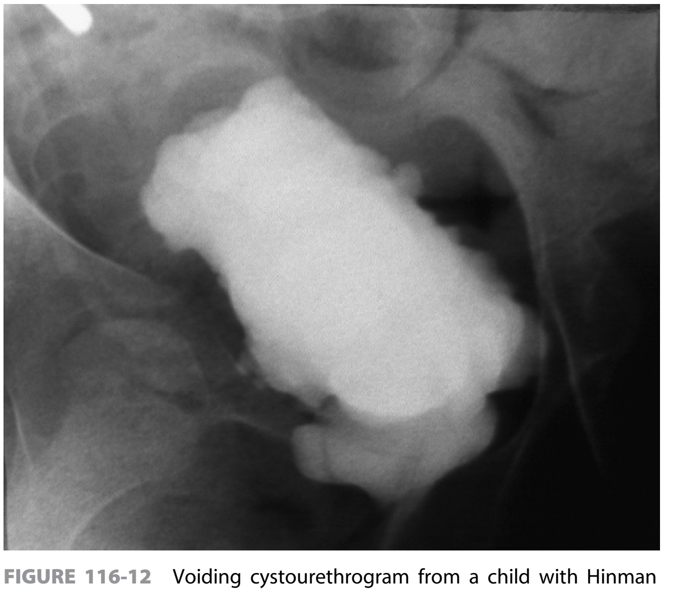

**FIGURE 116-12** Voiding cystourethrogram from a child with Hinman syndrome. Note the significant irregularity of the bladder outline secondary to bladder wall thickening.

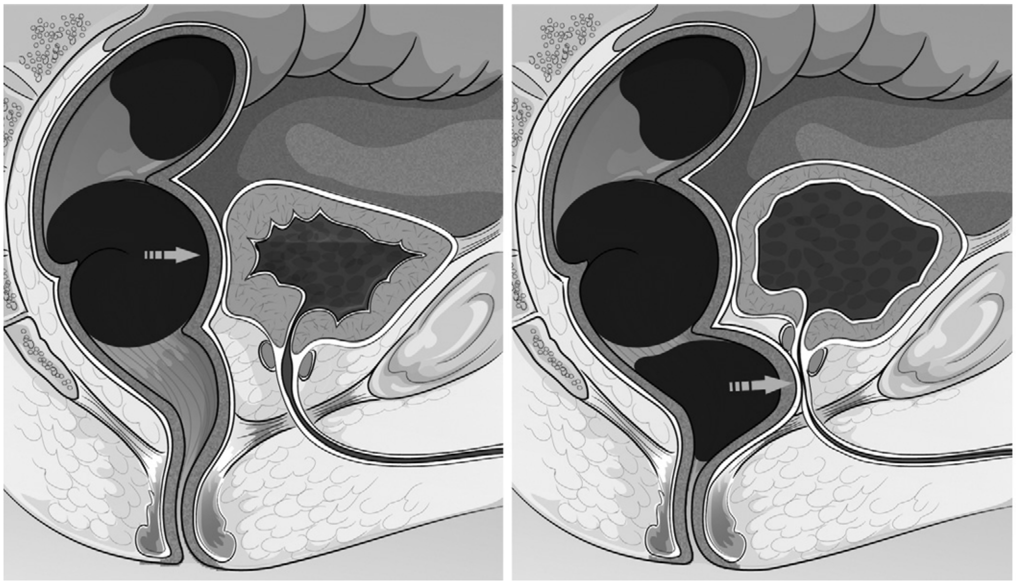

**FIGURE 116-13** The effect of constipation on bladder function. *Left,* Stool in the rectum may push up on the posterior aspect of the bladder, resulting in bladder instability. *Right,* Severe forms of constipation have the potential to externally compress the bladder neck and inhibit bladder emptying.

Children affected by this condition do not empty their bowel or bladder as often or as completely as they should, or they require high bladder pressures to empty their bladders. As a result of poor bladder emptying, the bladder is constantly distended and as such leaves the patient prone to urge incontinence. If children fail to empty completely, they will reach a state of fullness more often and this may be reflected in the symptom of urinary frequency. The maintenance of a high postvoid residual leaves the patient more prone to UTIs and incontinence. Constipation can contribute bladder irritability from the mass effect on the posterior aspect of the bladder and in severe cases may also inhibit bladder emptying (Fig. 116-13). Poor bladder emptying has been shown by Dohil and colleagues[61] to improve following bowel treatment in constipated children, with postvoid residual urine dropping from 66% at baseline assessment to 21%. Chronic constipation is associated with significant hypertrophy of the internal anal sphincter and abnormal anal sphincter EMG activity.[62] This may generate increased urethral sphincter and pelvic floor activity and explain the association between voiding dysfunction and incomplete voiding.

Radiographic findings that are highly suggestive of this diagnosis include a large stool burden on the plain abdominal film or evidence of a full rectosigmoid segment behind the bladder on ultrasound, a large postvoid residual on bladder ultrasound, and the "spinning top" image of the bladder neck on voiding cystourethrogram (Fig. 116-14).

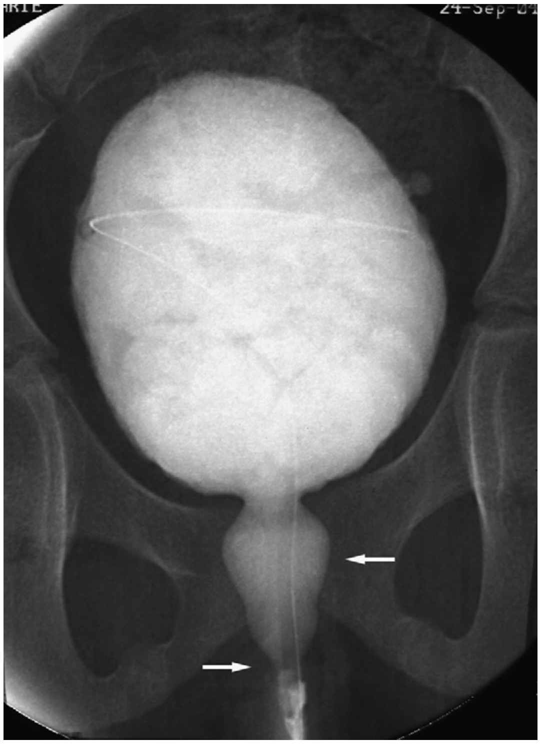

**FIGURE 116-14** Voiding cystourethrogram from a child with dysfunctional elimination syndrome demonstrating a full bladder with a small diverticulum and a distended proximal urethra *(uppermost arrow)*. The *lowermost arrow* depicts the site of the external sphincter. Because of failure to relax, the result is proximal urethral ballooning (the so-called *spinning top deformity*).

Treatment of the child with DES includes (1) timed voiding in which the child is asked to void every 2 hours, (2) double voiding in which the child is asked to attempt to void a second time after emptying the bladder (in an attempt to minimize the chances of carrying a large postvoid residual), and (3) establishing good bowel emptying habits. The latter behavior can be supported by increasing dietary fiber, using stool softeners, and taking plenty of time to defecate completely. Providing adequate foot support can be beneficial in achieving a state of balance and thereby enhancing adequate relaxation. Should these conservative measures fail to result in adequate relaxation during voiding/defecating, biofeedback may prove beneficial. Many ingenious methods for performing biofeedback including the use of videogames have been developed.[63] Although biofeedback has proven to be highly beneficial in

many patients, this modality may require multiple office visits with skilled nursing care, which can often be difficult due to time and/or financial constraints. An alternative that has recently gained much attention is treatment with α-adrenergic inhibitors. The exact mechanism and site of action for α-blocker therapy in children with poor bladder emptying remains in question. There are documented reports of $\alpha_1$-adrenergic receptors at the bladder outlet and in the proximal urethra.[64,65] It is felt that the primary mechanism of action is smooth muscle relaxation at the base of the bladder and decreased outlet resistance in the proximal sphincter complex. Both tamsulosin and doxazosin have been studied in the pediatric setting.[66] Selective α-blocker therapy appears to be effective for improving bladder emptying in children with wetting, recurrent infection, and increased PVR urine. Early treatment of increased postvoid residual urine volumes with α-blockers may significantly reduce the number of patients who will need biofeedback therapy. The more commonly reported side effects of these medications are nasal congestion, dizziness, and postural hypotension. We recommend administering the medication before bedtime so as to minimize the potential for experiencing dizziness during the waking hours. It is also imperative that the blood pressure be evaluated 3 days following initiation of the medication to ensure that the child is not experiencing orthostatic hypotension.

## OVERACTIVE BLADDER SYNDROME

Although the majority of children who present to the pediatrician with wetting and urinary frequency will have a retentive behavior as the etiology, a smaller population will demonstrate these symptoms due to a state of relative detrusor overactivity in the absence of demonstrable neurologic impairment. As a result, bladder filling even to moderate volumes will often trigger a bladder contraction. This group of children does not demonstrate retentive bladder or bowel behavior and carries minimal postvoid residual when evaluated by bladder ultrasound. An effective treatment for this condition is the use of anticholinergic medications. Anticholinergic medications are competitive inhibitors of acetylcholine that block the neurotransmitter's muscarinic effects. Anticholinergic medications are typically titrated to effect. Common side effects consist of dry mouth, flushing, and constipation. Constipation especially may pose a problem because children with detrusor overactivity have a predilection for constipation, and the development of constipation may aggravate detrusor overactivity and thus counteract the beneficial effects of the drug. Oxybutynin (0.2 mg/kg twice daily or three times daily) has been the most often used anticholinergic medication. The newer antimuscarinic drug tolterodine has, in adults, shown a more favorable therapeutic profile, with the same clinical efficacy and a lesser frequency of side effects compared with oxybutynin.[67] Tolterodine has also been shown to be safe and effective in children.[68] A commonly used dosage for tolterodine in children is 0.1 mg/kg twice daily. Sustained release formulations, which can be taken once daily, are also a choice for children who can tolerate medication in pill form. In patients who experience minimal side effects, studies have shown increased effectiveness by doubling the recommended daily dosage.[69,70] Overactive bladder symptoms are typically self-limiting with even the most recalcitrant cases showing resolution within an 18-month period.[71] Failure to improve on anticholinergic medication may warrant a more thorough investigation of the patient in the form of a urodynamic evaluation.

## NOCTURNAL ENURESIS

Whether a true problem of bladder function, a failure of adequate nocturnal urinary concentrating ability, or an issue related to a relatively poor state of nocturnal arousal, nighttime wetting is often discussed in chapters on bladder dysfunction.[72] Various series have reported the incidence of isolated nocturnal enuresis as between 6% and 10% in children who have reached age 7 years. The spontaneous cure rate in children between the ages of 5 and 20 is 15% annually.[73] Most children who are enuretic eventually obtain normal control.

Nocturnal enuresis is a genetically complex and heterogeneous disorder. Genetic factors play an important role in the etiology. A positive family history may be elicited in more than 50% of cases. Within families different members can show the same or different forms of wetting. Studies evaluating the incidence of nocturnal enuresis in twins have shown 46% for monozygotic pairs and 19% for dizygotic pairs.[74] The most common mode of transmission appears to be autosomal dominant.

Various pathophysiologic mechanisms appear to be at play including nocturnal polyuria, bladder overactivity at night with a small functional bladder capacity, and disorder of arousal.[75] Furthermore, these groupings show considerable overlap. In humans there is a marked circadian rhythm of urine production so that there is a nighttime reduction in diuresis of up to 50% of daytime levels.[76] In children this is controlled by increased nocturnal release of arginine vasopressin, as well as angiotensin II and aldosterone.[77,78] It has long been known that children with nocturnal enuresis have significantly larger nocturnal urine production than nonenuretic children. This group of patients has a favorable response to the arginine vasopressin analogue dDAVP.[79] Although a certain subset of enuretics has a smaller nocturnal functional bladder capacity, the incidence of functional abnormalities seems rather low in children with isolated nocturnal enuresis. Whether wetting is primarily due to a problem of urinary concentrating ability, functional bladder capacity, or other as of yet unrecognized etiology, a prerequisite for wetting is failure to awake when micturition is imminent. This has caused many to conclude that sleep disturbance per se is the major pathophysiologic factor in enuresis, and it is still a widely held belief that enuretics are deep sleepers. However, a number of studies have been unable to convincingly show abnormalities in sleep patterns.

Treatment of nocturnal enuresis takes many forms. If present, daytime symptoms should be treated. The child should be asked to void regularly and not to delay urinating after experiencing a sense of bladder fullness. Symptoms of urgency and frequency, as well as constipation, should be addressed. A rate of enuresis cure up to 72% has been reported after constipation has been adequately addressed.[80] To minimize the possibility of nocturnal polyuria, fluids should be limited several hours before bedtime. A low calcium and sodium dietary content of the afternoon and evening meals may also be useful. The child should be instructed to void before bedtime. This helps to minimize the nocturnal bladder volume.

Enuresis that persists after age 6 may be treated with medication and/or a bed alarm device. Desmopressin (dDAVP) is easy to administer and has an immediate effect on urinary

volume. Dosing is between 0.2 and 0.6 mg orally. Intranasal dDAVP has recently lost its indication for nocturnal enuresis by the U.S. Food and Drug Administration due to the side effect of water intoxication. In most trials response to desmopressin (defined as >50% reduction of the number of wet nights) was noted in 60% to 70% of patients.[81] Another pharmacologic option is the tricyclic antidepressant imipramine (Tofranil), which exerts a direct effect on bladder smooth muscle and has sympathomimetic effects. Unlike anticholinergic medications, which have a relatively short half-life, the blood levels of imipramine build up over a period of several days. The true beneficial effect of this medication may therefore not become apparent for up to 2 weeks. Approximately 50% of enuretic children improve with imipramine, yet a significant number will relapse after treatment is discontinued. It has been reported that only 17% of children who were dry during imipramine medication stay dry 6 months after cessation of the medication.[82] The major drawback to imipramine therapy is its cardiotoxic side effects, even in therapeutic doses.[83] Although anticholinergic medications should not be expected to be effective in true isolated nocturnal enuresis, this medication can occasionally be of help.

Alarm therapy is the most effective method for treating nocturnal enuresis. A meta-analysis of the world literature revealed an average success rate of 68%.[72] Efficacy is reported to increase with duration of therapy to as high as 90% by 6 months.[84] Although most children will not awaken, they will stop emptying the bladder at the onset of the alarm. It therefore requires that a parent assist the child in awakening and proceeding to the toilet to finish voiding. Once the undergarments have been changed, the alarm should be reset. The exact mechanisms of alarm treatment are not known, although it is clearly an operant type of behavioral approach.

CHAPTER 117

# Reconstruction of the Bladder and Bladder Outlet

Eugene Minevich and Curtis A. Sheldon

Effective surgical management of the abnormal bladder requires a thorough understanding of both normal micturition and dysfunctional voiding (see Chapter 116). Urinary continence is a complex balance between intravesical pressure and bladder outlet resistance. Several variables determine intravesical pressure, only one of which is compliance, which reflects both muscular tone and interstitial elasticity. This measure is not static but rather varies with bladder capacity. Consequently, urine output, postvoid residual volume, and frequency of bladder emptying determine the working compliance range of the bladder. Pathologic alterations (e.g., uninhibited detrusor contraction or interstitial fibrosis) may markedly alter compliance and resultant intravesical pressure characteristics.

Bladder outlet resistance also depends on several variables and must be highly coordinated in order to prevent incontinence but allow voiding to occur. Reflex contraction of the sphincteric mechanism helps prevent incontinence after sudden increases in intra-abdominal pressure. Conversely, bladder outlet sphincteric mechanisms reflexively relax at the time of detrusor contraction. At this point, volitional voiding ensues. In addition, voluntary contraction of the striated muscle of the urinary sphincter adds supplementary support to prevent incontinence. In some circumstances, however, reflex contraction of the bladder sphincteric mechanism or inappropriate voluntary contraction (e.g., dysfunctional voiding) can result in dangerously high intravesical pressures. Furthermore, the bladder outlet sphincteric mechanism may fail to relax during attempts at voiding, a condition known as *detrusor-sphincter dyssynergy*. Pathologic bladder outlet resistance may be caused by congenital anatomic obstruction (e.g., posterior urethral valves) or acquired lesions (e.g., stricture).

The structural consequences of unbalanced voiding are highly variable and ominous. Bladder consequences include hypertrophy of detrusor musculature with trabeculation. Sacculation and diverticula may develop, leading to urinary tract infection (UTI) and urolithiasis. Interstitial fibrosis may also occur and cause a progressive loss of bladder compliance. Of particular concern are the consequences of high bladder pressure on renal function. Even without vesicoureteral reflux, a close correlation exists between intrapelvic renal pressure and intravesical pressure.[1] Renal pelvic pressures greater than 40 cm of $H_2O$ deform the renal papillae, which may distort the orientation of the tubules draining into the papillae and result in intrarenal reflux.[2] This increases the vulnerability of the kidney to pyelonephritis.

In patients with neurogenic bladder (such as those with myelodysplasia), bladder pressure and renal prognosis are closely correlated. Spontaneous urine leakage through the bladder outlet mechanism at a bladder pressure greater than 40 cm $H_2O$ has been associated with poor prognosis for the upper urinary tract.[3] A similar correlation with the maximal urethral pressure on urodynamic testing has also been demonstrated.[4] Furthermore, elevated intravesical pressure has been shown to adversely affect the renal allografts.[5]

Otherwise healthy children with increased intravesical pressure have an increased risk for UTI and vesicoureteral reflux (VUR).[6] Anticholinergic medications, which reduce intravesical pressure, can dramatically alleviate reflux and UTI.[7,8]

The surgeon must realize that the cause of bladder injury cannot be reliably determined from end-stage abnormalities because the ability of various primary diseases to cause bladder injury overlaps considerably. Secondary changes due to chronic retention, infection, stones, or surgery also confound the issue. Therefore one cannot predict the degree of bladder function on the basis of knowledge of such primary diseases as myelodysplasia, posterior urethral valves, prune-belly syndrome, and imperforate anus. Measurement of physiologic properties of the bladder by formal urodynamic investigation is essential in planning any major surgical intervention.

Although it is accepted that bladder dysfunction can damage the kidney, it is less well recognized that renal disease can contribute to bladder injury. Polyuria caused by primary renal disease can substantially alter bladder function. It can result in a hypertensive bladder with extensive detrusor hypertrophy or, if decompensated, a massively dilated, flaccid, hypotonic bladder that cannot empty completely. These effects can also accompany secondary renal disease (e.g., polyuria accompanying posterior urethral valves). Such lesions injure the renal medulla and lead to a loss of concentrating capacity; the resulting polyuria may further damage the bladder.

Bladder outlet obstruction is a major factor in progressive bladder and kidney injury. Structural lesions such as posterior urethral valves or urethral strictures are particularly problematic. Also important is detrusor-sphincter dyssynergy. This condition may be volitional or nonvolitional. With the latter, the sphincteric periurethral muscle inappropriately contracts (rather than relaxes) during detrusor contraction. In the former, the child closes the bladder outlet to prevent incontinence that results from uninhibited detrusor activity or to delay the need for voiding when the bladder has become overfilled. Such activity may also be used to prevent painful voiding. This activity is often manifested clinically by the occurrence of Vincent curtsy, in which the child sits on a foot, squats, or squeezes the legs together to help prevent voiding.

The "valve bladder" best exemplifies the interplay of these factors (Fig. 117-1). Even after valve resection, the bladder may still operate at high pressures because of residual bladder wall changes such as altered compliance and uninhibited detrusor contractions. The bladder may not empty completely, and substantial VUR may be present. During voiding, urine is emitted through the urethra but also refluxes into the kidneys. When the patient completes voiding, this urine immediately drains back into the bladder. This drainage, along with elevated postvoid residual urine volume caused by abnormal bladder function, forces the bladder to continuously work within a range that results in high storage pressure with subsequent adverse effects on the kidneys.

Recent advances in surgical technique, the successful application of intermittent catheterization to the reconstructed urinary tract, and the lessons learned from the pioneering work on urinary undiversion[9] allow even the most anatomically devastated children to be reconstructed for continence, as well as preservation of renal function. Such reconstructive principles may now be applied to virtually all urinary tract anomalies with a good expectation of success. Reconstructive options are presently available even for children with end-stage renal disease for whom renal transplantation will ultimately be required. Reconstruction involves many challenges in achieving the goals of low-pressure storage of urine and complete bladder emptying. Most frequently, such reconstruction is necessary for treatment of bladder exstrophy; posterior urethral valves; and neurogenic bladder related to myelomeningocele, other sacral dysraphisms, or the VATER complex (*v*ertebral defects, imperforate *a*nus, *t*racheoesophageal fistula with *e*sophageal atresia, and *r*adial and renal dysplasia). Other disease states necessitating reconstruction include urogenital sinus and cloacal anomalies, cloacal exstrophy, and bilateral single ectopic ureters. All of these are commonly associated with abnormal storage pressures of urine or problems with emptying.

# Disorders of Bladder and Urethra

## ANATOMIC DISORDERS OF BLADDER AND URETHRA

Primary structural abnormalities are important and are best exemplified by posterior urethral valves (Fig. 117-2), the most common cause of structural lower urinary tract obstruction in male infants. As a consequence of obstruction, the proximal urethra is elongated and dilated, and the bladder neck is relatively narrowed because of secondary detrusor hypertrophy. The distal urethra is of normal caliber, resulting in an abrupt transition between the dilated proximal urethra and the thin anterior urethra. The bladder exhibits detrusor hypertrophy and is irregular because of trabeculation, sacculation, and the presence of diverticula. The upper urinary tracts typically show severe hydronephrosis with or without vesicoureteral reflux. Renal impairment is frequent and often presents from birth; recovery is incomplete even after valve ablation.

Most patients are recognized during infancy, and more than two thirds are identified within the first year of life. With the

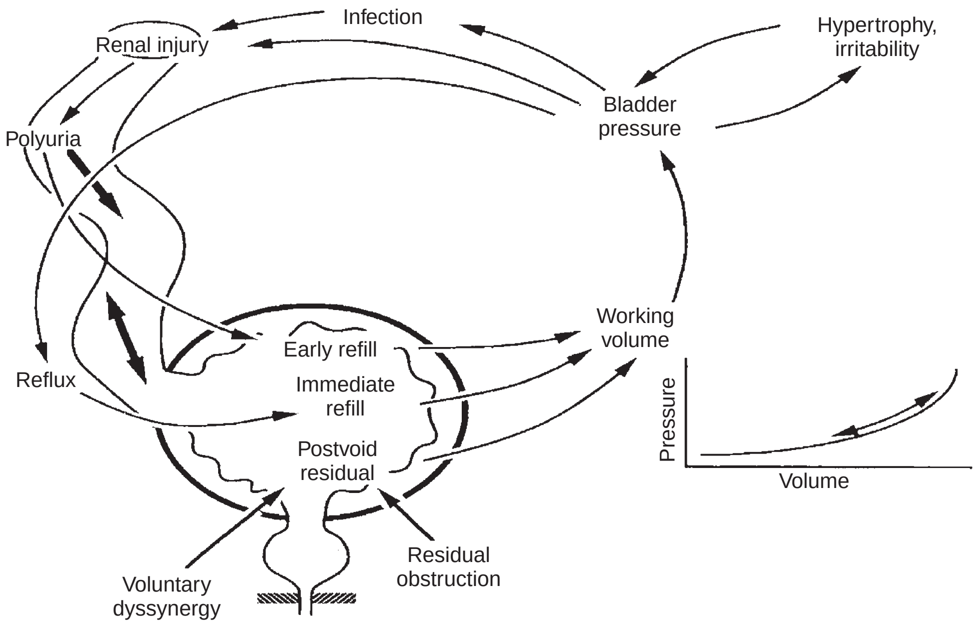

FIGURE 117-1 Pathophysiology of the valve bladder. (From Minevich E, Sheldon CA: Structural disorders of the bladder, augmentation. In Grosfeld JL, O'Neill J, Fonkalsrud E, Coran A [eds]: Pediatric Surgery. St. Louis, Mosby, 2006.)

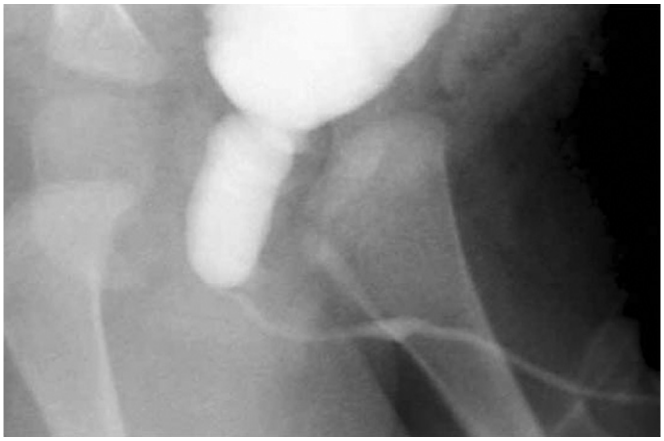

FIGURE 117-2 Radiographic appearance of posterior urethral valves. (From Minevich E, Sheldon CA: Structural disorders of the bladder, augmentation. Grosfeld JL, O'Neill J, Fonkalsrud E, Coran A [eds]: Pediatric Surgery. St. Louis, Mosby, 2006.)

advent of perinatal ultrasonography, in utero diagnosis has become common. A newborn may have an enlarged palpable bladder or kidneys as a result of hydroureteronephrosis. An infant may have UTI or failure to thrive because of azotemia, whereas in older children the initial manifestation may be incontinence. Diagnostic evaluation includes ultrasonography of the upper urinary tract and radiographic voiding cystourethrogram (VCUG). Renal function can be evaluated by renal scanning. Urodynamic investigation may later be indicated if hydronephrosis, reflux, azotemia, or incontinence persists in a child whose valves have been ablated successfully.

Infants should initially be stabilized by catheter drainage of the bladder, intravenous resuscitation, and respiratory support when needed. Urine is drained with a 5- or 8-French infant feeding tube because larger catheters or catheters with balloons may cause intense detrusor contraction, which may impede urine flow through the ureterovesical junction. Most patients are subsequently treated by valve ablation. In premature infants with a urethra too small for endoscopic fulguration, either antegrade ablation or a vesicostomy may be created; with current miniaturized cystoscopes, however, these procedures are rarely necessary. Patients with massive reflux, particularly when accompanied by azotemia, are also candidates for vesicostomy.

The rare infant with profound azotemia who is unresponsive to catheter drainage may benefit from upper urinary tract diversion by way of cutaneous pyelostomy. Such low-pressure drainage may allow sufficient return of renal function so that dialysis or renal transplantation can be deferred until the child is older. Both cutaneous vesicostomies and cutaneous pyelostomies are readily reversed. It is important to avoid fulguration of valves in a dry urethra (e.g., in the patient who has undergone diversion by vesicostomy or pyelostomy), which may result in urethral stricture.

Anterior urethral valves, Cowper duct cysts, urethral polyps, urethral duplication (Fig. 117-3), and urethral diverticula can produce structural changes in the bladder that are related to obstruction. Acquired obstructive lesions include stricture and meatal stenosis. Exstrophic bladder abnormality, epispadias, and hypospadias are other structural lesions, discussed elsewhere in the textbook.

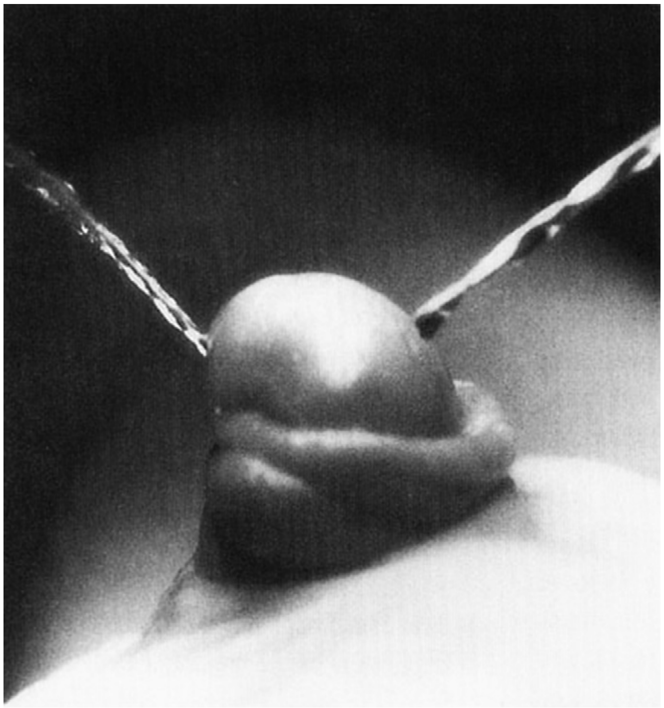

FIGURE 117-3 Urethral duplication. (From Sheldon CA, Bukowski TP: Male external genitalia. In Rowe MI, O'Neill J, Grosfeld JL, et al [eds]: Essentials of Pediatric Surgery. St Louis, 1995, Mosby-Year Book, p 779.)

## NEUROGENIC DISORDERS OF THE BLADDER AND URETHRAL FUNCTION

The surgeon is commonly faced with a primary abnormality of bladder innervation (a neurogenic bladder). Myelodysplasia, an open dystrophic state, is particularly common. Myelomeningocele, in which neural tissue and the meninges protrude beyond the confines of the vertebral canal, is the most common defect. The neurologic effect of these entities on the lower urinary tract varies and cannot be predicted by the observed level of the anomaly; urodynamic testing is, therefore, essential. The risk for upper urinary tract deterioration can be predicted urodynamically. Both a leak point pressure exceeding 40 cm $H_2O$[3] and the presence of dyssynergy[10] have been clearly shown to be associated with poor prognosis for the upper urinary tract (Figs. 117-4 and 117-5). The risk for deterioration exceeds 70% in the presence of dyssynergy; sphincteric synergy or sphincteric denervation is associated with an incidence of deterioration of 15% and 25%, respectively. Unfortunately, the neurologic defect is often a dynamic one in which dyssynergy, if not present initially, may develop over time. The development of dyssynergy is often related to tethering of the spinal cord, which may result in spinal injury or spinal root injury as the child grows. The greatest risk occurs within the first 2 years of life, especially the first year, but such injury can occur throughout childhood.

Occult (closed) spinal dysraphisms include tethered cords, intradural lipomas, dermoid cysts or sinuses, diastematomyelia, and cauda equina tumors. These children commonly have urologic manifestations as UTIs and incontinence. Fortunately, however, cutaneous manifestations are obvious in most patients. Such lesions as cutaneous dimpling, the presence of a skin tag, a subcutaneous lipoma or a patch of hair over the bony sacrum, dermal vascular malformation, and pigmentation may

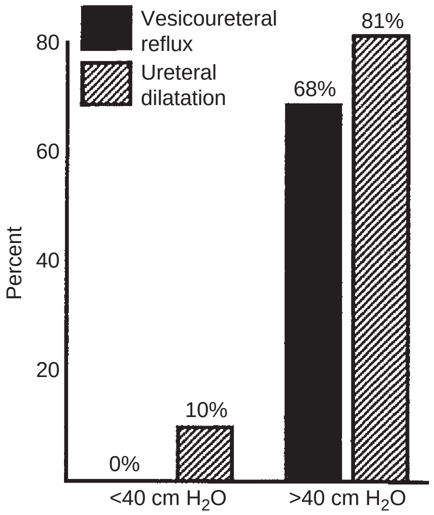

FIGURE 117-4 Risk for upper urinary tract injury as a function of urethral opening pressure. (From McGuire EJ, Woodside JR, Borden TA, Weiss RM: Prognostic value of urodynamic testing in myelodysplastic patients. J Urol 1981;126:208.)

indicate an underlying spinal disorder. The presence of these findings in any child with urinary incontinence or other evidence of bladder dysfunction requires exclusion of occult spinal diastrophism. These diagnoses may be confirmed by urodynamic investigation and spinal magnetic resonance imaging (MRI) or, in the first 6 months of life, ultrasonography of the spinal cord. Abnormal urinary tract function occurs in approximately 40% of patients.[11]

Another important cause of neurogenic bladder is sacral agenesis, often seen in imperforate anus or in the infant of a diabetic mother. This condition is characterized by congenital absence of all or part of two or more sacral segments. The lesion may be suggested on physical examination by the presence of an abnormal gluteal cleft or detection of an incomplete sacrum on direct palpation. The diagnosis may be confirmed by anteroposterior and lateral lumbosacral spine radiographs. Approximately 75% of such patients have abnormal urinary tract function.[12]

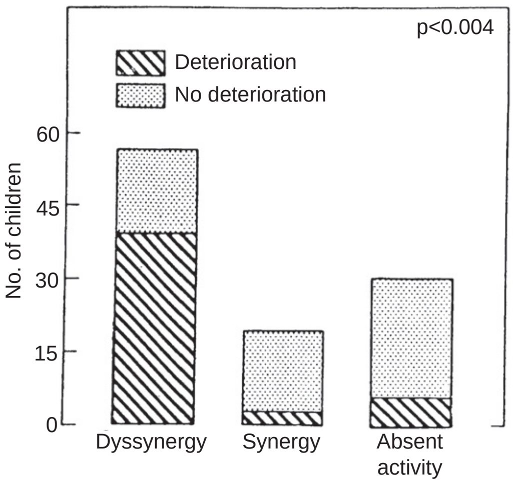

FIGURE 117-5 Urinary tract deterioration as a function of dyssynergia, synergy, and absent sphincteric activity. (From Bauer SB: Early evaluation and management of children with spina bifida. In King LR [ed]: Urologic Surgery in Neonates and Young Infants. Philadelphia, WB Saunders, 1988, p 256.)

## COMBINED ANATOMIC AND NEUROGENIC DISORDERS

A third group of infants requiring bladder reconstruction are those with both functional and structural bladder abnormalities such as imperforate anus or cloaca. In these cases, a full anatomic assessment must be done early in life, which at a minimum requires renal ultrasonography, radiographic VCUG, and ultrasonographic assessment of the spinal cord. The combination of both anatomic and functional abnormalities creates a high risk for substantial urologic morbidity. A study by McLorie and colleagues involving 484 consecutive patients revealed a high risk for end-stage renal disease.[13] Nonfistula genitourinary anomalies were encountered in 60% of patients with high lesions and 20% of those with low lesions. Substantial upper urinary tract abnormalities were encountered in more than one third of cases, and bilateral upper urinary tract abnormalities occurred in 14%.

Our review of 90 consecutive cases of imperforate anus showed an 18% incidence of significant neurovesical dysfunction.[14] The greatest risk was encountered in patients with a high imperforate anus. However, neurovesical dysfunction was also encountered in some patients with low lesions. In many patients, a tethered spinal cord must be addressed because of the risk for progressive injury to innervation of the bladder, urethra, anorectum, and lower extremities.

The importance of these anomalies was demonstrated in a review of 23 of our patients with imperforate anus reconstructed for either upper urinary tract preservation or achievement of continence.[15] As shown in Figure 117-6, 9% of patients presented with end-stage renal disease, 65% had significant renal abnormalities, and 57% had vesicoureteral reflux. Ureteral anomalies were encountered in 30% of patients, and neurovesical dysfunction was encountered in 70%. A wide spectrum of urologic reconstructive procedures was required for these patients (Fig. 117-7). Of particular note, 43% required ureteral reimplantation, 43% required bladder augmentation, 35% required a Mitrofanoff neourethra, and 22% required bladder neck reconstruction. The urethra in boys with imperforate anus may be difficult to catheterize because of urethral irregularity related to the congenital rectourethral fistula. This, along with intact urethral sensation, may necessitate the creation of a Mitrofanoff neourethra to assist intermittent catheterization.

Other lesions, described elsewhere in this text, may also require bladder reconstruction. Patients with urogenital sinus anomalies, in which the bladder and vagina drain through a common channel, often have associated neurovesical dysfunction. In addition to urethral and vaginal reconstruction, these patients may have an incompetent bladder outlet, necessitating reconstruction. As with other conditions associated with neurovesical dysfunction, bladder augmentation may be required. Patients with exstrophy or cloacal exstrophy characteristically require complex urinary tract reconstruction. Patients with the prune-belly syndrome can usually be managed medically but sometimes require surgical intervention. These patients typically have a hypotonic bladder that operates at low pressure but empties incompletely, is highly irregular, and is prone to infection. Some patients, however, lose capacity and compliance over time. Consequently, urodynamic investigation is often necessary to facilitate therapy.

# Reconstructive Philosophy

The goals of urinary reconstruction are to preserve the upper urinary tract, attain socially acceptable continence, and maximize the child's ease of care and potential for self-care. Patients at risk for upper urinary tract injury are evaluated during the newborn period, and therapy to protect the upper urinary tracts is initiated at that time. Urinary incontinence is evaluated and treated just before school age in order to make social integration easier. In general, an attempt is made to manage the urinary tract with medical therapy before subjecting the child to surgical intervention. Such therapy may include intermittent catheterization to facilitate bladder emptying, anticholinergic therapy to diminish intravesical pressure, and α-adrenergic agents to enhance bladder outlet resistance. Surgical therapy is undertaken only if medical therapy is unsuccessful. When contemplating urinary tract reconstruction, meticulous preoperative evaluation is critical, and it is essential to tailor the reconstruction to the individual needs of the patient.

Four components of balanced urinary tract function must be achieved to ensure long-term success with urinary reconstruction.[16] The first component is that of adequate bladder (reservoir) capacity and sufficient compliance to provide low-pressure storage. Optimal bladder capacity should allow a 4-hour catheterization or voiding interval during the day and an 8-hour interval at night without reaching excessive pressure or precipitating incontinence. The second component is adequate bladder outlet resistance to maintain urinary continence. Third, there must be a convenient, reliable mechanism for bladder (reservoir) emptying. Ideally, this should be achieved by spontaneous voiding; otherwise, intermittent catheterization is necessary. The native urethra may be an acceptable conduit for this maneuver, although should catheterization of it prove excessively difficult or uncomfortable (preventing patient compliance), an alternative catheterizable conduit may be necessary. Finally, unobstructed and nonrefluxing sterile upper tract drainage of urine into the bladder (reservoir) is desirable in order to protect the upper tracts.

# Compensating for Inadequate Bladder Capacity or Compliance

## PHYSIOLOGIC CONSIDERATIONS

Bladder capacity and compliance are increased by bladder augmentation. Indicators that augmentation is necessary include clinical symptoms, such as incontinence caused by bladder dysfunction unresponsive to medical therapy, and upper urinary tract deterioration due to inadequate low-pressure storage volume. Also suggestive is a measured bladder capacity that is significantly less than that expected for the patient's age. Caution must be exercised because with an incompetent

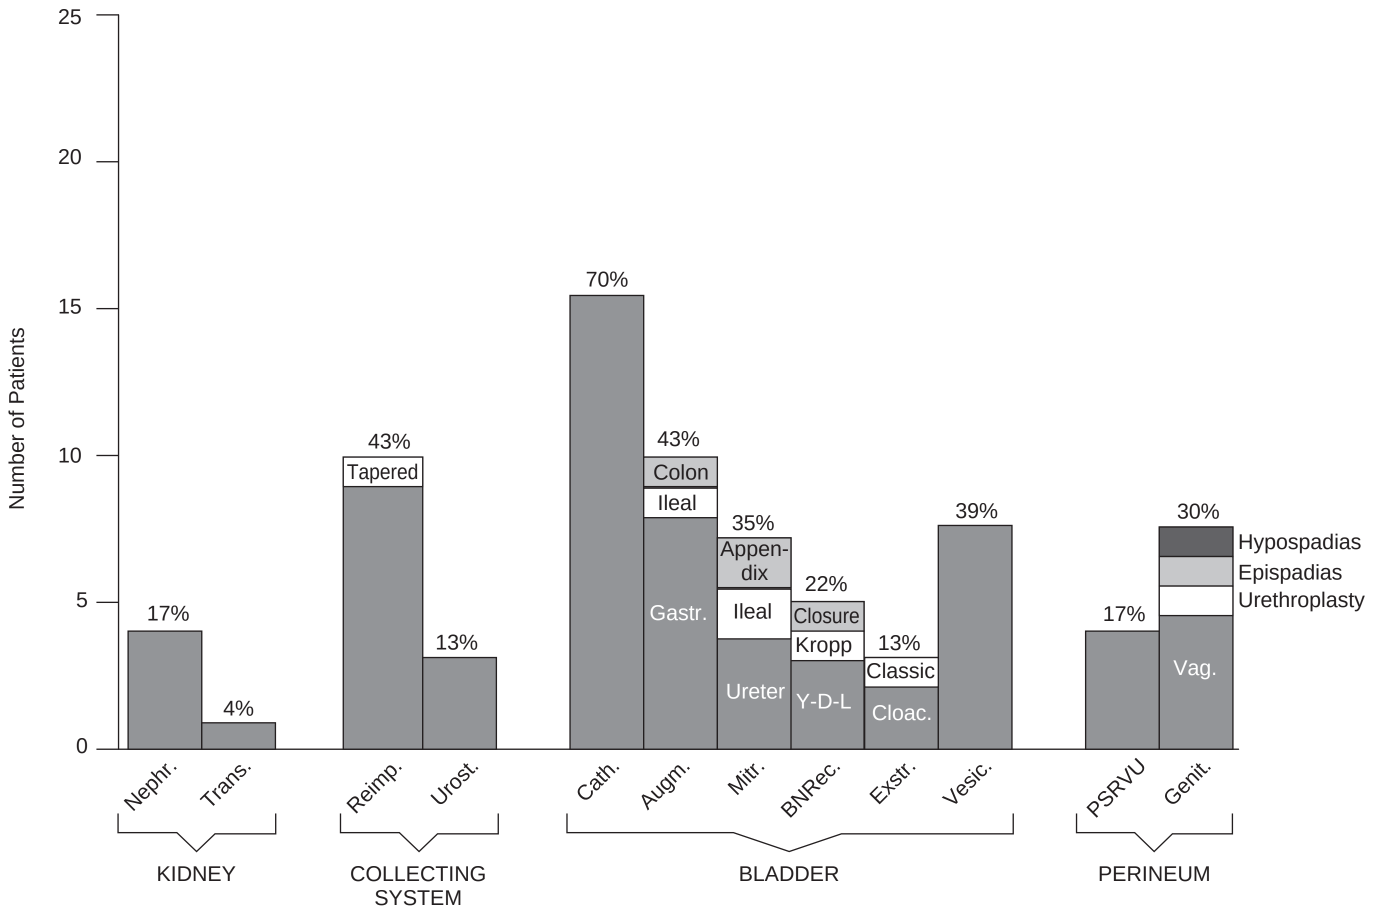

**FIGURE 117-7** Surgical procedures performed in patients with imperforate anus. *Augm.*, Augmentation; *BNRec.*, bladder neck reconstruction; *Cath.*, intermittent catheterization; *Exstr.*, exstrophy; *Gastr.*, gastrocystoplasty; *Mitr.*, Mitrofanoff neourethra; *Nephr.*, nephrectomy; *Reimp.*, reimplantation; *Trans.*, renal transplantation; *Urost.*, ureterostomy; *Vag.*, vaginoplasty; *Vesic.*, vesicostomy; *Y-D-L*, Young-Dees-Leadbetter procedure. bladder outlet, the bladder may drain at low pressure, making determination of functional bladder volume more difficult. Performing cystometrography with a Foley catheter balloon that occludes the bladder neck may provide more reliable data on functional bladder capacity. The generation of pressure exceeding 35 to 40 cm $H_2O$ with urine volumes equal to those anticipated during 4 hours of urine production during the day or 8 hours of urine production during the night during maximal medical therapy further suggests that bladder augmentation should be considered.

Several important reconstructive concepts are pertinent to bladder augmentation. The first regards management of the recipient bladder. If bowel augmentation is performed, with the detrusor essentially left intact to generate high pressure, the former will act urodynamically as a capacious diverticulum.[17] The problem can be avoided by an extended sagittal opening of the bladder from the level of the bladder neck anteriorly to the trigone posteriorly ("clam cystoplasty"). Essentially, this is a reconfiguration of the bladder from a sphere into a flat plate so that the detrusor is no longer capable of generating a contraction that produces a significant pressure elevation.[18,19]

Just as pressure generated by the bladder detrusor is an important contributor to the pressure generated in an augmented urinary reservoir, so also is the pressure generated by the tubularized bowel segment itself. With peristaltic contractions, pressures ranging from 60 to 100 cm $H_2O$ may be encountered.[20] This observation led Kock to develop his concept of turning the intact bowel into a reservoir incapable of effective peristalsis by creating a "pouch."[21] Opening the bowel along its antimesenteric border and closing it with disruption of the circular muscle ("detubularization") inhibits peristalsis. Once unable to undergo peristalsis, the reservoir dilates and stores urine at a low pressure (Fig. 117-8).[22,23] Additionally, there is a significant increase in the geometric capacity of the intestinal segment.[23] A third important concept is accommodation (Fig. 117-9). It is well known that the reconstructed bladder will gradually enlarge over time. At a constant pressure, a structure with a larger radius will accommodate a greater volume—again, an advantage of detubularized bowel segments.

Several considerations must be entertained when choosing an augmentation donor site. Anatomic considerations such as mobility of the blood supply favor the use of ileum, sigmoid, the ileocecal region, and the greater curvature of the stomach. The ability to implant a ureter or a Mitrofanoff neourethra may also be a consideration. Additionally, it may be important to avoid the peritoneal cavity so that the option of performing peritoneal dialysis or placement of a ventricular peritoneal shunt is preserved. Such considerations favor the use of ureteral augmentation or autoaugmentation.

The choice of augmentation donor site may be limited by the patient's primary disease. Patients with short gut may not tolerate a loss of the ileocecal region or a significant length of ileum. Patients with borderline fecal continence (such as

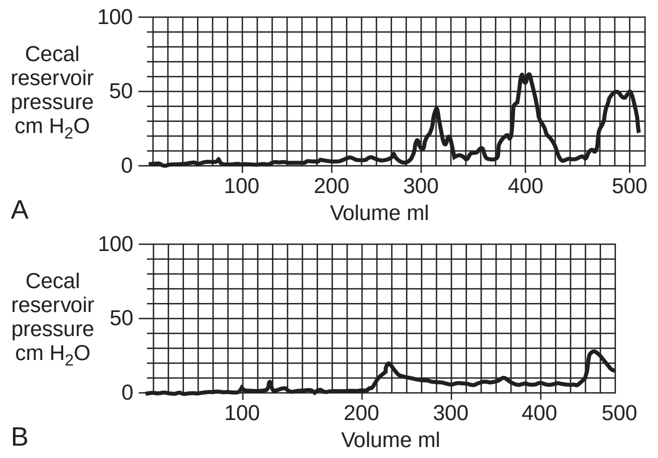

**FIGURE 117-8** Urodynamics of cecal reservoir. **A,** A tubular bowel produces high-pressure peristaltic waves. **B,** A cup patch bowel with disrupted peristalsis stores large volume without pressure rise. (From Goldwasser HR, Webster GD: Augmentation and substitution enterocystoplasty. J Urol 1986;135:221.)

those with imperforate anus or myelodysplasia) may not tolerate loss of the ileocecal valve or the water reabsorptive capacity of the right colon. Metabolic consequences may assume an overriding influence: The risk of absorptive acidosis and growth retardation, which may be exacerbated by chronic renal insufficiency, may favor the use of autoaugmentation, ureteral augmentation, or gastrocystoplasty techniques. Because the reconstruction must be tailored to the individual needs of the patient, the surgeon must be familiar with a wide variety of reconstructive alternatives and prepare the patient accordingly including bowel preparation even when gastrocystoplasty, autoaugmentation, or ureteral augmentation is anticipated.

## SMALL BOWEL PROCEDURES

Ileocystoplasty (Fig. 117-10) is one of the most commonly used bladder augmentation techniques.[24,25] The bladder is prepared by a "clam" cystoplasty incision, and a segment of ileum 20 to 40 cm in length is isolated and incised along its antimesenteric border. It is reconfigured as a "cup patch" and anastomosed to the bladder plate with running 3-0 Vicryl suture (inner-layer interlocking). Bowel continuity is reestablished by end-to-end anastomosis. Advantages of this procedure include its technical simplicity. However, antirefluxing implantation of the ureter or Mitrofanoff neourethra into the ileal segment is less reliable than implantation into the native bladder or other augmentation donor segments.

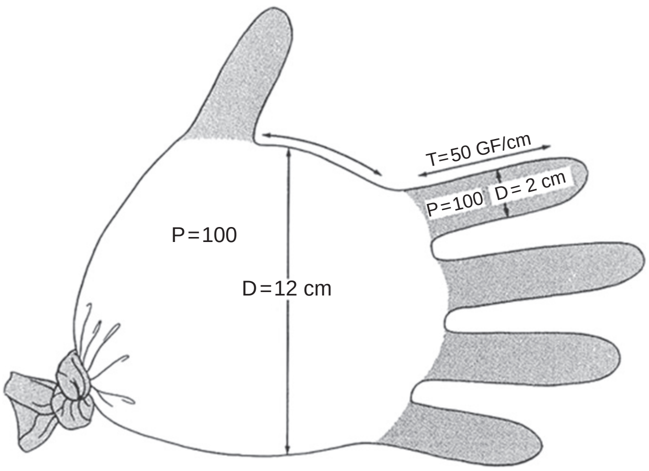

**FIGURE 117-9** Inflated surgeon's glove illustrates the LaPlace relationship. Although pressure (*P*) is equal throughout, tension (*T*) is greater in portion with greater diameter (*D*). (From Hinman F: Selection of intestinal segments for bladder substitution: Physical and physiological characteristics. J Urol 1988;139:522.)

Other techniques of bladder augmentation or replacement using small bowel include the Camey procedure (Fig. 117-11),[26] Kock pouch (Fig. 117-12),[21] and ileal neobladder.[27,28] These procedures are less successful in achieving continence and have a significant rate of complications and reoperation.

## ILEOCECAL SEGMENT PROCEDURES

The ileocecal bowel segment has been favored by urologists for bladder reconstruction because of the natural configuration of the cecum, which gives it the appearance of an ideal substitute for the bladder.[29] This technique is technically simple to perform and also has the major advantage of allowing antirefluxing implantation of massively dilated ureters into the ileum. Reflux is prevented by the ileocecal valve, bolstered by intussusception. Unfortunately, the intussusception antireflux mechanism is inherently unstable. Consequently, various surgical modifications of the ileocecal valve have been introduced in an effort to try to lessen the incidence of reflux. Of greater impact is the fact that loss of the ileocecal valve from fecal continuity risks devastating fecal incontinence in patients with marginal anorectal continence (e.g., myelomeningocele or the VATER complex).

When the cecal or ileocecal segments have been used intact for bladder augmentation, nighttime incontinence has been a significant problem in most series.[30] This problem most likely reflects peristaltic waves in the intact bowel segment because enuresis is rare when the cup patch technique is used. Other continent diversions using the ileocecal valve have included the Maintz pouch,[31] the Penn pouch,[32] the Indiana pouch,[33] and the Florida pouch.[34] Of these techniques, the Indiana pouch has been applied most frequently in pediatric practice and has met with variable results.[35]

## LARGE BOWEL PROCEDURES

Mathisen[36] reported sigmoid augmentation of the bladder performed in a manner similar to that described for ileocystoplasty earlier. This procedure, too, is relatively simple to perform but allows a better antirefluxing implantation of the ureter or Mitrofanoff neourethra into the tenia. This technique did not appear to differ from other bowel segments with respect to ability to empty, infections, or surgical complications.[37] In patients who have previously undergone reconstruction for imperforate anus, this procedure may interrupt blood supply to the rectum because the anorectum depends on a descending blood supply. Positive experiences with construction of a colonic neobladder have been reported,[38,39] although nocturnal incontinence continues to be a problem in up to 33% of patients.[39]

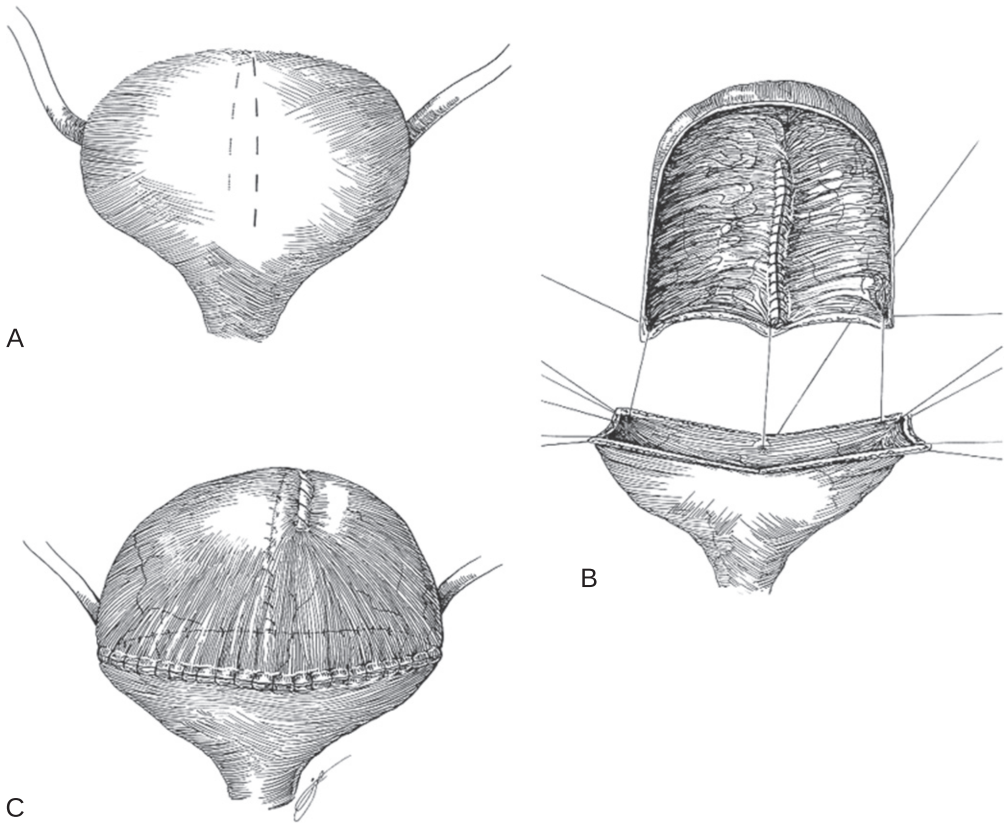

**FIGURE 117-10** Technique of "clam" ileocystoplasty. **A,** Small, high-pressure bladder. **B,** Bladder has been prepared by a long, longitudinal incision, and a segment of ileum has been detubularized and fashioned into a cup patch. **C,** Cup patch is anastomosed to bladder. ### GASTRIC SEGMENT PROCEDURES

The work of Mitchell and colleagues[40] ushered in the modern era of the use of stomach in urinary reconstruction (Fig. 117-13). They demonstrated gastrocystoplasty to be highly successful, versatile, and well tolerated even in the face of azotemia. This procedure is associated with a reduced risk for infection, mucus production, and urinary stone formation and provides excellent compliance characteristics. Implantation of a ureter or Mitrofanoff neourethra is technically easy. Our long-term follow-up with gastrocystoplasty or gastric neobladder reveals a continence rate of 91%, stable renal function in all patients, and upper tract deterioration in only one patient who became noncompliant with intermittent catheterization.[41,42] Additionally, gastrocystoplasty has proved to be an excellent alternative for patients with end-stage renal disease facing subsequent transplantation.[41,42] The gastric or composite neobladder has been successfully used for reconstruction[43] with the native urethra,[44] the orthotopic ureteral neourethra,[41,45] and the orthotopic appendiceal neourethra.[41] The major complication and limiting application of the gastrocystoplasty is the development of hematuria-dysuria syndrome, which can be refractory to medical management and may require reversal of the augmentation.

### URETERAL AUGMENTATION AND AUTOAUGMENTATION

Ureteral augmentation[46] (Fig. 117-14) and autoaugmentation[47] (Fig. 117-15) hold great promise because of their ability to prevent absorptive metabolic disorders and to be performed via an entirely extraperitoneal approach.[48] However, these procedures are more likely to fail to attain adequate capacity and compliance because of an inherent restriction in the availability of surface area.[49] In case of ureterocystoplasty the ureter is made available either by nephrectomy or transureteroureterostomy. Unfortunately, a sufficiently dilated ureter is rarely available for this procedure. In addition, some reports indicate that the long-term ability of ureteral augmentation to maintain low storage pressure and adequate capacity may be suspect.[50]

## Procedures to Correct Deficient Bladder Outlet Resistance

Urinary continence is maintained by a complex relationship between bladder outlet resistance and pressure. In order to maintain dryness, the bladder outlet resistance must exceed

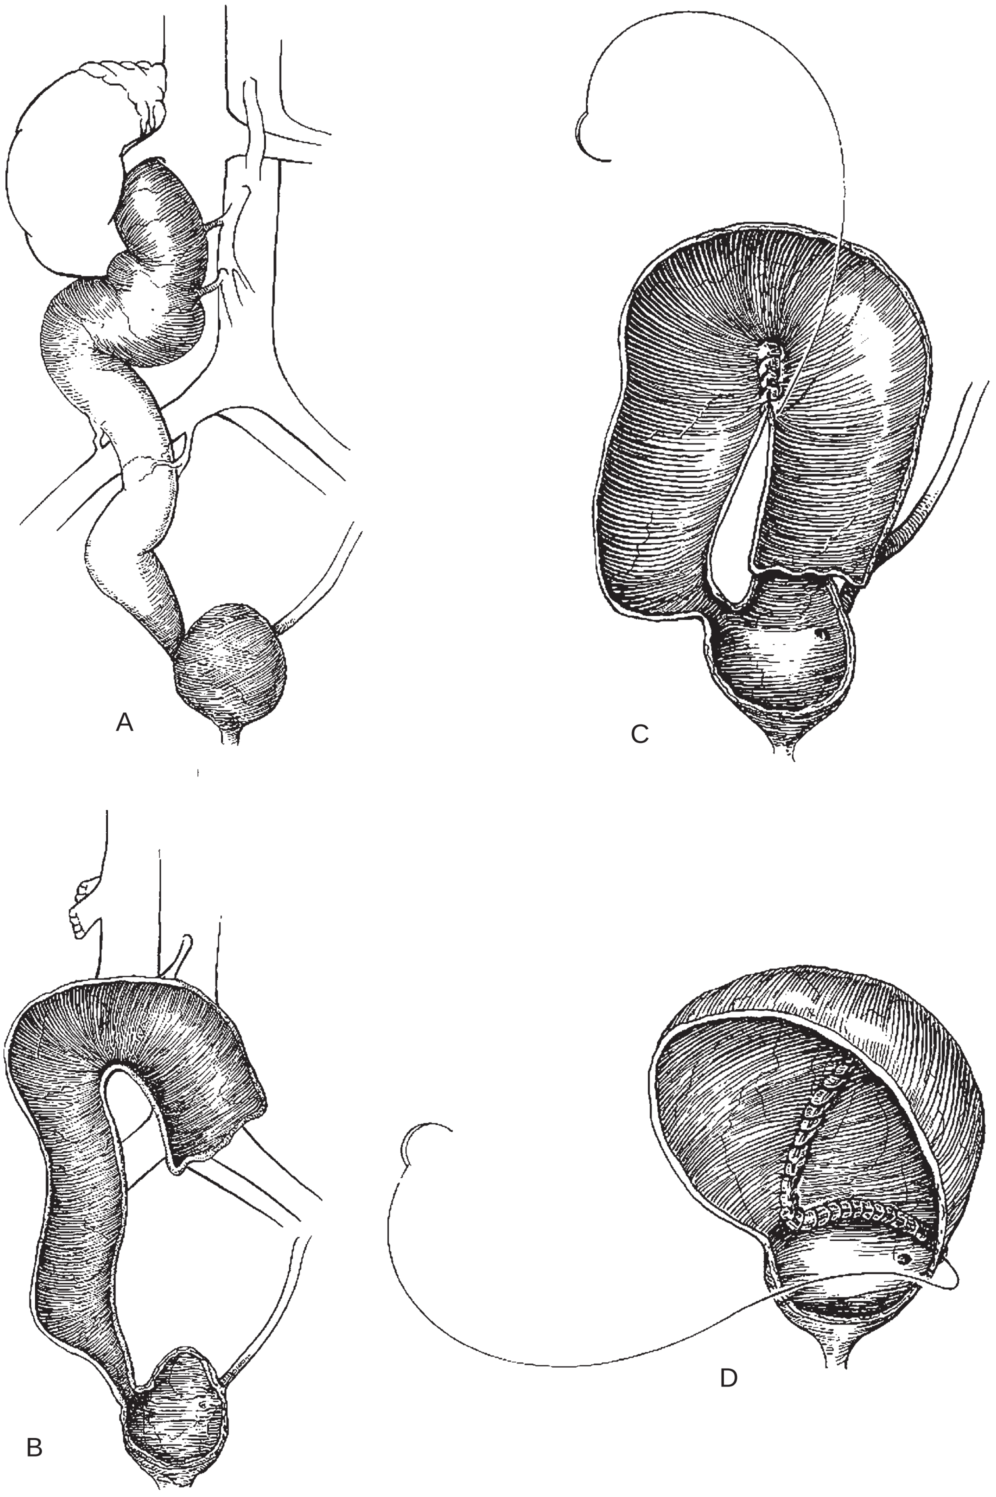

**FIGURE 117-14** Operative stages of ureteral bladder augmentation. **A,** Normal blood supply to ureter. **B,** Ureteral detubularization following mobilization. **C,** Reconfiguration of ureter into U-shaped patch. **D,** Anastomosing ureteral patching to native bivalved bladder. (From Minevich E, Sheldon CA: Urinary tract reconstruction for continence and renal preservation. In Ziegler MM, Azizkhan RG, Weber TR, et al [eds]: Operative Pediatric Surgery. Norwalk, Conn, Appleton & Lange, 2003, p 919.)

intravesical pressure not only at rest but also during changes in posture, coughing, sneezing, and straining. Bladder outlet reconstruction is necessary in patients with incontinence despite low-pressure storage of urine in the bladder. The bladder outlet in patients who have a high-pressure or low-capacity bladder is more difficult to assess because incontinence may be caused by these storage characteristics alone. The likelihood of a competent sphincteric mechanism in this setting is suggested by a stress leak point pressure greater than 100 cm $H_2O$.[51] Urethral pressure profilometry and static leak point pressure have not proven to be reliable, independent indicators of sphincteric competence. Most surgical interventions designed for the

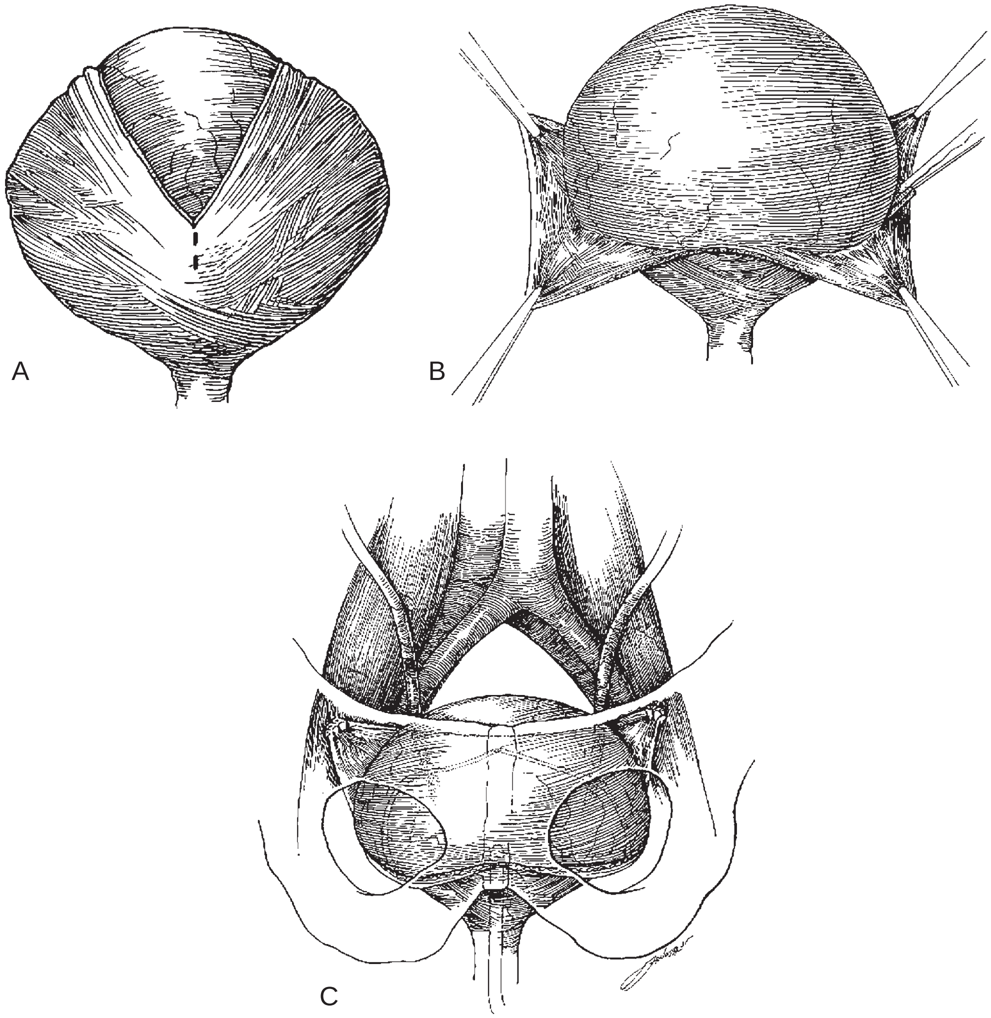

**FIGURE 117-15** Autoaugmentation. **A,** Detrusor incised. **B,** Detrusor stripped from intact bladder epithelium. **C,** Epithelium bulges with bladder filling. (From Minevich E, Sheldon CA: Urinary tract reconstruction for continence and renal preservation. In Ziegler MM, Azizkhan RG, Weber TR, et al [eds]: Operative Pediatric Surgery. Norwalk, Conn, Appleton & Lange, 2003, p 920.)

achievement of continence include procedures to lengthen the urethra, suspend the bladder neck, or compress or completely close the urethra.

Efforts to proximally lengthen the existing urethra through tubularization of the posterior detrusor grew out of the early work of Young.[52] In the procedure, which was later modified by Dees[53] and Leadbetter,[54] the urethra is lengthened by tubularization of a long (4- to 5-cm) segment of the posterior bladder wall. Two triangular sections of urothelium are excised, and the resultant urothelial strip is approximated over a small catheter (8- or 10-French)[55] to fashion the neourethra. The adjacent detrusor is approximated to itself over this mucosal tube to add muscular support (Fig. 117-16). Anterior urethral suspension is usually performed by suture fixation and may be supplemented by the placement of a compressive fascial sling. Several variations in technique have been described.[56,57]

The specific goals of this procedure are to achieve continence and allow spontaneous voiding if the detrusor can contract. Intermittent catheterization must also be attainable if the detrusor cannot effectively contract to empty the bladder. Benefits of this technique are that it may allow spontaneous voiding, uses native tissue, and affords a “pop-off” mechanism. The procedure does, however, reduce bladder capacity and may make the urethra difficult to catheterize. Further, catheterization may injure the continence mechanism and result in reconstructive failure.

The placement of an adjuvant Mitrofanoff neourethra in patients undergoing Young-Dees-Leadbetter bladder neck reconstruction allows a channel for intermittent catheterization, which has been useful for all such reconstructions.[58] With time, as the patient learns to void through the reconstructed urethra, the Mitrofanoff neourethra can be removed in a simple outpatient surgical procedure or, because it does not leak, it can be left in situ.

The Kropp procedure (Fig. 117-17) involves the creation of an extended length of urethra by tubularization of an anterior strip of bladder wall that is left in continuity with the urethra. This tube is then implanted suburothelially into the bladder.[59] This procedure allows reliable continence and uses native tissue. It can, however, lead to difficulty in catheterization. The Pippi Salle modification,[60] which uses an onlay detrusor strip (with preservation of the posterior bladder strip), may permit easier catheterization. Neither the Kropp tube nor the Salle

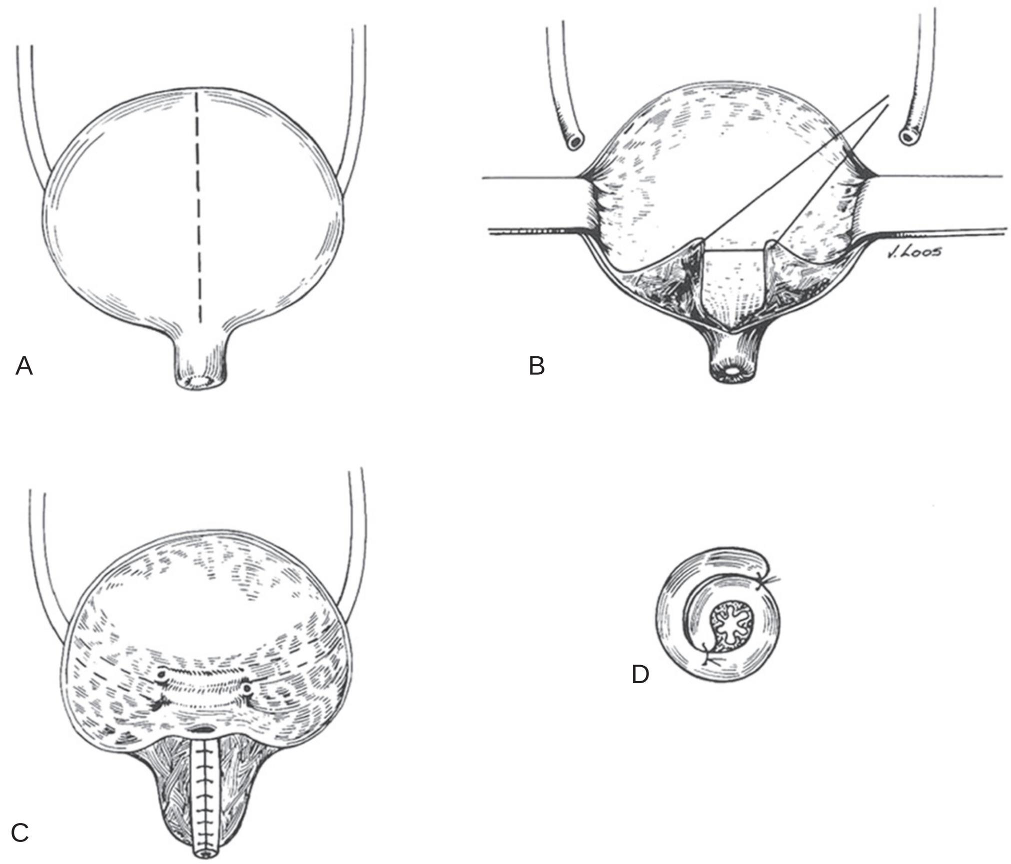

FIGURE 117-16 Young-Dees-Leadbetter bladder neck reconstruction. (From Sheldon CA, Bukowski TP: Bladder function. In Rowe MI, O'Neill JA, Jr., Grosfeld JL, et al, [eds]: Essentials of Pediatric Surgery. St Louis, Mosby-Year Book, 1995, p 742.)

onlay allows a "pop-off" mechanism; thus the potential for spontaneous voiding is eliminated and bladder capacity is reduced.

Another option for the creation of bladder outlet resistance is the fascial sling. A free fascial graft is frequently used; the graft may be placed transvaginally with an endoscopically assisted technique[61] or by open retrourethral dissection.[62] Alternatively, the fascial strip may be developed in such a way that it remains attached to the ipsilateral pyramidalis (Fig. 117-18).[63] The latter approach is particularly applicable to children who have a denervated but anatomically intact sphincteric mechanism and require concomitant bladder augmentation. These procedures are technically fast and relatively simple to perform, involve native tissue, and are readily reversible. They can also be used as an adjunct to the Young-Dees-Leadbetter procedure. Spontaneous voiding is possible if angulation is not excessive, and a "pop-off" mechanism is maintained. Excessive angulation may, however, interfere with spontaneous voiding or catheterization.

The artificial urinary sphincter (Fig. 117-19) has been shown to be effective for compressing the urethra and thus contributes to bladder outlet competence. The most popular model consists of a cuff placed around the bladder neck or bulbar urethra, a reservoir placed intra-abdominally, and an activating pressure bulb located in the scrotum or labia. Controlled pressure is maintained in the cuff until the pump is squeezed, transferring fluid from the cuff into the reservoir balloon and permitting bladder emptying to take place. A delay-fill resistor in the control mechanism provides 1 to 2 minutes of lowered intraurethral pressure before automatic refilling of the cuff takes place from the reservoir balloon. Pressure-regulating balloons of various pressure ranges are available, and a 60 to 70 cm $H_2O$ balloon is generally selected for pediatric reconstruction.[64]

Several series have documented the utility of the artificial urinary sphincter in patients who have bladder augmentation.[65–68] The advantage of this procedure is that it allows spontaneous voiding, but there are several disadvantages. Multiple mechanical problems have occurred in patients with the artificial sphincter in place. The most common problems have been fluid leaks from the cuff or tubing kinks requiring surgical revision. The most serious complications are erosion of the sphincter into the urethra or the development of infection around the cuff. The latter problems generally require removal of the device. Consequently the artificial sphincter is recommended primarily for those patients who have a chance of maintaining spontaneous voiding.

Finally, surgical urethral closure may be necessary. This is obviously a highly effective means of ensuring urethral continence but should be a last resort.[69,70] Simple oversewing of the mucosa at the level of the bladder neck is insufficient because recanalization occurs. Urethral division, which allows muscular approximation (proximally and distally), eliminates this risk. This procedure requires the placement of an alternate catheterizable conduit as discussed later. The advantages of this procedure are that it is definitive and technically simple. It does, however, place the patient at increased risk for bladder calculi and is difficult to reverse. In addition, the lack

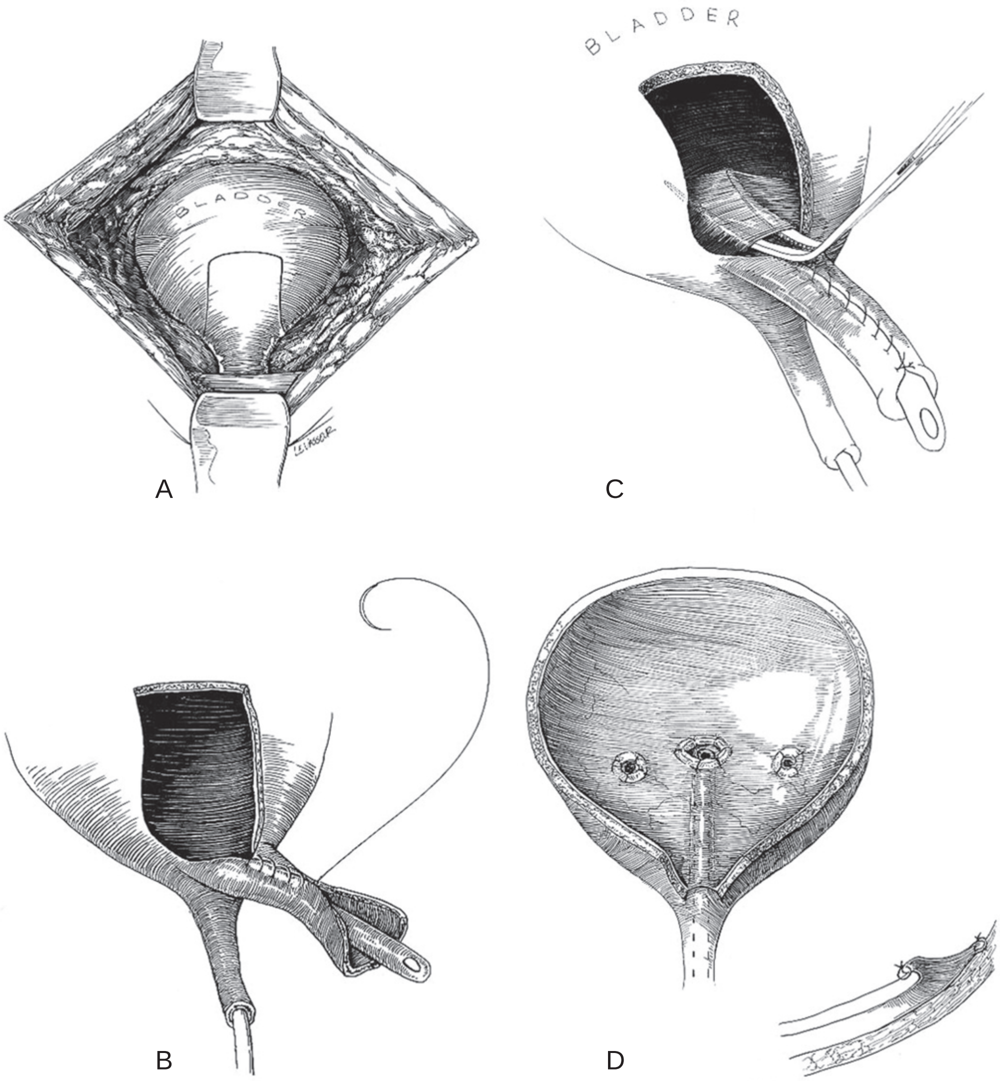

FIGURE 117-17 The Kropp procedure. A detrusor tube is created (anterior shown, posterior tube also possible) and tunneled submucosally in the bladder to create a competent flap valve. (From Minevich E, Sheldon CA: Urinary tract reconstruction for continence and renal preservation. In Ziegler MM, Azizkhan RG, Weber TR, et al [eds]: Operative Pediatric Surgery. Norwalk, Conn, Appleton & Lange, 2003. p 925.)

of a "pop-off" mechanism increases the risk for bladder rupture if the patient does not comply with regular catheterization to empty the bladder.

## Providing for Alternate Continent Urine Drainage

The procedures discussed in the preceding section require the creation of a continent catheterizable conduit that connects the bladder to the skin of the abdominal wall or perineum. An alternative to catheterization of the native urethra is indicated when a urethra is difficult to catheterize because of (1) tortuosity from either previous urethral surgery or congenital irregularity or (2) physical limitations of the patient that impede access to the native urethra. Procedures directed at urethral functional replacement are based on the creation of a tubular conduit of sufficient length that is exposed to external compressive forces, thereby providing outlet resistance that cannot be overcome by intravesical (intrareservoir) pressure. The success of these procedures in terms of continence relies on attaining controlled reservoir-neourethra balance. Neourethral resistance to reservoir outflow must be sufficient to exceed both resting and intermittently elevated intravesical pressure associated with gravity (upright posture), as well as episodic additive intra-abdominal pressure spikes (coughing, sneezing, straining, and sudden postural changes). The creation of neourethral resistance must be complemented by low intravesical (intrareservoir) pressure. This may entail bladder augmentation or replacement by bowel and should include reconfiguration by detubularization. A large capacity is imperative, as is intermittent catheter drainage before the low compliance portion of the reservoir's pressure-volume curve is entered.

Alternate techniques include those associated with a nipple valve (procedures involving the ileal-cecal junction or ileal-ileal intussusception) or those associated with a flap valve (Fig. 117-20). The nipple valve is inherently unstable because wall tension causes distraction of the base of this continence

mechanism over time, often resulting in a loss of effectiveness of the valve and thus incontinence. The flap valve mechanism is considerably more durable because the continence mechanism is a stable component of the reservoir wall.

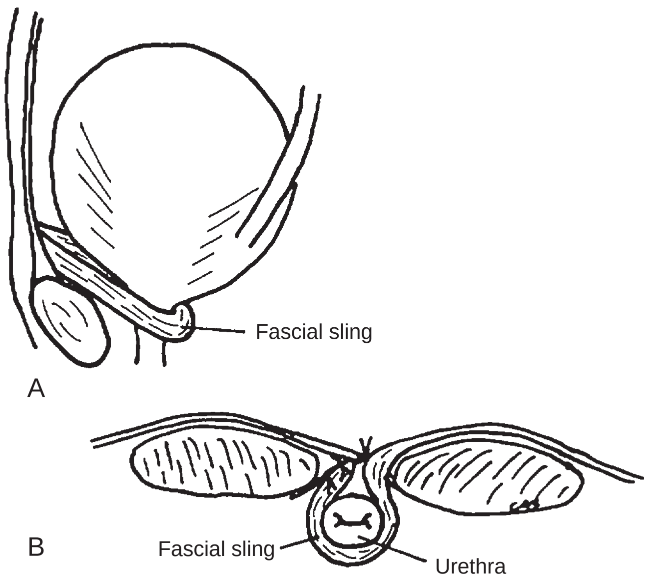

**FIGURE 117-18** Placement of a fascial sling to enhance bladder outlet competence. (From Sheldon CA: Urinary reconstruction (rather than diversion) for continence in difficult pediatric urologic disorders. Semin Pediatr Surg 1996;5:10.)

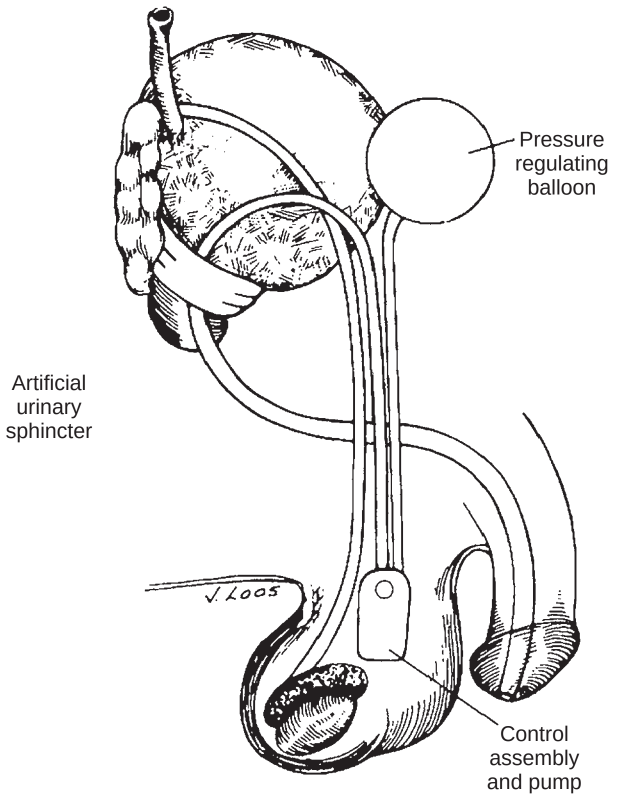

**FIGURE 117-19** Artificial urinary sphincter. (From Sheldon CA, Bukowski TP: Bladder function. In Rowe MI, O'Neill JA, Jr., Grosfeld JL, et al [ed]: Essentials of Pediatric Surgery. St Louis, Mosby-Year Book, 1995.)

The Mitrofanoff neourethra is an example of a flap valve mechanism that is particularly applicable to children.[71] In this procedure, a continent, catheterizable tubular conduit (neourethra) connecting the urinary bladder to the skin is achieved. This provides a one-way flap valve mechanism that permits a catheter to be easily passed into the bladder. The flap valve is also a secure mechanism to prevent incontinence (Fig. 117-21). The appendix, the most common type of Mitrofanoff tube used, is removed from its cecal origin and the appendiceal mesentery is preserved. A submucosal plane is developed in the bladder by either detrusor incision or cystotomy with creation of a long submucosal tunnel. The cecal end of the Mitrofanoff neourethra is exteriorized to the skin; a U-insertion flap technique is used to help minimize the risk for stomal stenosis. The Mitrofanoff neourethra concept has proven extremely versatile and has been implanted into the bladder, colon, and stomach with equal efficiency.[58,72] Multiple sites for exteriorization are possible including the lower abdomen, umbilicus, and perineum.[58] The versatility of this technique has been enhanced by extending the length of the appendix using tubularized cecum.[58,73,74] Mitrofanoff's concept and extension of these principles have permitted successful continent reconstruction of the lower urinary tract in a wide variety of situations.[71,75,76]

If the appendix is unavailable, a tapered segment of ileum (over a 12- to 14-French catheter) can be used, although currently a transverse retubularized segment of ileum is more commonly used.[71,77,78] The length of these ileovesicostomies is limited by the circumference of the bowel segment used, which is inadequate in some cases. Casale introduced a technique that allows a doubling in length of the continent conduit.[79] The ureter also provides a source for a Mitrofanoff conduit when available (this conduit can be created if nephrectomy had been or is being done or if a transureteroureterostomy is being performed).[80] Because an ileal conduit is readily constructed, a transureteroureterostomy is not recommended unless otherwise indicated. If the ureteral segment is refluxing, concomitant ureteral reimplantation may be required. Other continent, catheterizable mechanisms are available including the Benchekroun procedure,[81] the Indiana pouch,[33] the Kock pouch,[82] and the hemi-Kock.[83] Although used less commonly in children than the Mitrofanoff flap valve, they may prove useful in selected circumstances.

The most common complication of the Mitrofanoff conduit is that of stomal stenosis, requiring stomal revision.[76,84,85] Mitrofanoff neourethras that could not be negotiated or were lost due to ischemic necrosis were only rarely encountered.

## Interface with Fecal Incontinence

The urinary tract should not be reconstructed without consideration of anorectal function. Achievement of urinary continence in the patient who will still require a diaper for fecal incontinence can hardly be considered a success. Further, persistent fecal soilage may potentiate the risk of UTI and progressive deterioration of the reconstructed bladder and upper urinary tracts. Therapy for urinary continence can significantly compromise gastrointestinal function. For example,

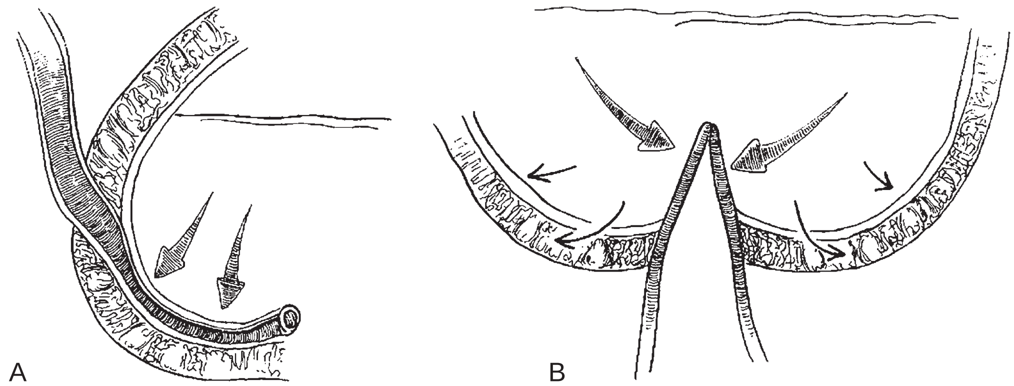

**FIGURE 117-20** **A,** Flap valves. **B,** Nipple valves. Nipple valves are continent because the nipple is circumferentially compressed by pressure within the reservoir. Unfortunately, the intrareservoir pressure also has a laterally destructive force on the base of the nipple, causing a shortening or total effacement of the valve with loss of the continence mechanism. Flap valves are continent because the submucosal segment is compressed by filling of the reservoir (as for a reimplanted ureter for vesicoureteral reflux). Unlike nipple valves, flap valves are stable because they are fixed to the wall of the reservoir. Thus reservoir filling does not tend to cause loss of the continence mechanism. (From Minevich E, Sheldon CA: Urinary tract reconstruction for continence and renal preservation. In Ziegler MM, Azizkhan RG, Weber TR, et al [eds]: Operative Pediatric Surgery. Norwalk, Conn, Appleton & Lange, 2003, p 928.)

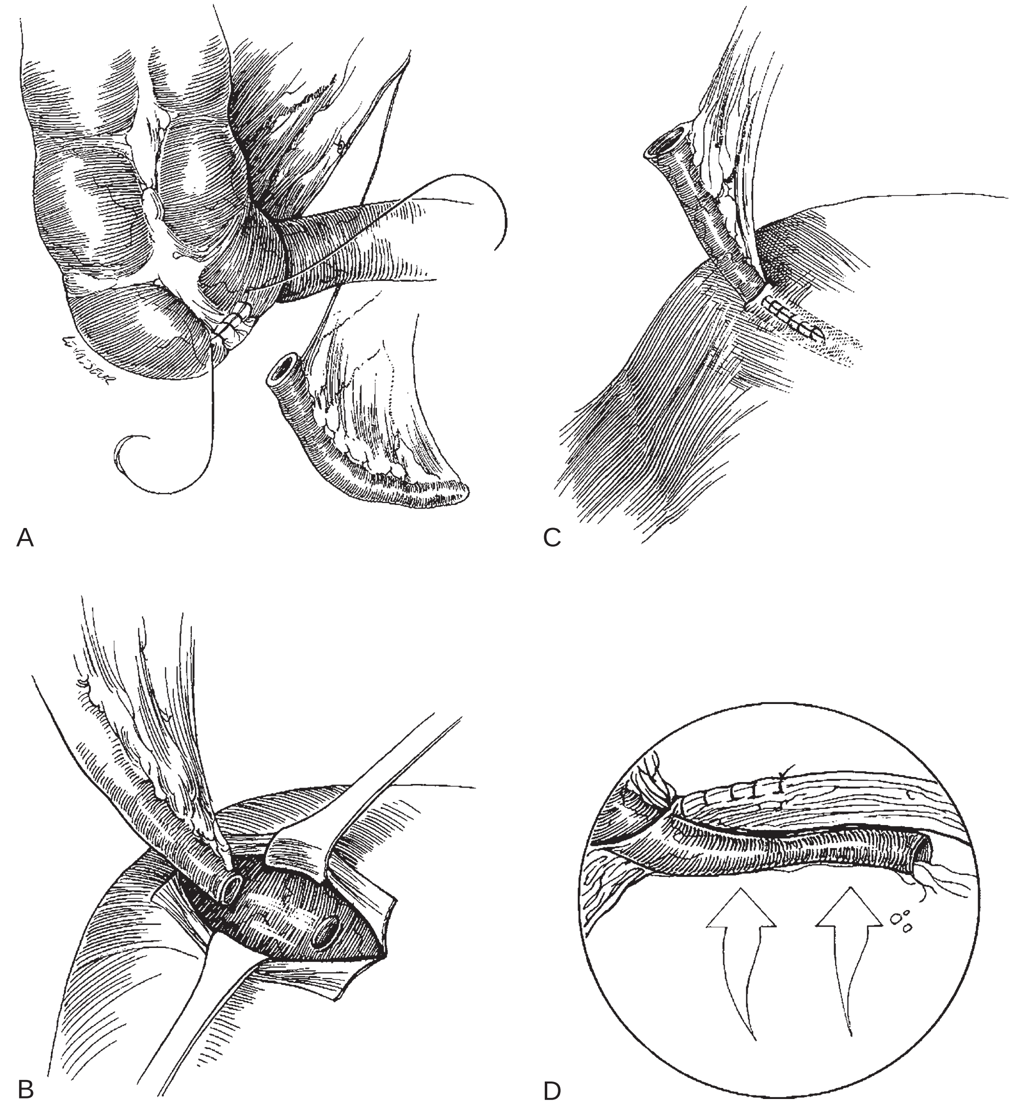

**FIGURE 117-21** Mitrofanoff procedure. **A,** The appendix has been mobilized on its mesentery, and cecal segment is closed. **B,** Extravesical dissection shows mucosal orifice in which the distal end of the appendix will be implanted. **C,** The detrusor is closed over implanted appendix, and its proximal end is then brought to the skin to serve as a catheterizable stoma. **D,** This diagram depicts the resulting continent flap-valve mechanism of the Mitrofanoff procedure; a rise in intravesical pressure compresses the conduit against the detrusor, thereby occluding its lumen and achieving continence. (From Minevich E, Sheldon CA: Urinary tract reconstruction for continence and renal preservation. In Ziegler MM, Azizkhan RG, Weber TR, et al [eds]: Operative Pediatric Surgery. Norwalk, Conn, Appleton & Lange, 2003, p 929.)

anticholinergic therapy may result in severe constipation, and ileocecocystoplasty may facilitate fecal incontinence.

The management of intractable fecal incontinence may be addressed at the time of urinary reconstruction and thus should be evaluated before this undertaking. Because most patients can be managed nonsurgically by dietary restrictions, bulking agents, behavior modification, and expansion enemas, an exhaustive trial of these interventions should be undertaken before surgical reconstruction. In the patient who is refractory to these treatments, the antegrade continence enema (Fig. 117-22) has been shown to be an excellent alternative.[86–89] This procedure is indicated when nonoperative management is ineffective or when expansion enemas prove effective but cannot be administered by the patient.[90]

The technique is similar to the Mitrofanoff neourethra. The appendix or a retubularized ileal segment[91] is implanted into a tenia in the cecum, and the other end is exteriorized to skin. The appendix or ileal segment is prepared in a manner identical to that described for the Mitrofanoff procedure. An incision is made along the anterior tenia of the cecum; an anastomosis is performed between it and the conduit; and a mucosal defect is created distally in the mucosal trough. The muscle is covered over the conduit while the other end is exteriorized to skin. Once daily a catheter is inserted into the continent cecostomy while the patient sits on the commode. An antegrade enema consisting of tap water and table salt is administered by gravity flow. If this is unsuccessful, additives of mineral oil, polyethylene glycol (MiraLax), or glycerin can be added to the irrigant daily.[92]

## Urinary Reconstruction and End-Stage Renal Disease

Congenital urologic disease is reported to occur in 20% to 30% of pediatric end-stage renal disease patients.[5,93] The adverse effects of congenital urologic disease on the success of

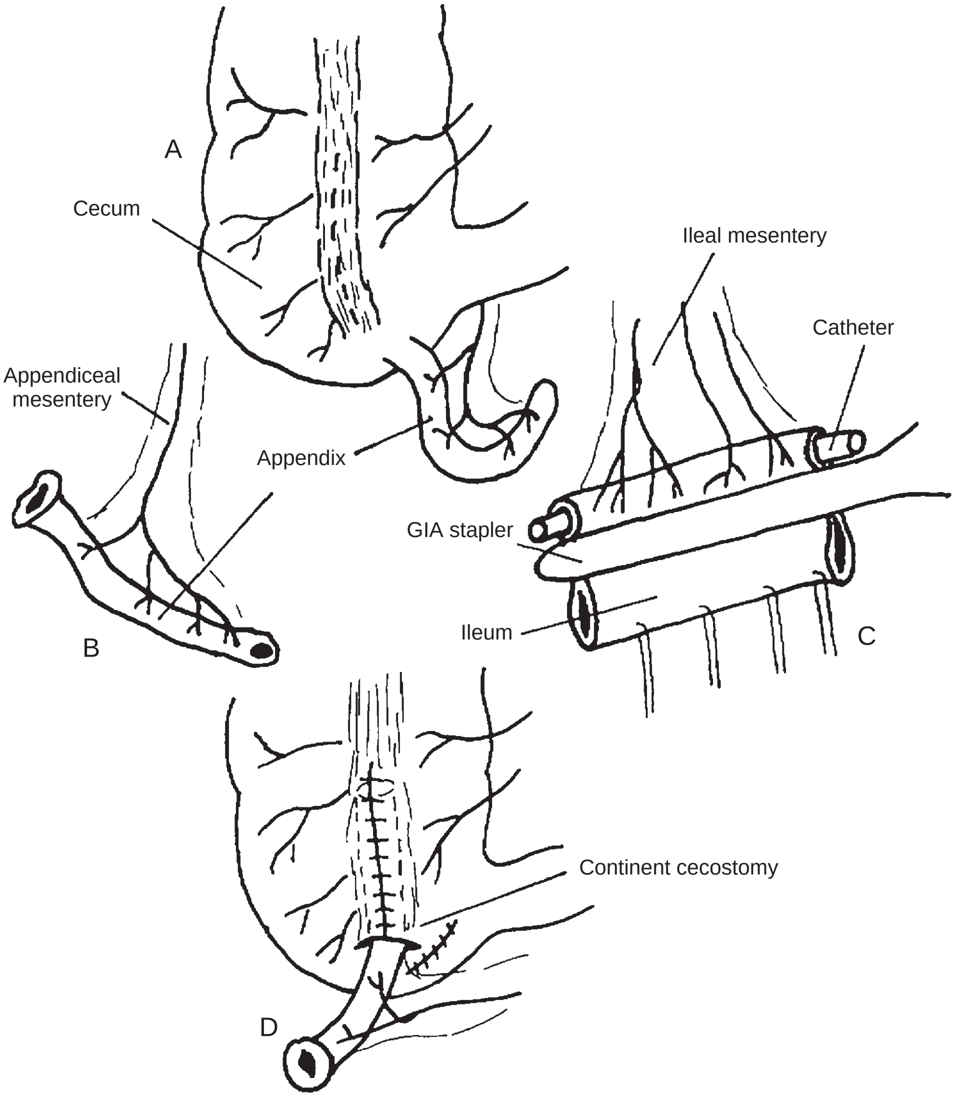

**FIGURE 117-22** Technique for performing continent cecostomy for antegrade continence enema. **A,** Anatomy of the appendix and the anterior cecal tenia. **B,** Appendix is mobilized on its vascular pedicle. **C,** Alternatively, a segment of ileum is tapered and mobilized on its vascular pedicle. **D,** Final appearance of continent cecostomy. renal transplantation are demonstrated by the increased incidence of UTI, allograft dysfunction, technical complications, and graft loss in such patients. UTI can be particularly deleterious to both graft and recipient in the face of immunosuppression. The risk of UTI is higher in transplant recipients with posterior urethral valves as the etiology of their renal failure.[94,95] An analogous problem is seen in patients whose primary disease is vesicoureteral reflux and who continue to have reflux into the native kidneys at the time of transplantation.[96]

These data demonstrate that patients with a history of significant urologic disease must be extensively evaluated before transplantation.[97] Significant vesicoureteral reflux should be resolved either by ureteral reimplantation or nephrectomy. Whenever possible, nephrectomy is avoided to allow the production of urine output so that a functionalized bladder is maintained and dialysis therapy is still an option, either before transplantation or after, should the graft fail. Any endogenous erythropoietin production will be maintained, and this may help avoid presensitization from frequent transfusions. In addition, the ureters are preserved, which may be necessary for subsequent transplant reconstruction should a ureteral complication occur. Indications for nephrectomy include the presence of recurrent UTIs, UTI-prone upper tract anatomy, refractory hypertension, severe proteinuria, and severe polyuria.

When necessary, nephrectomy is performed via lateral flank incisions or dorsal lumbotomy incisions, through which the peritoneal cavity is rarely, if ever, entered. Such procedures can be performed without interrupting peritoneal dialysis. Alternatively, a laparoscopic approach is applicable. If bilateral nephrectomy is considered necessary and preemptive (to avoid dialysis) transplantation is desired, one may remove the worst-functioning kidney first, and if the second kidney provides adequate function, dialysis can be avoided. At the time of transplantation the remaining kidney can be removed via the transplant incision.

Elevated intravesical pressure must be stabilized by either pharmacologic measures or intermittent catheterization (or both) and, when necessary, augmentation cystoplasty. When undertaking pretransplant surgery it is important to plan the surgical incision so that it minimizes interference with current or anticipated peritoneal dialysis, as well as the subsequent transplantation itself. The best means for avoiding loss of access to the peritoneal cavity for purposes of dialysis is an extraperitoneal approach to the urinary tract, which can readily be achieved for nephrectomy and ureteral reimplantation.

Surgical reconstruction of a dysfunctional bladder can be successfully performed and has been demonstrated to allow transplantation with acceptable results.[98,99] Such an approach allows optimal allograft preservation and appliance-free continence and is preferable to the alternative of transplantation into an intestinal conduit. Transplantation is applicable to even the most anatomically complicated child with end-stage renal failure.[100,101] The principles of transplantation into a reconstructed bladder include the following: (1) Avoid a dry reconstruction. The capacity and compliance of a reconstructed bladder can be lost if the interval to transplantation is long. This can be avoided by undiversion of native kidneys (if present) or by using a living-related donor allograft where timing can be optimized. (2) The risk of reabsorptive acidosis occurring either before transplantation, with drainage of the native kidneys into the reconstructed bladder, or after transplantation if the allograft fails over time can be minimized by avoiding the use of intestine and colon for bladder reconstruction. Specifically, gastrocystoplasty, augmentation with the ureter and pelvis, and autoaugmentation all have the potential for minimizing reabsorptive acidosis. (3) Autoaugmentation and augmentation using the ureter have the potential for being performed retroperitoneally, thereby avoiding interference with present or future peritoneal dialysis or with ventricular peritoneal shunts. (4) Whenever possible, ureteral implantation into the native bladder is preferable. If not possible, the colon, an ileocecal segment, or the stomach is the only source of augmentation tissue that will permit reliable antirefluxing anastomosis. (5) During the performance of such transplantations, the blood supply of the augmented bladder and any associated Mitrofanoff neourethra must be meticulously identified and preserved.

# Complications

## ACUTE ABDOMINAL SURGICAL ILLNESS

Acute abdominal surgical illness is a grave concern in the patient who has undergone urinary tract reconstruction, particularly when associated with bladder augmentation or creation of an intestinal reservoir. The most common causes of an acute surgical abdomen in this setting are perforation of the augmented bladder or intestinal reservoir or small bowel obstruction. Even though the etiology remains conjectural, the majority of perforations have been associated with augmentation of a remnant of neurogenic bladder.[102] More than two thirds of such patients have been on intermittent catheterization, and total continence appears to be a common factor. Although the clinical findings are usually those of an acute abdomen, the symptoms may be quite nonspecific and a high index of suspicion is essential. It is important to be aware of the fact that the rupture may occur many years after reconstruction. Altered sensation in patients with dysraphic states or spinal cord injury and steroid administration in renal transplant patients may confound the diagnosis. In establishing the diagnosis a cystogram is essential but is associated with a significant false-negative rate.[103,104] A computed axial tomographic study of the abdomen (with contrast in the bladder or reservoir) may be the most accurate method of making the diagnosis. However, any patient with an augmented bladder on intermittent catheterization who has abdominal pain, fever, or vomiting should be presumed to have a bladder perforation unless the symptoms can be conclusively attributed to another etiology. Exploratory laparotomy may be required to make the diagnosis. Less common, but important, etiologies of the acute abdomen include small bowel obstruction, pseudomembranous enterocolitis, toxic shock syndrome, and ventricular-peritoneal shunt complications.[37]

The performance of laparotomy following urinary tract reconstruction is of critical concern. Certainly, elective laparotomy should be preceded by formal bowel preparation in the face of augmentation or continent diversion. The surgeon should have access to a catheter in the bladder to allow insufflation and deflation for identification purposes, and a catheter should be placed in any catheterization conduit

such as a Mitrofanoff neourethra. Efforts must be directed at identification and preservation of mesenteric blood supply to any gastric or intestinal segments used in reconstruction. Whenever possible, an experienced reconstructive urologist should be present.

## METABOLIC COMPLICATIONS

Metabolic alterations may be encountered when gastrointestinal segments are incorporated into the urinary tract.[105,106] These metabolic derangements are due to solute flux, both active and passive, between the urine and blood across the gastrointestinal segment wall. The character and severity of such derangements depend on the nature of the segment used, the absorptive surface area, the dwell time, and the metabolic reserve of the individual patient. Compensatory mechanisms for metabolic changes are provided by the kidneys, liver, and lungs. Significantly compromised function of any of these organ systems may exacerbate an underlying metabolic defect. Syndromes include alterations in acid-base status, disorders of serum electrolyte composition, hyperammonemia, and bone demineralization.

Systemic acidosis may result from the incorporation of jejunal, ileal, or colonic segments into the urinary tract. Jejunal conduits have been found to be associated with acidosis in 20% to 40% of instances.[107,108] In the jejunum, passive diffusion of solutes occurs along their concentration gradients. The passage of hypertonic urine into a jejunal segment will result in a loss of sodium, chloride, and water, resulting in hyponatremia, hypochloremia, and volume contraction, with subsequent contraction acidosis.[109] Additionally, diminished renal blood flow results in secondary hyperaldosteronism, resulting in a more hypertonic urine and hyperkalemia. The latter is further aggravated by the potassium shift as a result of acidosis.

The metabolic consequences of interposing ileal and colonic segments within the urinary tract relate to the active secretion of sodium (in exchange for hydrogen) and bicarbonate (in exchange for chloride), as well as the reabsorption of ammonium, hydrogen, and chloride. Ammonium absorption appears to be quantitatively the most important, explaining many of the abnormalities encountered when ileal or colonic segments have an interface with urine. Hydrogen ion, generated from ammonium, is buffered by serum bicarbonate producing water and $CO_2$. The latter is readily eliminated by the lungs and results in a chronic compensatory respiratory alkalosis. Additional buffering is provided by bone, resulting in a variable degree of demineralization and secondary hyperparathyroidism. This is manifest by hypercalciuria, hyperphosphaturia, hyperoxaluria, hypocitraturia, hypocalcemia, and hypomagnesemia. Osmotic diuresis and acidosis combine to result in total-body potassium depletion.

Metabolic alkalosis is a unique complication of gastrocystoplasty. Though uncommon,[42] hypokalemic-hypochloremic metabolic alkalosis has been reported.[110,111] Excessive bicarbonate absorption is postulated to occur secondary to the combination of mineralocorticoid excess and potassium/chloride depletion.

Hypokalemia, hypocalcemia, and hypomagnesemia are significant potential sequelae of incorporating intestinal segments within the urinary tract.[106] Sufficiently severe hypokalemia to result in muscular paralysis has been reported. Although hypocalcemia is rarely severe enough to be symptomatic, it may present with irritability, tremors, tetany, and coma and may even prove fatal. Hypomagnesemia is also rarely severe enough to be symptomatic, but it may be manifested as altered sensorium, personality changes, delirium, psychosis, weakness, tremors, tetany, and seizures and may likewise be fatal.

Hyperammonemia complicating urinary tract reconstruction with intestine may cause altered sensoria and coma. As previously noted, ammonium ions are actively absorbed from intestinal segments and may be present in large amounts in urine because of their generation by renal tubules and production from urea by urea-splitting organisms.

Perhaps the most overriding concern of incorporating intestinal segments is the effect on childhood growth and development. Several studies have provided data strongly suggestive of defective linear growth in such cases.[112,113] This concern is particularly worrisome in patients with diminished renal function. Here, the metabolic insult is more likely and more severe because growth and development are often already significantly impaired.

Strong evidence exists for a primary effect of incorporating intestinal segments into the urinary tract on bone mineralization.[114] Metabolic acidosis results in defects in bone mineralization, bone disease, and linear growth failure through decreased renal tubular calcium reabsorption, depressed intestinal absorption of calcium and phosphorus, and vitamin D metabolism. Treatment with alkalinizing agents has been partially successful in preventing or reversing demineralization disease.

## HEMATURIA-DYSURIA SYNDROME

Although rare in our own experience[42] the hematuria-dysuria syndrome is an important complication of bladder reconstruction using stomach.[115] This syndrome is characterized by severe pain and urinary bleeding as a result of urothelial erosion from acid secreted in the urine after gastrocystoplasty.[116] Endoscopic evaluation of children with the hematuria-dysuria syndrome suggests greater involvement of the urethra than the bladder itself. Three major factors appear to be of importance in the genesis of this complication: acid hypersecretion, profound oliguria,[41] and bladder neck incompetency. True acid hypersecretion appears to be quite rare and, presumably, the predominant mechanism for this would be hypergastrinemia that has been reported in some instances.[117] $H_2$ receptor blockers and proton-pump inhibitors such as omeprazole have been shown to be reasonably effective in this syndrome.

## ALTERED GASTROINTESTINAL FUNCTION

The incorporation of intestinal segments into the urinary tract may result in significant alterations in gastrointestinal tract function. Alterations in gastric function have been reported following gastrocystoplasty.[118] Functional alterations reported include weight loss, feeding intolerance, dumping syndrome, delayed gastric emptying, and esophagitis. Our own review of gastrocystoplasty with emphasis on long-term follow-up (minimum follow-up of 5 years) failed to demonstrate any significant incidence of altered gastric function or altered acid base status in 44 consecutive patients.[42] Technical emphasis must be placed on avoiding the vagus nerves, avoiding significant dissection in the region of the gastric pylorus, and

avoiding traction-distortion of the angle of His (e.g., by gastrostomy tube), which may predispose to gastroesophageal junction incompetence.

Several potentially important sequelae of intestinal malabsorption may accompany intestinal resection including diarrhea, vitamin deficiency, and fecal incontinence. Diarrhea is most frequently a result of alterations in bacterial colonization and impairment of bile acid reabsorption (with or without accompanying steatorrhea).[119] Malabsorption from ileal resection is directly related to the length of resection. Resections of greater than 100 cm of ileum (adult equivalent) diminish bile acid reabsorption to a degree that cannot be compensated by increased hepatic synthesis. As a result, the bile salt pool is diminished and steatorrhea develops. Another important sequela of the diminished bile salt pool in this population is cholelithiasis, which, like urolithiasis, is clinically seen at a significantly increased incidence following ileal resection. Diarrhea induced by altered bile acid reabsorption (with or without accompanying steatorrhea) is further enhanced by the rapid emptying of ileal contents into the colon, causing a tendency for osmotic diarrhea.

Although most of the data involve adult patients, it is estimated that 10% of children undergoing resection of ileocecal valve segments will experience chronic diarrhea. This may be resolved after restoring intestinal continuity by returning the ileocecal segment to its normal position within the gastrointestinal tract.[120]

Despite these data, the use of intestinal and gastric segments appears to be extremely well tolerated in most children. It would, however, appear prudent to avoid the removal of large segments of ileum or removal of the ileocecal valve for purposes of urinary reconstruction, particularly in those already compromised. Such patients include those with preexisting malabsorption or short-gut syndromes and patients with marginal fecal continence, in whom fecal soilage may become incapacitating by loss of stool consistency. The latter patients include those with myelomeningocele and imperforate anus, who commonly require urinary tract reconstruction.

## MALIGNANCY

A majority of our understanding of urointestinal malignancy following reconstruction comes from the experience with ureterosigmoidostomy.[121,122] The incidence of malignancy developing in conduits and continent diversion has been comparably small.[123–125] In most cases there is a long interval between surgery and the onset of cancer. This latency interval has several important implications: A carcinogenic effect is clearly implied. Moreover, there is a potential for early surveillance diagnosis. Clearly, long-term follow-up is mandatory.

CHAPTER 118

# Incontinent and Continent Urinary Diversion

Audrey C. Rhee, Elizabeth B. Yerkes, and Richard C. Rink

Urinary diversion can be either incontinent or continent. With incontinent diversion the reservoir is external to the body (ostomy bag or diaper in children) and is emptied routinely when full. With continent urinary diversion the urinary reservoir is routinely emptied by clean intermittent catheterization (CIC). Classically when the reservoir has been made entirely of gastrointestinal segments, it has been known as a *continent urinary diversion* (CUR). In children, the primary diagnoses requiring urinary reconstruction are spinal dysraphism, exstrophy, posterior urethral valves, or complex cloacal anomalies. In these disorders, the diseased native bladder can be incorporated into the reconstruction so that true CURs are rare in children. However, most will require intestinocystoplasty and a catheterizable abdominal wall channel and therefore they are "continent reservoirs" and are considered as such in this chapter. The term *undiversion* used in this chapter previously refers to the situation in which a child was previously treated with an incontinent urinary diversion and is converted to a continent diversion. Due to the infrequency of this situation, it is not covered in this chapter.

Historically permanent incontinent urinary diversion was used to protect the kidneys from the deleterious effects of increased bladder and renal storage pressures or to manage urinary incontinence. In more contemporary practice, medical management of bladder dysfunction with CIC[1] and anticholinergic agents has limited the indications for surgical intervention. Urodynamic expertise has allowed identification and aggressive management of the high-risk patients.[2] The development of surgical techniques to allow storage of urine at safe pressures has virtually eliminated the use of permanent forms of incontinent urinary diversion, but this still remains an appropriate option for some patients. Temporary diversion is still required for select patients but is rarely first-line management for the bladder or the upper urinary tract.

## Incontinent Urinary Diversion

Although eventual urinary continence is desirable for all children, protection of the integrity of the upper urinary tract is the primary concern. Several forms of incontinent urinary diversion are still occasionally used on either a temporary or permanent basis to prevent upper urinary tract deterioration or to simplify day-to-day care of patients with limited capability for self-care.

Temporary urinary diversion is most commonly performed in infants or very young children, and the urine is easily collected in the diaper. Most permanent incontinent diversions require an ostomy appliance for hygienic collection of the urine. Compared with the alternative of continence by clean intermittent catheterization, the incontinent stoma carries a stigma and body image issues that are better avoided in the pediatric population. For select patients and families, however, this remains a reasonable option.

### CUTANEOUS VESICOSTOMY

Cutaneous vesicostomy is the most common form of incontinent urinary diversion in children today, but it is rarely used as first-line therapy and has limited indications. Infants with a neuropathic bladder and unsafe storage pressures may require a vesicostomy if CIC and anticholinergic medications fail or if the family is unable or unwilling to execute these medical measures. Inability to incise posterior urethral valves safely due to the small urethral caliber in some premature infants is another indication for cutaneous vesicostomy. In these patients the vesicostomy is closed when the child has grown enough for incision of the valves. Young infants with high-grade vesicoureteral reflux and multiple breakthrough urinary tract infections on antibiotic prophylaxis may benefit from vesicostomy.[3–4] Improvement in the efficiency of both bladder and upper tract drainage reduces the incidence of urinary infection. In persistent cloaca refractory hydronephrosis, hydrocolpos or urinary infection despite intermittent catheterization of the common channel is another uncommon indication for vesicostomy.[5]

Ideally the vesicostomy provides low-pressure drainage of the bladder contents with minimal residual volume. Multiple series have confirmed the benefits of vesicostomy.[3–4,6–9] Improvement in upper urinary tract dilation and stabilization or improvement of renal function is achieved. Reflux may

resolve, or the degree of ureteral dilation may improve enough that ureteral tapering is not required at the time of reimplantation.[3–4] Although bacterial colonization of the open system is common, symptomatic infections and urosepsis are reduced. One concern about prolonged vesicostomy drainage in the non-neuropathic population is failure of the bladder to develop normally in the absence of cyclic filling and emptying.[10–11] Several studies have refuted this concern.[4,12–13]

Once the urinary tract is stabilized and the long-term potential of the bladder becomes clearer, the vesicostomy is easily closed. It may be closed primarily or in combination with continent diversion. Some patients and families are not appropriate candidates for vesicostomy closure or find that vesicostomy and diaper drainage is an acceptable low-maintenance permanent option. Vesicostomy, with or without the use of an ostomy appliance, can also be performed in adult patients who are not candidates for continent diversion.[9]

Two techniques for cutaneous vesicostomy have been used for many years. Lapides described elevation of an anterior bladder wall flap with deep insertion of an abdominal skin flap to fashion the cutaneous vesicostomy.[14] The more common technique was described by Blocksom in 1957[15] and modified by Duckett (Fig. 118-1).[16] The Blocksom vesicostomy is fashioned through a small transverse incision halfway between the umbilicus and the pubis. The fascia is incised, and the peritoneum is pushed superiorly off the dome of the bladder. The urachal remnant is divided, and the dome of the bladder is pulled up to the skin. The fascia is secured to the bladder wall to form a 24-Fr defect, and the bladder is matured as a flush stoma.

Complications of cutaneous vesicostomy include stomal stenosis, prolapse, peristomal dermatitis, and bladder calculi. Stomal stenosis is more common with a stiff or thick bladder wall as in posterior urethral valves. Failure to fashion the vesicostomy from the dome of the bladder may allow the posterior bladder wall to prolapse through the vesicostomy. This is one advantage of the Blocksom technique over the Lapides vesicostomy. Prolapse is managed by manual reduction with temporary catheter drainage and revision of the low vesicostomy. Dermatitis is particularly bothersome in some patients and is managed with application of a zinc oxide barrier cream or topical treatment for obvious candidiasis. Bladder calculi are unusual provided that the vesicostomy is functioning well and the upper tracts are drained.

## CUTANEOUS URETEROSTOMY

Ureterostomy for temporary supravesical urinary diversion is rarely performed today. It has been used historically for drainage of a profoundly dilated upper urinary tract in the face of urosepsis[17] or to maximize drainage of the renal units in cases of severe obstruction. Percutaneous or endourologic drainage of these systems is possible now in children, but tube size limits the utility of this in very small infants.[18] Low diversion can be performed as a loop or end cutaneous ureterostomy (Figs. 118-2 and 118-3), and subsequent takedown involves ureteroneocystostomy. The diversion allows the caliber of the ureter to decrease, thereby reducing the complexity of the reimplantation. Diversion at the level of the kidney is performed through a flank incision and can be performed as a

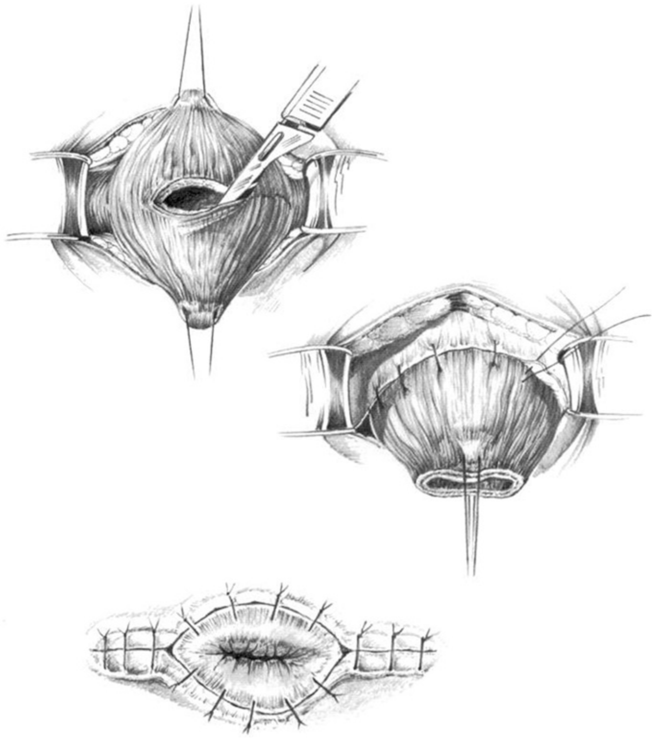

**FIGURE 118-1** The Blocksom vesicostomy, showing the incision in the dome of the bladder, the fixation to the overlying fascia, and the everted stoma.

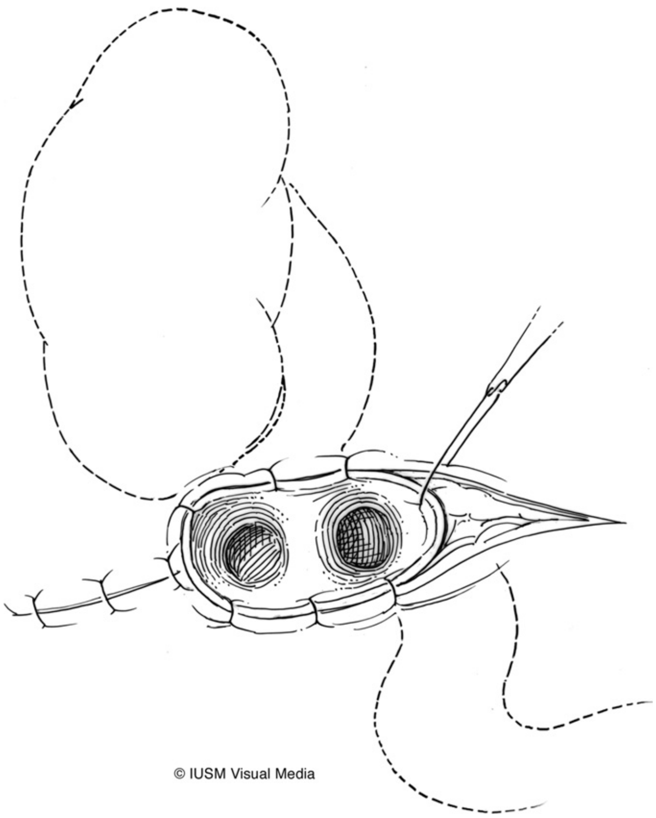

**FIGURE 118-2** The loop ureterostomy is easily taken down and therefore allows for an excellent temporary diversion.

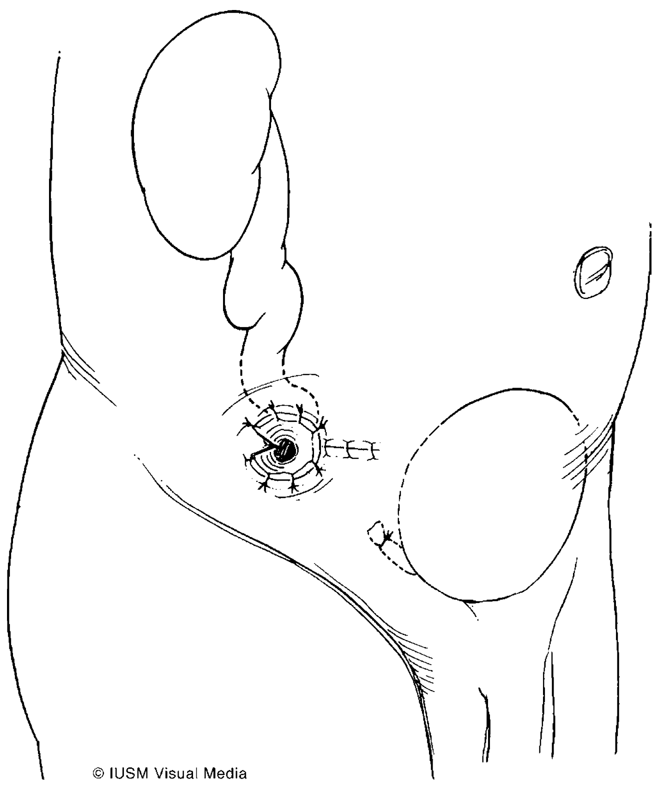

FIGURE 118-3 The end ureterostomy requires formal reimplantation to reverse.

loop ureterostomy, Sober ureterostomy, or end ureterostomy. A loop ureterostomy can easily be taken down and is the more appropriate choice for temporary diversion. End ureterostomy just below the ureteropelvic junction makes reconstitution of the ureter more difficult and should be reserved as a rare permanent form of diversion in cases of severe bladder dysfunction.[18] Sober ureterostomy, with its proximal diverting limb and reanastomosis of the distal limb to the renal pelvis, is rarely used today and is technically much more involved and may therefore be less appropriate for diversion during acute illness. On the other hand, it offers the advantage of diversion and continued antegrade drainage to cycle the bladder.[19] In all cases, care should be taken to preserve the medial blood supply and adventitial vessels and to create a tension-free anastomosis to the skin. Given the profoundly dilated nature of the ureter in most of these cases, stomal stenosis is rarely an issue.

Supravesical diversion may be warranted in select posterior urethral valve patients when renal function fails to improve after bladder drainage.[19] Persistent ureterovesical junction obstruction is the concern. Ureterostomy and pyelostomy would maximize upper tract drainage, but percutaneous nephrostomy is a less invasive temporary means to assess the potential of the affected kidney.[20] Patients who demonstrate improvement in renal function after supravesical diversion may do so because of better drainage or just due to normal renal maturation.[21] As with cutaneous vesicostomy, there is concern that the valve bladder will fail to develop normally if the urine is diverted. In patients with a solitary functioning kidney, a loop ureterostomy or an end ureterostomy would defunctionalize the bladder. Several studies suggest that bladder dysfunction is due to bladder wall abnormalities from infravesical obstruction rather than supravesical diversion of urine.[13,22]

Another method to treat distal ureteral obstruction is creation of a freely refluxing end-to-side or side-to-side ureteral reimplant.[23] This alternative approach, while obviating the continual drainage of urine via a cutaneous stoma, remains controversial.

## CUTANEOUS PYELOSTOMY

As with cutaneous ureterostomy, proximal diversion by pyelostomy has limited indications in current practice. The controversies surrounding this type of diversion are similar. With direct drainage of the renal pelvis, pyelostomy may be used for temporary diversion in select cases of obstruction at the ureteropelvic junction but could also be used as discussed earlier for posterior urethral valves. Pyelostomy requires a dilated extrarenal pelvis to create a tension-free anastomosis to the skin. Takedown of the pyelostomy at the time of a definitive procedure is relatively simple due to reliable blood supply to the renal pelvis.

## ILEAL CONDUIT/COLON CONDUIT

Permanent supravesical urinary diversion was popular many decades ago as reliable means to manage neuropathic bladder, bladder outlet obstruction, and severe urinary incontinence. Conduit diversions have been created with most intestinal segments, although the ileum (Fig. 118-4) and colon are used most commonly. Both simple refluxing and tunneled nonrefluxing ureterointestinal anastomoses have been used. The primary advantage of the colon conduit over an ileal conduit is the reliable antireflux reimplantation achievable with colon.

The risk of upper tract deterioration after ileal conduit diversion has exceeded 50% in some series.[24–26] Although this is not a tremendous concern in the older patient after cystectomy for bladder carcinoma, the long-term impact on the kidneys is extremely relevant in the pediatric population. The ability to create a nonrefluxing anastomosis between the ureter

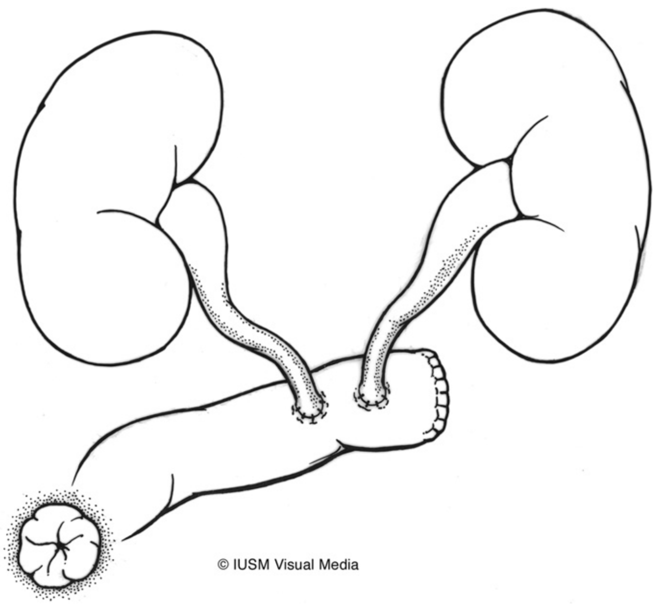

FIGURE 118-4 The ileal conduit is the standard permanent supravesical diversion for patients whose bladder is absent.

and colon gives colon conduits a theoretical advantage over ileal conduits. Unfortunately, deterioration of the upper tracts occurs in 26% to 48% of cases and ureteral reflux persists in 8% to 58% of colon conduits.[27] Anastomotic stricture occurs with similar frequency with ileum and colon (9% to 22%).[24,27]

Koch and colleagues[24] compared a cohort of myelomeningocele patients with ileal conduit diversion to another group managed with CIC. The ileal conduit group suffered renal deterioration, nephrolithiasis, and pyelonephritis significantly more than the catheterization group. Bone density was decreased in both groups and the incidence of fractures was equal, but the diversion group had impaired linear growth, more spinal curvature, and more complications from orthopedic procedures. The metabolic alterations associated with incorporation of intestinal segments into the urinary tract do occur with incontinent diversions.[24]

Other complications of conduit diversion included stomal stenosis, stomal prolapse, peristomal hernia, and peristomal dermatitis. Stomal stenosis occurred in 8% to 61% of cases. Stoma complications are best prevented with careful surgical technique including preservation of intestinal perfusion, creation of a straight and adequate caliber fascial window, and fixation of the conduit to the fascia. A protuberant rosebud stoma enhances the fit of the stoma appliance and prevents stenosis.

Bacteriuria is nearly universal but does not cause upper tract damage if the ureterointestinal anastomosis and the conduit itself function appropriately.[27–28] Stasis of colonized urine, however, may contribute to upper tract stone formation and may have other implications as well. Nitrosamines produced by the mixture of urine and bacteria appear to have some role in induction of malignancy in the isolated intestinal segment.[27,29]

Austen recently reviewed the world literature and identified 81 tumors collectively in a variety of continent and incontinent diversions with incorporated bowel segments. This total is exclusive of the large number of malignancies reported after ureterosigmoidostomy. Neoplasia was reported in 12 ileal conduits and 5 colon conduits with a mean latency of 22 and 10 years, respectively. Colon conduit tumors were exclusively adenocarcinoma, but transitional cell carcinoma, squamous cell carcinoma, and carcinoid and anaplastic tumors were also found in ileal conduits. Chronic inflammation of the intestinal segment may play a role in the malignant changes. Early yearly surveillance for tumor is recommended.[30]

Preoperative preparation for conduit diversion involves a full mechanical and antibiotic bowel preparation and parenteral antibiotic to sterilize the urine on the day before surgery. Patients with severe neuropathic bowel may actually require more than one day of preparation for adequate cleanout. It is critical that an enterostomal therapist mark potential stoma sites bilaterally after examining the patient in multiple positions. The abdominal contour can change significantly in myelomeningocele patients when seated, and an ill-fitting ostomy appliance will be a lasting source of dissatisfaction.

### INCONTINENT ILEOVESICOSTOMY

Incontinent ileovesicostomy, initially described by McGuire and colleagues in 1994,[31] has primarily been used in the adult population with bladder and sphincter dysfunction secondary to spinal cord injury and multiple sclerosis. Patients had failed other efforts to manage the bladder pressures and urinary incontinence and refused or were not candidates for continent diversion. Many suffered severe complications from use of a chronic indwelling urethral catheter. Several series report excellent results with regard to preservation of renal function, incidence of urinary tract infection and urolithiasis, and stomal complications.[32–35] The ileovesicostomy functions as a pop-off valve to maintain safe bladder storage pressures. Stomal leak-point pressures are low, and a moderate residual urine remains.[35]

Incontinent ileovesicostomy is an option to consider in select pediatric patients with limited dexterity and social support. Although it does require a permanent stoma, preservation of renal function appears superior when compared with standard conduit diversion. In addition, the disruption of the ureterovesical junction is not required. Parents may have difficulty accepting permanent diversion even if the child has limited potential to perform self-catheterization in the future. Some families are not ready to assume the care required for bladder augmentation or continent urinary reservoir, despite the fact that the child needs reconstruction to preserve the upper urinary tracts. In these instances, incontinent ileovesicostomy with both an efferent incontinent limb and a large open patch of ileum to augment the bladder can be considered. Consideration could be given to creation of a Mitrofanoff catheterizable channel at the time of the initial procedure. Should the family later embrace continence and the long-term care of bladder augmentation, the ileal chimney can be amputated to leave a continent diversion.[36]

Thorough preoperative bowel preparation and sterilization of the urine are required. A stoma site is carefully preplanned for the right lower quadrant to ensure optimal fit of the stoma appliance. The bladder is bivalved in the coronal plane in preparation for anastomosis to the isolated ileal segment. The proximal end of the ileum is opened widely on its antimesenteric border and anastomosed to the bladder in a running fashion. The length of the ileal segment can be tailored to account for body habitus and for the need to augment the native bladder capacity.[32] A rosebud stoma is fashioned in the right lower quadrant, and a 22-Fr catheter is left in place for 3 weeks to maintain the caliber of the ileovesical anastomosis. If significant augmentation is performed, a suprapubic catheter should be left as well to maximize perioperative drainage. In select patients with perineal excoriation from urinary incontinence, a bladder neck or urethral procedure in conjunction with an ileovesicostomy may be used to create outlet resistance.

## Continent Urinary Diversion

Many different types of continent urinary diversions have been developed to improve or replace the native lower urinary tract. The chosen technique depends largely on the surgeon's experience and preference, but the primary pathology plays a large role in any given patient. Reconstruction is tailored to the specific anatomy and related functional deficits. A fundamental difference exists in pediatric lower urinary tract reconstruction versus that of adults. In adult reconstruction, a particular type of reconstruction (i.e., Kock pouch, Indiana pouch) may

be chosen preoperatively. In children, the principles of a low-pressure reservoir with a means of catheterization without leakage or reflux must be achieved from the tissues available at this time of reconstruction. Whenever possible, enhancement of the native bladder and outlet is preferred to avoid the potential complication associated with ureteral anastomosis to a CUR. CUR would be performed if the native bladder is absent or not salvageable. Patients with bladder agenesis syndromes, the most severe bladder exstrophy, and pelvic organ destruction secondary to trauma or malignancy would be candidates for CUR.

Continent urinary diversion is now common, but one must remember that it requires a broad spectrum of surgical skills and must address the varied underlying diagnoses. By definition, a reservoir that must be emptied by intermittent catheterization is created. This may include the augmentation of an intact but severely diseased bladder or the creation of a reservoir completely from heterologous tissue. The surgical goals and principles are similar: to create the ideal storage reservoir for urine that can be easily emptied with the minimum of complications. Because the gastrointestinal (GI) tract is plentiful and accessible, it is the most common source of tissue. The physiologic variability along the GI tract allows the surgeon to tailor the reconstruction to the patient. However, these complex surgeries are not without complications, and these have to be understood and anticipated.

## BLADDER AUGMENTATION

Bladder augmentation is an essential component of the pediatric urologist's surgical armamentarium. It has a prominent role in the management of many lower urinary tract (LUT) disorders including neurogenic bladder, posterior urethral valves, and bladder exstrophy. The modern application often includes the use of a continent catheterizable abdominal wall stoma based on the Mitrofanoff principle. This is generally performed using either the appendix (appendicovesicostomy) or reconfigured ileum (Monti) and may require an additional procedure to improve the continence mechanism at the bladder neck. Intermittent emptying via the native urethra remains an option.

As previously discussed, children with severe LUT dysfunction were historically treated with urinary diversion. Lapides' introduction of clean intermittent catheterization ensured that any child could safely empty his or her bladder.[1,37] This brought the dawning of lower urinary tract reconstruction and allowed the urinary tract to remain intact and avoid the use of external collecting devices. Advances in urodynamic monitoring improved our ability to predict who would best benefit from bladder reconstruction and therefore prevent renal deterioration.[2] Parallel medical advances ensured the survival of these complex patients and allowed for the shift of focus toward continence as an important aspect of their quality of life.[38–39] Recent advances with cutaneous catheterizable channels continue to simplify care and increase its popularity.[40]

The primary goal of lower urinary tract reconstruction is to store urine safely without leakage. Adequate storage requires a low-pressure, highly compliant reservoir of adequate volume, whereas continence results from limited contractility and an effective sphincter mechanism.

The vast majority of augmentations are performed with gastrointestinal segments because bowel segments are readily available and easily configured. Ileum is currently the most popular segment,[41–43] but sigmoid is often used. Stomach and ileocecal segments have been used but have only a small role in contemporary management.[44–47] Their abundance ensures that adequate capacity is obtained while detubularization and the natural viscoelastic properties allow for the low-pressure reservoir.[48–49] However, the secretive[50–51] and absorptive[52] nature of this tissue is also responsible for most of the common complications associated with this procedure.

Requirements for a successful augmentation include proper patient selection,[53] the ability and willingness to perform CIC,[50,54] proper selection of augmentation material, and recognition and treatment of complications.

## PATIENT EVALUATION AND SELECTION

The patient, family, and entire health care team must be involved in the decision to pursue major surgery. The common risks of incorporating GI segments into the urinary tract include mucus production, urinary tract infection, bladder and renal calculi, and metabolic changes. Life-threatening risks such as malignant degeneration and spontaneous perforation must be explained to the family and child, and they *must* be understood.[50,51,54] Everyone involved in caring for the child must be committed to the appropriate postoperative care including mandatory use of CIC and regular bladder irrigation.[50,54,55]

Clinical evaluation requires a thorough history and physical examination. Particular attention should be paid to latex allergy because this can be a fatal complication. Preoperative evaluation should include a renal-bladder ultrasound (RBUS) and a voiding cystourethrogram (VCUG). Serum chemistries are required because impaired renal function may change the gastrointestinal segment used.[54] Initially, it was suggested that a creatinine clearance of less than 60 mL/minute might be a contraindication for the use of ileum as a continent urinary reservoir,[56–57] but augmentation often stabilizes renal function and reconstruction has been done before renal transplantation. Urodynamic studies are necessary to determine outlet resistance, bladder capacity, and storage pressures. Cystoscopy will confirm anatomy and ensure that no untoward findings that may hinder reconstruction are present.[50]

The net result of these investigations is a comprehensive surgical plan. The exact procedure will depend on which segment is to be used and whether the patient requires concomitant ureteric reimplantation, bladder neck procedure, and a catheterizable channel. Patients with a neurogenic bladder may also undergo an antegrade continence procedure to assist evacuation of their neurogenic bowel.[58]

Preoperative preparation usually involves bowel preparation, as described previously for conduit diversion. Perioperative antibiotics and a sterile urine are required and are particularly important if the patient has a ventriculoperitoneal shunt.[59]

Long-term follow-up is required with all patients. After the postoperative visit, and assuming the absence of complications, the patient should be seen annually with a history, physical examination, creatinine and electrolytes, an ultrasound, and an annual cystoscopy 5 to 10 years out from surgery.[50,54]

## GASTROINTESTINAL CYSTOPLASTY

Most children undergoing lower urinary tract reconstruction for hostile bladder dynamics can have their native bladder preserved but need to have it augmented to lower intravesical pressures, limit contractility, and improve compliance. Gastrointestinal segments are generally used, but this requires reconfiguration and detubularization to prevent their own inherent contractile properties.[44,48,49,60] Maximum storage capacity requires approximation of the spherical shape.[48] A widely bivalved bladder enables this and helps to prevent the augment behaving as a diverticulum (Fig. 118-5). The volume of the sphere is maximized by folding the ileum into a U or an S shape, which increases the potential radius and volume (Fig. 118-6).[54] This reconfiguration, as well as detubularization along the antimesenteric border, is critical to disrupting intestinal contractions because the intact intestine can create pressures of 40 to 100 cm $H_2O$.[61–63] The reconstructive surgeon should err on the side of a larger rather than smaller augmentation.[50] Regardless of the bowel segment selected, a water-tight anastomosis using absorbable suture is done. A suprapubic tube is placed into the native bladder and secured to the abdominal wall, and a perivesical drain is placed.

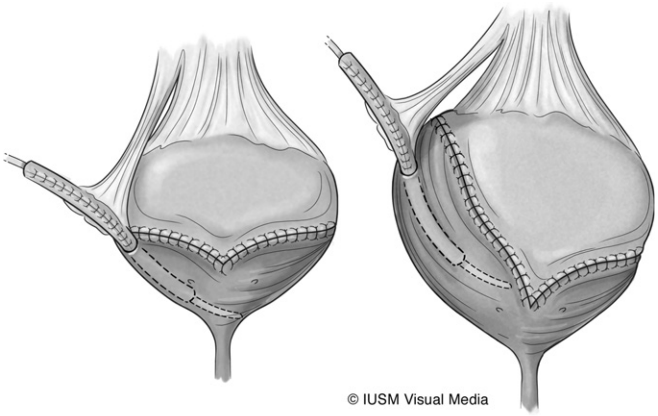

FIGURE 118-5 The offset cystoplasty allows for more mobility of the detrusor muscle and provides better access to the muscular backing that is essential for implantation of the catheterizable channel.

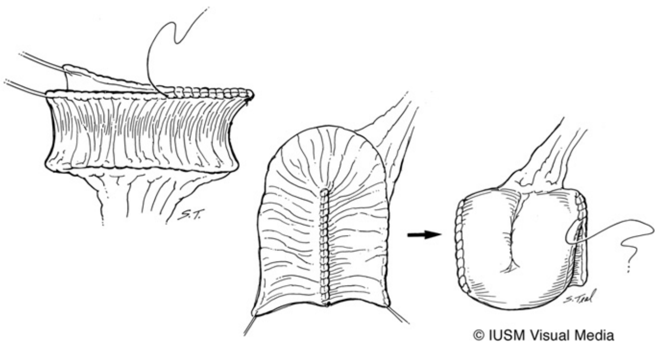

FIGURE 118-6 The ideal bladder augmentation will increase both capacity and compliance, which are required for continence and renal protection.

## ILEOCYSTOPLASTY

Ileum has become the segment of choice due to its inherently low contractility, abundance, and ease of manipulation.[41–43] In children 20 to 30 cm are harvested, with the distal margin located 15 to 20 cm from the ileocecal valve to prevent vitamin $B_{12}$ and bile salt malabsorption.[49,64] Ileum is known to produce less mucus than colon, and we noted a lower rate of perforation when compared with sigmoid.[35] It has the distinct disadvantage of being difficult to create submucosal tunnels for ureteral reimplantation or catheterizable channel placement.

## SIGMOID CYSTOPLASTY

Advantages of the sigmoid include its proximity to the bladder and its marked dilation in the neuropathic population. Approximately 15 to 20 cm are isolated and irrigated with an antibiotic solution. Due to the extreme contractile nature of the sigmoid, complete detubularization is essential.[46] Spontaneous perforation rates have been shown to be higher with sigmoid as opposed to ileal augmentations,[65] presumably due to their increased contractile pressure.[66]

## ILEOCECAL CYSTOPLASTY

The main advantage of the ileocecal segment is the consistent blood supply. Two main techniques exist, each with multiple variations. Either both the ileal and cecal segment are tabularized and reconfigured together, or solely the cecum is tubularized and the ileum used to create a continent stoma[47] or for ureteric replacement.[54] This segment is infrequently used in the neuropathic population because loss of the ileocecal valve can result in intractable diarrhea.[67]

## GASTROCYSTOPLASTY

The stomach is much less absorptive than other intestinal segments, and its secretion of hydrogen ions may be beneficial in patients with chronic renal failure and metabolic acidosis.[44,68] A 10- to 15-cm wedge from the greater curvature is mobilized along the right gastroepiploic vessel and passed through the mesentery of the transverse colon to the bladder. Originally felt to be an option for all augmentation candidates, its role is now limited primarily due to the hematuria dysuria syndrome, which occurs in up to 70% of patients.

# Autoaugmentation

Described by Cartwright and Snow,[69] in order to decrease intravesical pressures and increase bladder capacity, a large diverticulum is created at the dome of the bladder by a detrusorectomy while leaving the bladder mucosa intact. Unfortunately, although the initial reports of urodynamic improvements seemed promising, the results were not as durable as those patients treated with an enterocystoplasty and seem to do better in adults than in children.[70–72] In general, autoaugmentation will decrease intravesical pressures. It will not reliably increase capacity that is often necessary in children. It does remain an option for a select group of patients.

## SEROMUSCULAR SEGMENTS (WITH UROTHELIAL LINING)

To avoid the incorporation of intestinal mucosa with the urinary tract, Shoemaker and Marcucci described using seromuscular segments of bowel overlying an autoaugmented bladder.[73] Most experiences have demonstrated that whether the segment is facing the bladder lumen or is reversed, significant contracture develops.[74–75] Most recently, some have demonstrated success with demucosalized colon over urothelium with findings of increased bladder capacity and low filling pressures.[76] Long-term results and more experience are necessary to help determine the efficacy of this approach.

## CONTINENT CATHETERIZABLE CHANNELS

Bladder augmentation and bladder neck surgery markedly decrease the patient's ability to empty spontaneously while increasing the consequences of incomplete emptying. Not adhering to a strict CIC schedule can result in an increased risk of urinary tract infection, bladder stones,[77] and spontaneous bladder perforation.[78–79] In 1980 Mitrofanoff introduced the principle of a continent channel by using the vermiform appendix and implanting it submucosally into the bladder.[80] What is now known as the "Mitrofanoff Principle" states that any supple tube implanted submucosally with sufficient muscle backing acts as a flap valve and results in a reliable continence mechanism (Fig. 118-7).

The Mitrofanoff principle has been widely embraced and applied to a variety of tissues because the appendix (Fig. 118-8) is not always appropriate or available, especially if a simultaneous Malone antegrade continence enema (MACE) procedure is being performed. The use of stomach, colon, bladder, ureters, and fallopian tubes have all been reported with good success.[81–92] However, the utility of the tubularized ileal channel was introduced by Yang[87] and Monti[82] and has assumed a leading role in genitourinary reconstruction (Fig. 118-9).[84,93]

The continent catheterizable channel requires a supple tube, straight path, and short intra-abdominal segment. The appendicovesicostomy requires full mobilization of the right colon to ensure adequate mobility. Amputation should include some cecum because this allows for a larger-caliber cutaneous stoma or can be tubularized to increase stomal length.[81,94] The appendix is then carefully mobilized with the mesoappendix to ensure adequate blood supply. The

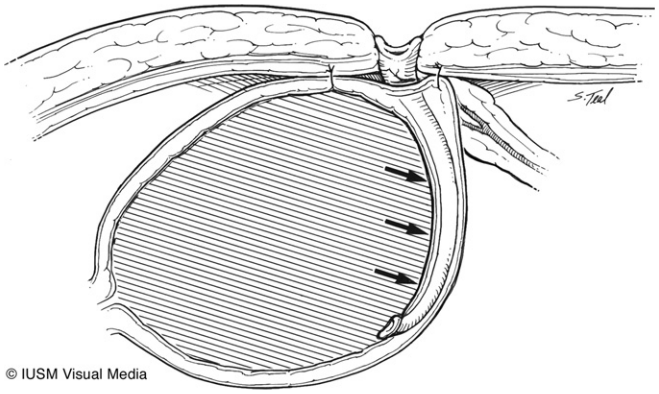

FIGURE 118-7 The Mitrofanoff principle states that a supple tube will compress with increasing intravesical pressure and provide continence.

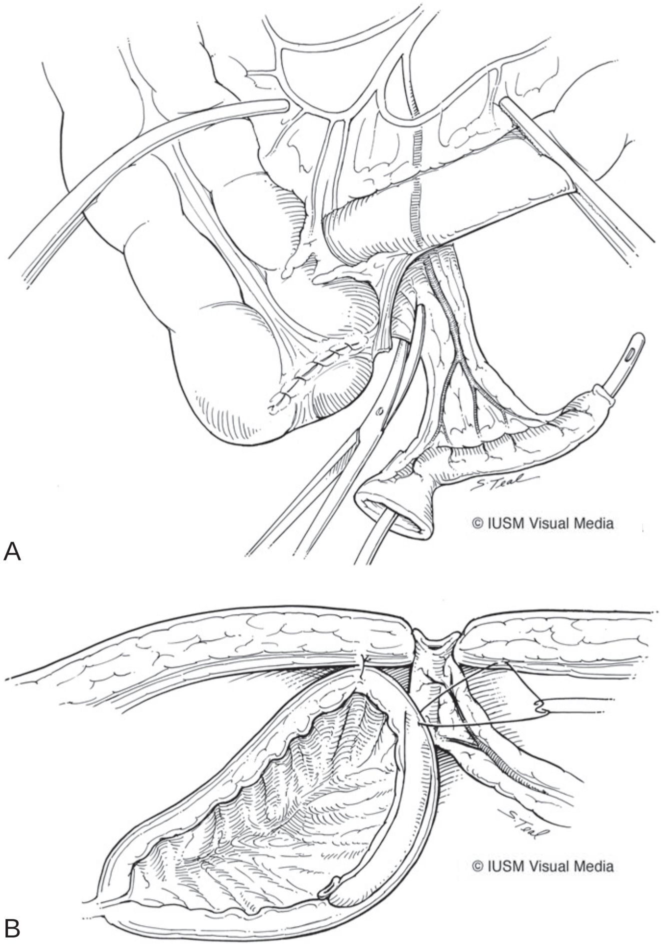

FIGURE 118-8 **A,** The appendix is readily accessible and mobilized with maintenance of its vasculature. **B,** It is implanted easily beneath the bladder mucosa to provide a reliable catheterizable channel.

Monti-Yang technique requires the isolation of 2 cm of ileum, opening it along its antimesenteric border and retubularizing it over a 12-Fr catheter. The channel is then preferentially implanted into the submucosa of the bladder because its thick muscle is ideal for a continent valve; however, stomach and the tenia coli have been successfully used. Reimplantation into ileum is the most challenging and requires the creation of a seromuscular trough. The stoma site can be hidden within the umbilicus or placed in the right lower quadrant, the latter being favored as a shorter and more direct route. Great care is taken to ensure a catheter, usually 12-Fr, passes easily and that the channel is as straight and tension free as possible. When satisfied, the surgeon fixes the channel to the abdominal wall with a permanent suture. Many ingenious skin flap techniques are used to minimize the chance of stomal stenosis, all inserting into the spatulated channel. An indwelling catheter is left for 2 to 3 weeks, and the first catheterization is usually performed in the clinic setting.

Stomal continence is excellent, and rates of 90% to 99% are reported in the two largest published series.[84,95] Complications pertain primarily to difficulties with catheterization, most commonly at the skin level, but may also occur deeper within the channel itself. Stomal stenosis is reported to occur in 5% to 25%,[95–96] with a lower rate potentially seen with tubularized ileum.[84]

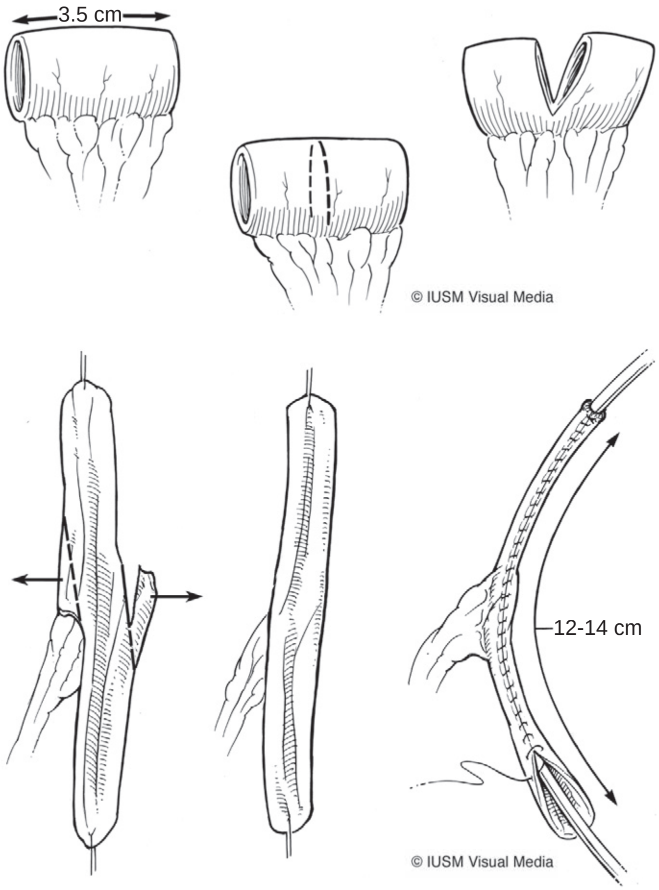

**FIGURE 118-9** Normally, a 2-cm segment of ileum can be opened along its antimesenteric border and tubularized for an effective channel. A slightly longer piece (3.5 cm) can be partially divided, both ends tubularized, and reanastomosed for a spiral Monti, for situations demanding more channel length.

Several authors have described continent catheterizable tubes fashioned from native bladder. Casale's original description of the "intravesical channel"[97] was modified by Rink.[98] Although continence rates of 100% were reported, the technique is hampered by a 45% incidence of stomal stenosis. Although still a useful technique if an intraperitoneal procedure can be avoided, it has been largely replaced by the appendicovesicostomy and reconfigured ileovesicostomies.

These channels provide a more convenient and more socially acceptable means of catheterization. It is especially beneficial for those with a sensate urethra and in the obese or wheelchair-bound female. It also assists caregiver comfort and, most importantly, patient independence.

## CONTINENT URINARY RESERVOIRS

If the entire bladder has been replaced by nonurothelial tissue (usually gastrointestinal) and requires emptying by means other than the urethra, it is referred to as *continent urinary diversion*. Although popular and with many refinements over the past several decades, it is not commonly used in pediatrics today because generally the bladder can be incorporated into the reconstruction.[50]

A few diagnoses such as bladder agenesis or malignancy resulting in cystectomy will require complete bladder replacement. When required, however, it allows the complex patient to achieve continence and enjoy the benefits of such. Patient selection for the procedure is as important as with bladder augmentation because noncompliance will result in the same myriad of complications, despite a technically perfect operation. Preoperative evaluation is similar to the bladder augmentation patient, with the acquisition of sufficient clinical, metabolic, anatomic, and functional data to develop a detailed surgical plan.

The goals of the continent urinary diversion include the creation of a reservoir of adequate capacity and compliance, nonrefluxing ureteric implantations, a continent cutaneous stoma, and a minimum of complications.

Although the gastrointestinal tract again provides for the reservoir, several key differences exist with an augmentation. Colon and stomach have assumed a larger role because the musculature of the tenia coli and stomach allow for more reliable nonrefluxing ureteric and catheterizable channel anastomoses. The three most common types of continent reservoir in children are (1) a reservoir fashioned solely from ileum (Kock pouch), (2) a gastroileal composite, and (3) an ileal reservoir (Indiana pouch).[95] Each has a myriad of variations described, all attempting to decrease complications and assist construction. However, because published reports in children are usually limited to small numbers, each reservoir having subtle variations and no published direct comparisons, it is impossible to determine an ideal reservoir.[55,95,99] Therefore the reconstructive surgeon must be familiar with several techniques because each has advantages that may require exploitation with any clinical situation.

## KOCK POUCH

Kock first described a continent ileostomy in 1971[100–101] and from this developed the Kock pouch in 1982.[102] This continent ileal reservoir was among the original nonorthotopic bladder substitutions used and remains popular today.[103–105] It requires the construction of an efferent nipple for continence and an afferent limb for the prevention of reflux. This technically demanding aspect usually requires the use of stapling devices, and these can be the source of its most significant complications (stone formation) and long-term failure rate.[106]

Approximately 80 cm of ileum is harvested in adults, with the proximal 15 to 20 cm used in an isoperistaltic fashion to create the antireflux mechanism. The distal 12 to 15 cm are used for the continent cutaneous stoma. These lengths are decreased appropriately depending on the size of the child. The bowel is intussuscepted through its full thickness, and this is secured by three rows of gastrointestinal staples, although absorbable mesh has also been described.[107] Significant modifications include removing the distal 6 staples from the device,[106] stripping the distal mesentery,[108] and the use of absorbable staples.[109]

## GASTROILEAL POUCH

The advantages of both gastric and ileal segments can be maximized while offsetting their complications by incorporating them both into a composite reservoir. The metabolic derangements complement each other, as the acidic gastric secretion will neutralize the absorptive properties of the colon or

ileum.[110–112] Furthermore, in patients at high risk for short gut syndrome, as in cloacal exstrophy, it allows a minimum of valuable absorptive tissue to be lost.[50] However, it is a more complex reconstruction, requiring two anastomoses and longer operating time, but is a valuable alternative for select patients.

## INDIANA POUCH

The ileocecal segment has been popularized due to the potential continence or antireflux mechanism inherent to the ileocecal valve. Many surgical techniques have been described, in the attempt to maximize cutaneous continence, simplify the surgical procedure, and minimize complications. The Indiana group modified the pouch described by Gilchrist and Merricks with a unique plication method that has retained its popularity. An Indiana pouch uses the detubularized cecum as its reservoir, with ureters implanted in a nonrefluxing manner into the tenia. The ileum is then plicated to the ileocecal valve, which is reinforced by Lembert sutures (Fig. 118-10). Continence has been reported in 95% to 99%,[113–114] in part due to its large capacity.[115] Complication rates have been acceptable, as low as 0.6%,[113] but not all surgeons have reported such success.[116]

## COMPLICATIONS FROM THE INCORPORATION OF INTESTINE IN THE URINARY TRACT

Despite the popularity of using the gastrointestinal tract as a urinary reservoir, the potential complications are numerous and can be significant. A broad categorization would include (1) complications due to structural defects, (2) complications secondary to the loss of the intestinal segment, (3) complications due to secretions, and (4) complications from absorption.

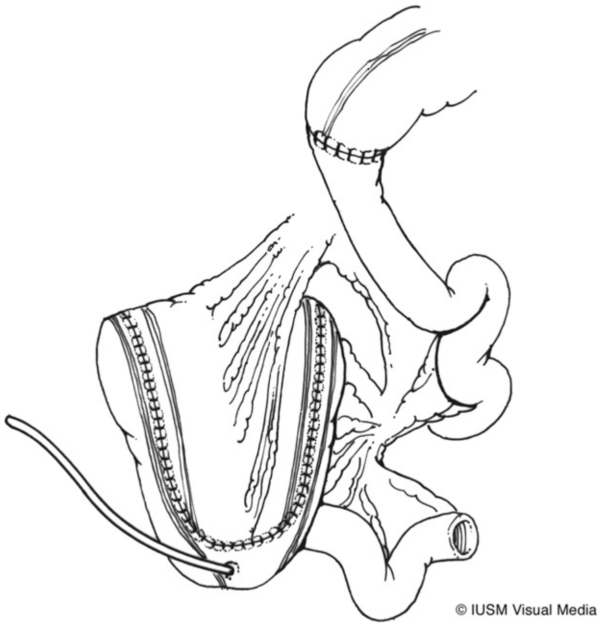

**FIGURE 118-10** The Indiana pouch uses the ileocecal valve as a continence mechanism and the cecum for urinary storage.

## STRUCTURAL COMPLICATIONS

Structural complications include the requirement of a second augmentation, spontaneous perforation, and long-term malignancy potential. A secondary augmentation may be required in up to 6% of patients,[66] and most are due to high intravesical pressures from persistent bowel contractility.[117–118] The hallmark clinical signs are incontinence or hydronephrosis with screening ultrasound, and this is confirmed with urodynamic studies.

A spontaneous perforation can be a fatal complication and must not be underestimated. Early urine leaks are likely due to technical error, but late complications usually originate in the bowel, approximately 1 cm from the anastomotic line.[50] Patients often present later in the course, as their neurologic deficit impedes symptoms. Therefore sepsis and death are realistic possibilities, and a high index of suspicion must prevail. Diagnosis is with a CT cystogram and treatment is usually by laparotomy and primary closure,[78] but conservative treatment with catheter drainage has been successful in select patients.[119]

The development of an adenocarcinoma is concerning due to the well-documented occurrence following ureterosigmoidostomy.[120–124] It arises from the ureterointestinal junction and occurs in these patients with a 7000-fold risk over the general population.[123] Although a tumor has been reported as soon as 3 years after augmentation,[125–126] the mean latency is 21.5 to 26 years.[30,123] At our institution, 3 malignancies have occurred in our series of more than 500 augmentations. All patients died of metastatic disease, with a mean time from augmentation to diagnosis of 19 years.[127] Husmann and colleagues[128] have suggested that patients with neurogenic bladders, exstrophy, and other congenital anomalies requiring CIC are at higher risk for malignancy regardless of whether enterocystoplasty is performed. The risk of carcinoma (both adenocarcinoma and transitional cell) in this patient population is increased with exposure to other carcinogens (e.g., tobacco) and immunosuppression.[129] Although most surgeons appreciate the risk, definitive guidelines for surveillance have not been established. Annual cystoscopy has been recommended to begin 3 to 10 years after augmentation.[30,50]

## LOSS OF INTESTINAL SEGMENT

Removal of an intestinal segment places the patient at risk for a bowel obstruction, and this occurs in approximately 3% of cases.[50,60,65,130] Because many of these are due to internal herniation through the pedicle of the augment, Leonard and colleagues[131] have recommended early exploration to minimize the risk of augmentation ischemia.

The removal of a gastrointestinal segment for CUR or augmentation is usually well tolerated; however, bowel dysfunction has been reported in 10% to 54% of patients.[132–133] Removal of the ileocecal valve can result in problematic diarrhea and rectal incontinence, especially in the neurogenic population.[134–135] Loss of the distal ileum can also result in diarrhea, in these cases due to an interruption in the enterohepatic circulation,[136] but can usually be prevented by leaving the distal 15 to 20 cm intact. Treatment of mild cases is usually successful with anion-exchange resins.[54]

Vitamin $B_{12}$ deficiency can develop in up to 35% of patients following an 80-cm small bowel resection for a Kock

pouch,[137] but it had not been demonstrated following ileocystoplasty in the past.[138–139] More recently, our group in Indiana has demonstrated that vitamin $B_{12}$ deficiency often occurs following standard ileocystoplasty using 25 cm or less of small bowel.[140] Of patients greater than 7 years from ileocystoplasty, 21% had low values of vitamin $B_{12}$ and 41% were found to be low-normal. Vitamin $B_{12}$ levels should be routinely tested, and if found to be low, patients can be adequately treated with oral therapy.[141]

### COMPLICATIONS DUE TO SECRETIONS

The acidic nature of gastric secretions can result in a hematuria-dysuria syndrome (HDS) in 9% to 70% of patients.[50,131,142–143] This troublesome complication can result in bladder spasms, suprapubic pain, dysuria, gross hematuria, and excoriation of genital skin. This is especially troublesome in sensate patients, where nearly 75% will have symptoms.[54,144–145] Treatment of mild cases is with histamine blockers or proton pump inhibitors[144] but may also require bicarbonate irrigations.[146–147] The net acid loss can result in a profound hypokalemic, hypochloremic, metabolic alkalosis and can be especially severe with a coexisting gastroenteritis.

Mucus production continues with all other bowel segments, although less so with ileum,[65,148–149] and can result in incomplete bladder emptying. Mucus production also predisposes the patient to urinary tract infection (UTI) and bladder stone formation.[50] Bladder stones occur in approximately 7% to 52% of augmentations,[77,150–151] with the two largest series recording an incidence of 10% to 15%.[151–153] The increased risk may be due to increased levels of calcium and phosphate in mucus.[154] Their struvite composition implies a common etiology with a urease-producing bacteria. The systemic acidosis common to the augmented population decreases stone inhibitors and promotes stone growth.[77] Prevention is aimed at regular CIC and daily bladder irrigations. Treatment is amenable to open or endoscopic means,[77,150,152,155] with open surgery reserved for the larger stones.

Bacteriuria is nearly universal in any patient performing CIC, especially when combined with an enterocystoplasty. A UTI most frequently presents with malodorous urine, but symptoms may include hematuria, incontinence exacerbation, suprapubic pain, or increased mucus production.[50] A symptomatic urinary tract infection is reported by Rink and colleagues[65] in 22.7% of patients with an ileal augmentation, but in only 8% of patients with a gastrocystoplasty. Overall occurrence of a febrile UTI was reported to be 14%. Treatment of asymptomatic bacteriuria is not indicated unless culture indicates a urease-producing organism or a virulent organism. However, treatment may decrease the risk of stone formation.

### COMPLICATIONS CAUSED BY ABSORPTION

The use of bowel for a urinary reservoir can be associated with profound metabolic changes due to its absorptive nature. Colon and ileum readily absorb ammonium, hydrogen ion, and chloride, and this will result in a hyperchloremic metabolic acidosis. This is tolerated in many patients with normal renal function[156] but may require medical therapy in others. The extent of ion absorption depends primarily on intestinal contact area and length of time for contact; therefore significant acidosis should prompt an investigation into incomplete emptying.[50] Although not all patients will be frankly acidotic, nearly all will have a rise in their serum chloride levels, albeit still in the normal range.[60] The acidosis prompts mobilization of buffers and can result in bone demineralization. Although some believe that somatic growth impairment occurs, it remains controversial. This has been demonstrated in animal models,[157–159] as well as in patients with bladder exstrophy, where there has been a reported 15% to 20% decrease in their overall height.[160] However, in the much more prevalent myelodysplastic population the clinical correlation has been more difficult to prove. The acidosis will also result in hypocitraturia and increase the risk of both renal and bladder stone formation.[77]

Medications such as Dilantin and methotrexate are readily absorbed across the bowel, and levels must be closely monitored.[161] Glucose is also absorbed, making urinary monitoring of hyperglycemia less reliable.[162]

## Summary

The description by Lapides of CIC revolutionized lower urinary reconstruction. It opened the door for primary reconstruction in children, allowing the urinary tract to remain intact. It virtually eliminated permanent incontinent urinary diversion with the social stigma of ostomy drainage, leaving only rare indications for temporary incontinent diversion. The Mitrofanoff principle allowed for an even more aggressive approach to achieving complete dryness in these children. Although there have been enormous gains in independence and social well-being in the affected children, the reconstructions have provided an entire new set of complications, some of which are potentially lethal. It is clear that the most important aspect is patient and family motivation. They must be willing and able to catheterize at 4-hour intervals, daily, forever. These reconstructions require a team approach, from the family, surgeon, and nursing, and they require lifelong follow-up evaluation.

CHAPTER 119

# Megaureter and Prune-Belly Syndrome

Mark C. Adams and W. Hardy Hendren III

## Megaureter

Megaureter describes a ureter that is abnormally dilated. The ureter can sometimes also be greatly elongated and tortuous. In general, the two principal pathologic types of megaureter are those that are obstructed and those with massive vesicoureteral reflux (Fig. 119-1). There may be both reflux and obstruction present, as in a megaureter ending ectopically in the bladder neck or urethra, which may be obstructed during the resting state but allow reflux during voiding when the bladder neck opens. In primary cases, the bladder is normal and the abnormality is located in the distal ureter. In other cases, megaureter may be secondary to bladder dysfunction. For example, impressive megaureters are seen in some males with high-grade urethral obstruction from posterior urethral valves. Ablating the valves can decrease intravesical voiding pressures and allow compensation of the ureters in time. Similarly, a neuropathic bladder secondary to meningomyelocele can cause physiologic obstruction of the bladder outlet with secondary megaureter. Occasionally, megaureters may represent a dysmorphic anomaly without obstruction or reflux despite the dilation (nonobstructive nonrefluxing megaureters). Megaureters may be classified on the basis of pathophysiology according to an international system proposed in 1977.[1]

When the abnormality is intrinsic in the lower ureter, the megaureter may be a unilateral problem, especially with a typical obstructive megaureter. These cases classically feature an abnormal terminal ureter with a variety of histologic and ultrastructural abnormalities.[2,3] Some have referred to this abnormality as an *adynamic segment,* but it is not comparable with the adynamic segment of lower colon in Hirschsprung disease or the lower esophagus in achalasia. The ureteral orifice often looks normal in obstructive megaureter, and true stenosis is rarely noted. Typically, a ureteral catheter can be passed through the segment without difficulty. The ureteral orifice of a refluxing megaureter is usually abnormally dilated. Indeed, an endoscope can often be passed readily up many such megaureters. In primary reflux, there exists an inadequate valvular mechanism related to the diameter of the ureter and the length of submucosal ureter within the bladder wall.

Ureterocele and ectopic ureter are commonly associated with megaureter, especially in the female infant with a duplex collecting system. Rarely, megaureter is the result of excessive urine flow, such as that seen in diabetes insipidus. The prune-belly syndrome features abnormal development of the entire urinary tract including the ureters, which are typically elongated and tortuous. Microscopic section of those ureters may show decreased musculature and excessive connective tissue in the ureteral wall, often affecting the lower ureter more than the mid or upper segments.

Megaureters are typically found in two patient populations. Newborns with the problem may be identified in follow-up of antenatally detected hydronephrosis. The relative incidence of megaureter compared with other congential upper tract anomalies is higher in this group than in older children presenting with clinical problems. The most common presentation in older children is urinary tract infection, although some children may have intermittent pain from obstruction. Infants may show failure to thrive.

Whenever megaureters are encountered during urologic evaluation, the entire urinary tract must be evaluated to determine whether they are a primary or secondary problem. The kidneys and ureters are often first visualized by ultrasonography. Intravenous pyelography may be useful; however, the diagnosis of obstruction is most often made by nuclear imaging with diuretic washout. The drainage curve after diuresis is informative, but care must be taken that the area of interest includes the entire upper system (ipsilateral kidney and ureter). Drainage of radionuclide out of the kidney into ureter and not bladder can lead to a false-negative examination. Particularly in newborns evaluated for antenatally detected hydronephrosis, the function of the kidney should be considered in interpreting nuclear renography, and significantly decreased relative function is generally considered an indication for surgical intervention in an otherwise asymptomatic child. Any decline in function (>10%) on serial renography is a strong indication for repair. Antegrade pyelography performed by inserting a needle into the kidney and infusing contrast medium is occasionally helpful in defining anatomy and demonstrating differential pressures between the upper tract and bladder (Whitaker test). Voiding cystourethrography is mandatory to determine if reflux is present and will demonstrate the ureteral anatomy if there is reflux. In addition, in males it

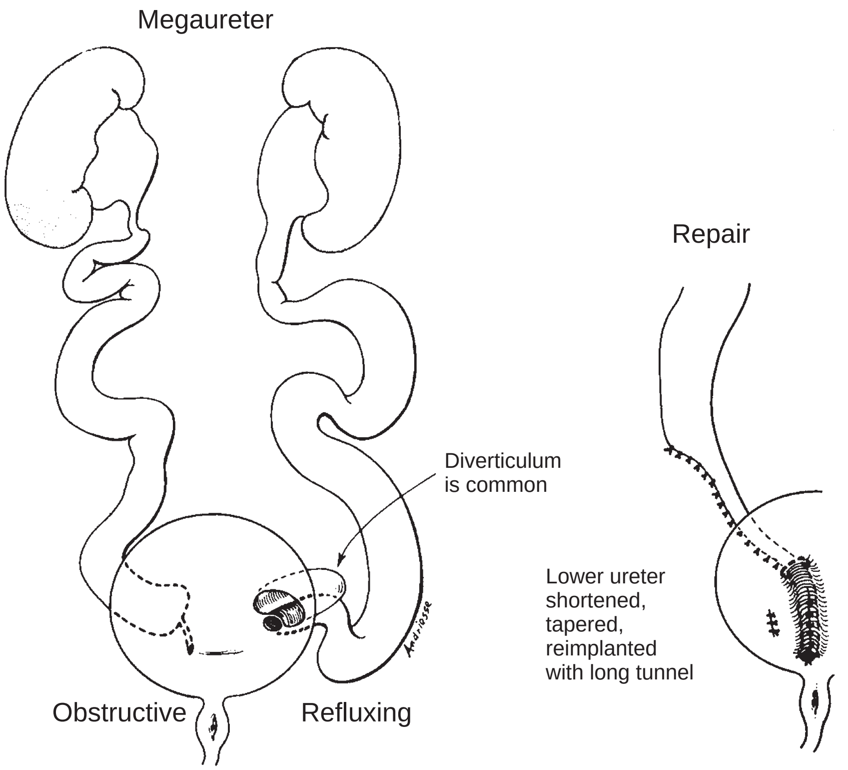

**FIGURE 119-1** Types of megaureter and scheme of lower repair.

will demonstrate any urethral pathology. Urodynamic study may be a valuable adjunct in assessing these cases if any bladder abnormality is suspected. Temporary placement of an indwelling urethral catheter may also differentiate between primary and secondary megaureter on serial imaging. Cystoscopy should define the appearance of the orifices but is generally only performed at the time of reconstructive surgery. As noted, the orifices in obstructive megaureter usually look normal; in refluxing megaureter, they are usually widely dilated with a "gopher hole" appearance.

The advent and widespread use of intrauterine ultrasonography has allowed early diagnosis of many cases of megaureter. Affected babies should have selective urologic investigation after birth. Obstructive megaureters without reflux may improve spontaneously. Thus in asymptomatic infants with mild or moderate obstructive megaureter and normal relative renal function, serial observation may be considered for a period of time to see whether spontaneous improvement occurs.[4,5] If improvement is not clear cut or if the patient develops symptoms, operative repair should be performed. Retrovesical ureteral diameter is a reasonable predictor of the likelihood of resolution of hydronephrosis or the necessity of surgical intervention in the absence of reflux. This is helpful in counseling parents.[6]

If the primary problem is a neuropathic bladder, anticholinergic therapy and intermittent catheterization may result in improvement in ureteral dilation. If the patient has severe urethral valves, fulgurating the valves may suffice. Valves occur in a spectrum of severity.[7] Thus treatment may be valve fulguration in some patients, valve fulguration followed by early megaureter repair in others, and, occasionally, valve ablation and immediate megaureter reconstruction.[8]

In summary, indications for repair of a primary megaureter vary with the etiology. In cases of primary obstructive megaureter, poor renal function ($\leq$35% to 40% of total function by renography), a severely scarred kidney, symptoms, or decreasing function on serial studies are generally considered as clear indications for intervention. Bilateral megaureters or one involving a solitary renal unit threaten total renal function and should be treated more aggressively. Finally, failure to improve after a reasonable period of observation may, at times, be an acceptable indication for surgical repair. Primary reflux into a megaureter, except in a newborn with normal renal function, is unlikely to resolve and usually will eventually require repair. Febrile urinary tract infection is another indication for surgical correction of primary megaureter whether reflux or obstruction is present. Secondary reflux may resolve with treatment of bladder outlet obstruction or bladder dysfunction. Intervention, when indicated, is virtually always open repair because the results are good even when dealing with large ureters in neonates. Endoscopic dilation followed by temporary internal stenting may result in temporary improvement in function or drainage but is unlikely to be lasting in effect.[9] Diversion by cutaneous ureterostomy has occasionally been used for an infected system or when renal function in a neonate is so poor that it is not clear whether repair or nephrectomy is more appropriate, or in premature infants who are symptomatic or have significantly compromised renal function. In those settings, temporary percutaneous nephrostomy drainage may be just as beneficial and less morbid. As such, cutaneous ureterostomy is rarely necessary.

## SURGICAL TECHNIQUE

In most cases, only the lower ureter requires repair.[10–14] Although the upper ureter may be tortuous, it often straightens out in time if the lower ureter is repaired and obstruction or reflux is relieved. This type of surgery requires gentle and

meticulous technique based on the principles of standard antireflux repair. The ureter should be handled minimally with forceps to avoid injury to its delicate wall. The ureter should be mobilized enough to taper and reimplant it into the bladder without angulation or tension. Its blood supply must be preserved. The ureter should enter into the bladder through the fixed posterior wall at a point at which it will not be obstructed or angulated when the bladder fills. The ratio of tunnel length to the diameter of the ureter must be high enough to prevent reflux, usually 4 or 5 to 1.

### Repair of the Lower Megaureter

The surgical steps are shown in Figure 119-2. A transverse suprapubic skin incision is usually made, and the midline fascia opened vertically. A vertical fascial incision may be preferable to give easy access not only to the bladder but also the middle and lower third of the ureter. Exposure or mobilization of the middle third of the ureter is rarely necessary in routine cases but may be accomplished by medial reflection of the colon. The Denis Browne universal retractor provides ideal exposure.

As shown in Figure 119-2, *A,* a catheter is sewn into the ureteral orifice for manipulation. After the orifice is circumscribed, ureteral mobilization begins intravesically and continues until mobilization is no longer easily accomplished through the bladder hiatus. Muscular and vascular attachments to the ureter within the intramural tunnel are divided and then cauterized on the bladder side but not the ureter. Shifting outside the bladder and dissecting up along the hypogastric vein, the lateral umbilical ligament is encountered and divided to allow upward and medial retraction of the peritoneum. After dissection cephalad along the anterior aspect of the ureter, it can be pulled through the hiatus and exposed in the gutter. Paravesical dissection, which can injure the bladder nerve supply, should be minimal. As the ureter is mobilized upward, all periureteral tissue should be swept toward the ureter to maintain its collateral blood supply (Fig. 119-2, *B*). In dissection of the ureter from peritoneum located medial to it, the peritoneum, not the ureter, should be skeletonized. In the male, the vas deferens should be identified where it lies on the peritoneum. Mobilization of the ureter is often easier if it is filled with saline.

After careful mobilization, periureteral tissue is undermined on the lateral aspect of the ureter and then opened to expose the wall to be tapered (Fig. 119-2, *C*). During the first 20 years of experience with repairing megaureters, which began in 1959, special megaureter clamps were used to exclude redundant circumference as an aid in tapering ureters. Some surgeons continue to find them useful. In more recent years, we have not used such clamps because the vascular periureteral tissue can be laid back, preserved, and then closed over the trimmed ureter more easily without clamps. The segment to be tapered is marked and trimmed appropriately (Fig. 119-2, *D*). Excision of redundant ureteral wall posteriorly places the eventual ureteral closure against the bladder muscle rather than next to mucosa and can usually be achieved. Occasionally, however, the dominant vessels in the ureteral adventitia are found there and should be avoided and preserved. It is important not to make the ureter too narrow, and it should be noted that closing the ureter uses 3 to 4 mm of ureteral circumference. Closure should be performed over a 10-Fr catheter except in infants, in whom 8-Fr may be more appropriate. Closure should never be tight over the catheter. The tapering should begin proximally enough that it begins well cephalad to the eventual bladder hiatus. The taper should begin gradually to avoid creation of an outpouching in the ureter that can behave as a diverticulum.

The ureter is closed with a running, locking suture (Fig. 119-2, *E*). It is helpful to interrupt the last few sutures in order to allow shortening, if necessary, during reimplantation. The periureteral tissue that had been saved is then closed to seal the primary suture line. Both layers should be closed with fine absorbable suture. It can be helpful to retain the distal tip of the ureter as a handle, trimming it off after placing the first anchoring sutures during reimplantation. The adynamic segment of an obstructed megaureter should be excised in this manner.

Selection of the new hiatus through which to bring the ureter (Fig. 119-2, *F*) is of prime importance. One mistake is to make the hiatus too lateral, which can result in angulation of the ureter and obstruction when the bladder fills. If the hiatus is located in the back wall of the bladder, it will not do so. The new hiatus must be large enough that it does not compress the ureter. Incising the lower rim of bladder muscle at the new hiatus helps create a smooth course for the ureter to enter the bladder. Care must be taken to avoid injury to the vas in males at this point in the repair.

After the ureteral hiatus has been prepared, the mucosa can be opened widely to prepare a bed in which to place the ureter (Fig. 119-2, *G*). Opening the mucosa is often more accurate than tunneling beneath intact mucosa. There is no disadvantage from this approach if the suture line in the ureter lies posteriorly against bladder muscle. In some bladders (such as in the prune-belly syndrome), elevating mucosa is difficult and requires a tedious sharp dissection. The old muscular hiatus is closed precisely. If a paraureteral diverticulum is present before surgery, the bladder mucosa must be dissected free from the original hiatus to eliminate the diverticulum and the muscular defect closed.

The ureter is then sutured in its bed (Fig. 119-2, *H*). The distal anchoring sutures at the orifice should include trigone muscle and mucosa and full thickness of ureter. The remainder of the orifice is completed with mucosal sutures. The tapered back wall of the ureter lies against the muscle of the bladder.

Figure 119-2, *I* shows the completed repair. The trigone mucosa is closed over the tapered ureter. A 5-Fr feeding catheter is passed through the opposite bladder wall and up the operated ureter to the kidney for 10 to 12 days of drainage after surgery. Alternatively, double J stents can be used, with the disadvantage of often requiring an additional anesthetic for removal. Nephrostomy drainage is generally not necessary. In patients with bilateral megaureters, we routinely repair both lower ureters simultaneously, although this involves a long operation. The technique of megaureter repair as described earlier is our preference for these cases. Some surgeons favor a cross-trigonal reimplantation technique, but it should only be considered if the bladder floor is wider than long so as to provide a long intramural tunnel. Refluxing megaureters have been repaired extravesically as well with the same success rates.[15,16] Likewise, primary megaureters have been repaired laparoscopically with and without robotic assistance[17] but should only be approached in that manner if the same surgical principles can be applied equally well.

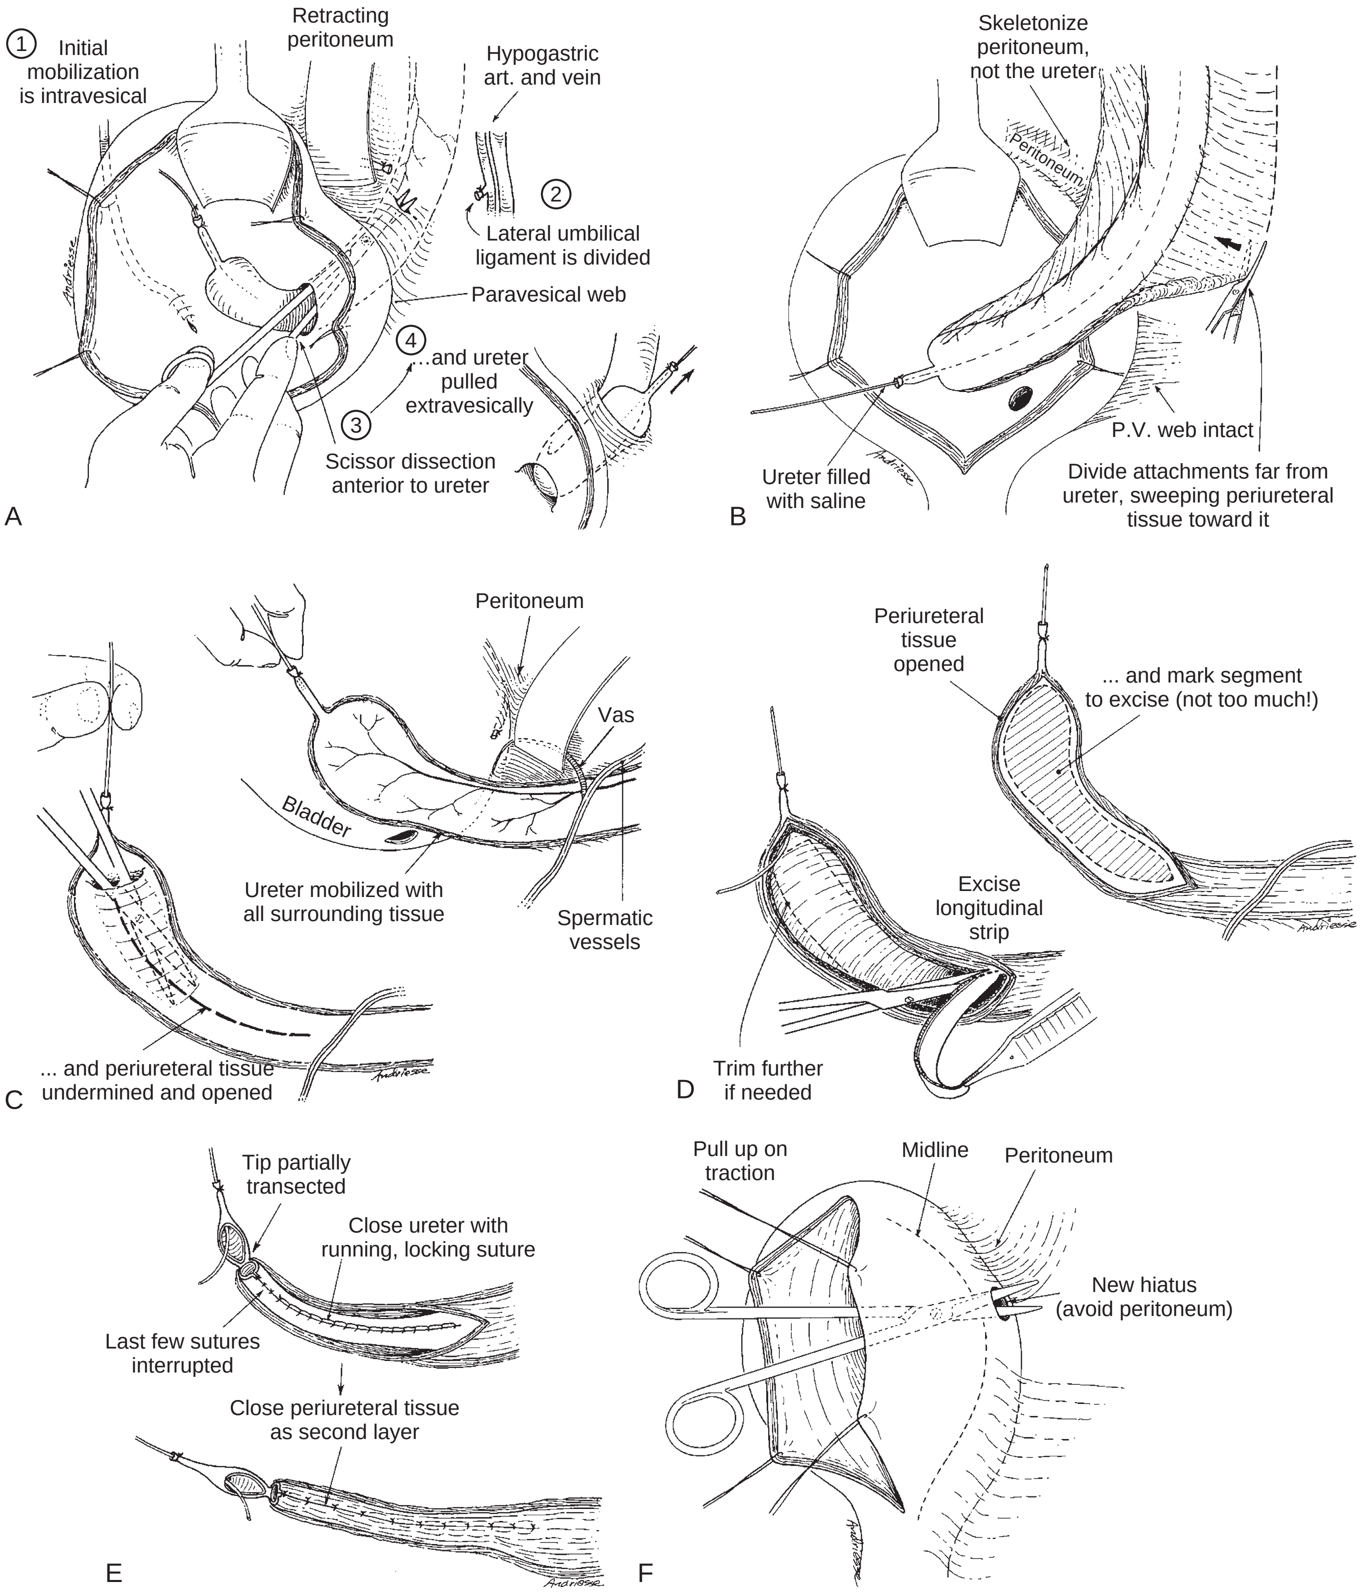

**FIGURE 119-2** Repair of the lower ureter. **A,** Initial intravesical mobilization. **B,** Extravesical mobilization. **C,** Opening periureteral tissue. **D,** Trimming of lower ureter. **E,** Closing lower ureter. **F,** Preparing new hiatus.

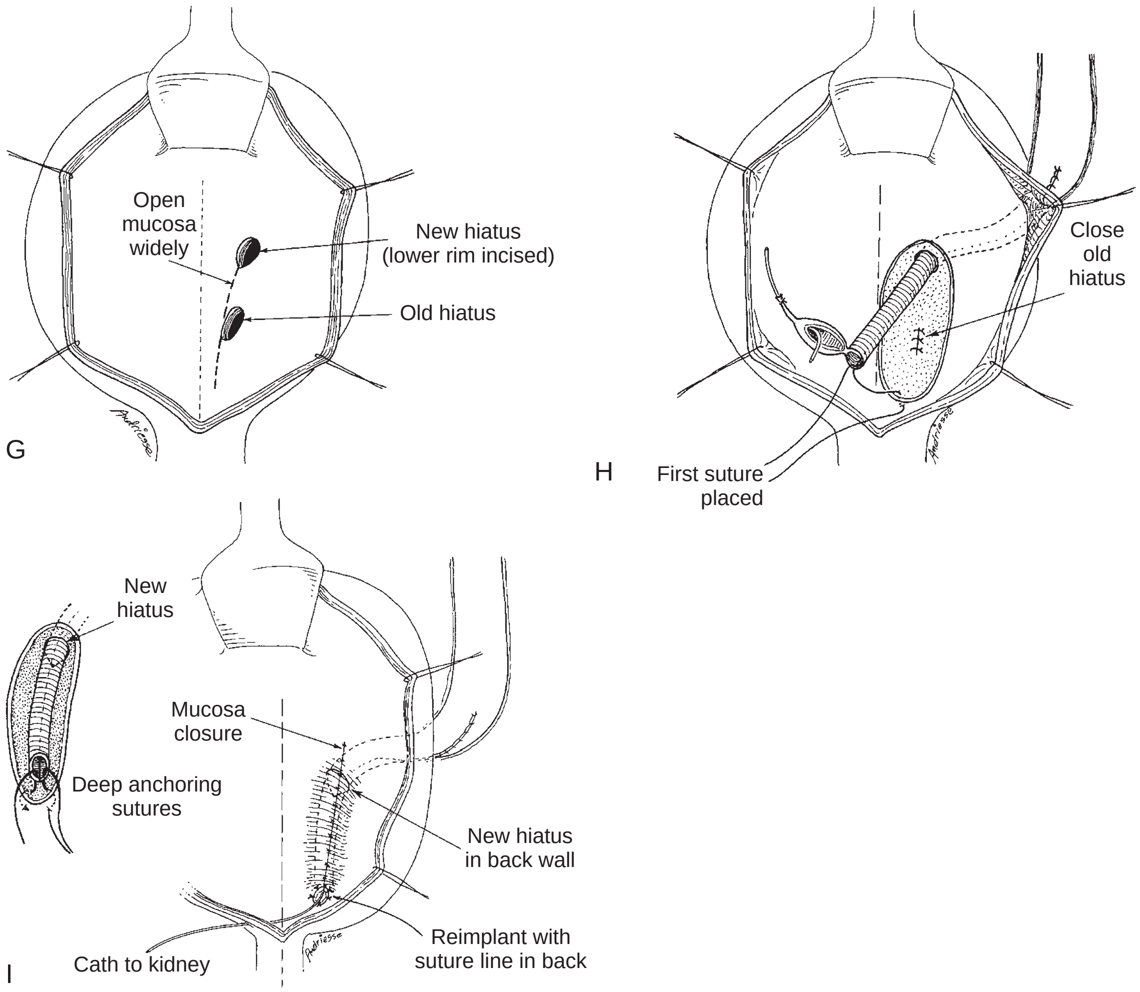

**FIGURE 119-2—CONT'D.** **G,** Creating bed for tapered reimplant. **H,** Suturing tapered ureter in its tunnel. **I,** Completed repair.

For bladder drainage after the repair, it is best to use a straight rather than Foley catheter through the urethra so that the balloon does not compress or irritate the ureteral repair. Only rarely is a suprapubic tube used, for example, in a patient undergoing incontinence surgery on the bladder outlet simultaneously. Ten to 12 days after surgery, contrast studies are performed by injecting the ureteral catheters. This testing rules out a leak, which should be rare. The catheters are then removed, one side at a time if both sides have been repaired. Measuring the urine output after each ureteral catheter is pulled indicates whether each kidney is draining.

## Imbrication

The classic description of megaureter repair involves excision of a part of the ureteral wall to reduce circumference, and this is our preference. Plication or folding may be considered for a moderately dilated ureter, although such techniques may create excessive bulk in the wall of the ureter when severely dilated or thickened. In either type of plication, atraumatic clamps are briefly placed onto the ureter to mark redundancy around an appropriately sized catheter. Again, the clamps should be placed to avoid major blood supply in the adventitia. After removal of the clamps, the ureteral wall is plicated by one of two techniques. Starr[18] described placement of Lembert sutures along the clamp marks (Fig. 119-3), which served to imbricate the ureteral wall and reduce lumen size. Kalicinski and colleagues[19] placed a running horizontal mattress suture, which excluded the redundant portion of lumen. A second running suture was then used to fold the accessory

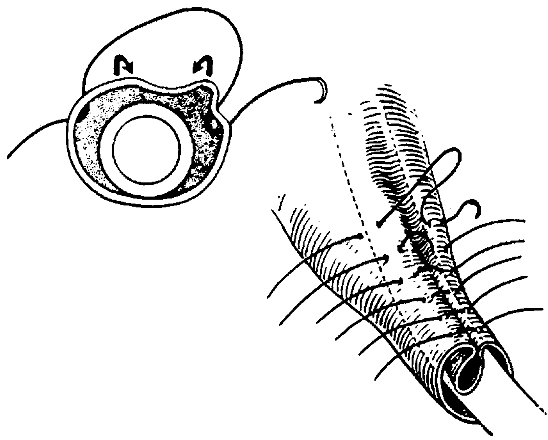

**FIGURE 119-3** Ureteral plication performed with small interrupted absorbable sutures placed in Lembert fashion. (From Keating MA, Retick AB: Management of failures of ureteroneocystostomy. In McDougal WS (ed): Difficult Problems in Urologic Surgery. Chicago, Year Book, 1989, p 131.)

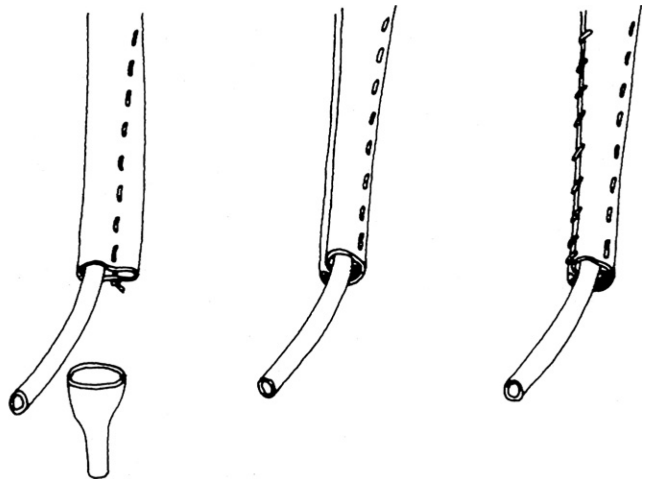

FIGURE 119-4 A running horizontal mattress suture isolates redundant lumen. The redundant portion is then folded and approximated to the main ureteral wall. (From Kalicinski ZH, Kansy J, Kotabinsia B, et al: Surgery of megaureters: Modification of Hendren's operation. J Pediatr Surg 1977;12:183.)

channel over against the wall of the ureter (Fig. 119-4). Histologic examination demonstrates that the folded segment undergoes progressive obliteration over months, although the second lumen remains patent.[20]

## Endoscopic Injection

Since early reports of subureteric injection for reflux using polytetrafluoroethylene (Teflon),[21] endoscopic treatment has been used for refluxing megaureters. The procedure is not indicated for obstructive megaureters. Higher grades of reflux have proven harder to stop endoscopically just as they are with open surgery. The success rate with a single injection for reflux may approach 60% to 80% with a normal-sized ureter. The failure rate increases significantly by as much as 20% or more when treating a refluxing megaureter, although success may increase with a second or third injection.[22] Recurrence rates are relatively low with long-term follow-up.[23] Alternative biocompatible, biodegradable materials have been evaluated with the most extensively used material being a dextranomer/hyaluronic acid copolymer (Deflux, Oceana Therapeutics, Inc., N.J.).[24] The material is easier to use and inject than Teflon and has been used with similar effect for all grades of reflux including megaureters.[25–28] Ureteral hydrodistention at the time of injection and use of an increased volume of injected material within the submucosal intraureteral space may result in more effective placement and less caudal migration of the bioimplant (Fig. 119-5).[26,29] Endoscopic injection has been used for complex patients with reflux including those with secondary reflux, duplication anomalies, and reflux after transurethral incision of ureterocele.[27,29] The least effective site for injection appears to be reflux into ectopic ureters. Open dissection of a ureter previously injected with any material may be more difficult if necessary. In general, the ureter with bioimplant should be mobilized together initially and the distal involved segment of ureter then excised.

Direct repair of megaureters has worked well for 45 years in our experience, and we continue to prefer it. The few cases in which we have used injection therapy with a dilated ureter are megaureters that have some residual reflux despite previous surgery and a long intramural tunnel.

## Repair of the Upper Ureter

If the primary pathophysiology was ureterovesical obstruction or severe reflux alone, upper ureteral obstruction after lower repair will be rare. Several points should be stressed regarding the upper ureter. First, tortuosity can considerably improve

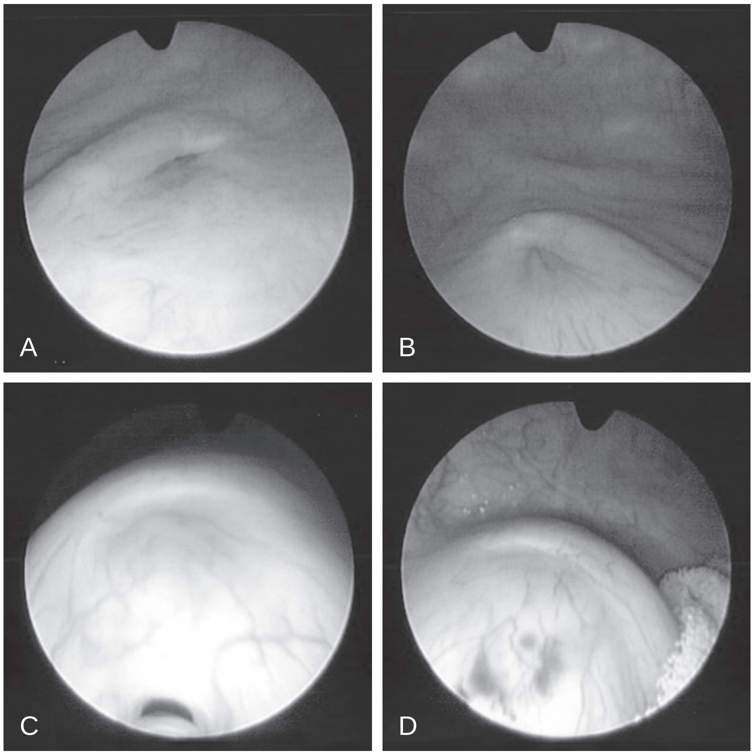

FIGURE 119-5 Endoscopic injection. **A** and **B** Orifice with hydrodistention. **C,** Needle for injection inserted in intraureteric submucosal space. **D,** Coaptation after injection. (Pictures courtesy Anthony Caldamone, MD.)

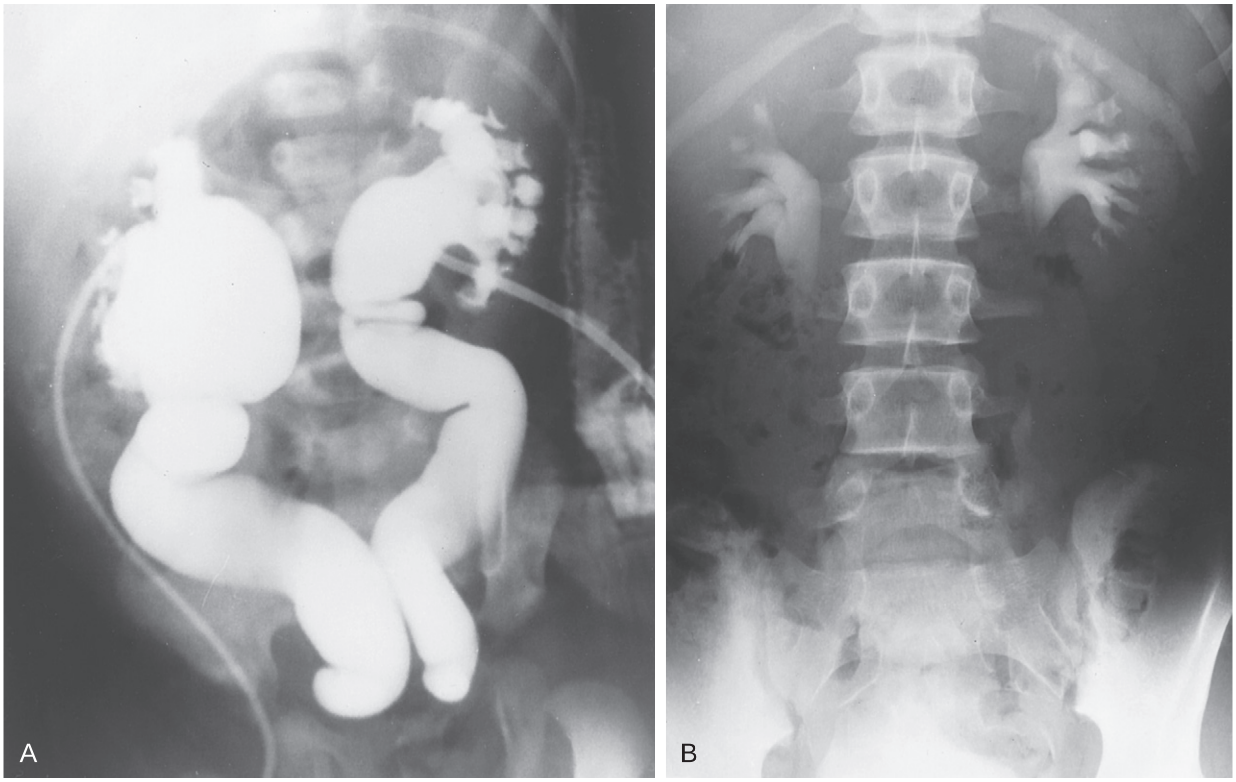

**FIGURE 119-6** Refluxing megaureters. **A,** Massive preoperative reflux at age 4 weeks. Previously placed nephrostomy tubes were unnecessary. **B,** Intravenous pyelogram 13 years after bilateral megaureter repair. Note proximal improvement after distal ureteral repair alone.

after successful repair of the lower ureter that was once obstructed or refluxing. Kinks can straighten, and dilation can recede (Fig. 119-6). If the patient is doing well clinically, it is best to wait for several months or longer to make any decision about proximal ureter. The upper ureter may be dilated immediately after repair of the lower end because of edema surrounding the reimplantation. Imaging studies of the kidney should be repeated to rule out a true obstruction. If the upper ureter remains persistently tortuous and dilated from documented obstruction, it should be tailored as shown in Figure 119-7. The tailoring sometimes merely resects a kink, which can cause poor drainage, particularly at the ureteropelvic junction. In extreme cases, tailoring includes reducing the caliber of the upper ureter. The ureter is incised longitudinally, in situ, and its width is trimmed appropriately. Clamps are not necessary to taper the upper ureter. Temporary urinary drainage with a nephrostomy catheter or indwelling ureteral stent should be used.

It is interesting to watch a dilated ureter fluoroscopically. If the walls of the ureter cannot coapt, active peristalsis may be present but ineffective. The urine churns back and forth with ureteral peristaltic waves instead of being passed effectively into the bladder. Figure 119-8 shows a ureteral peristaltic study in a dilated ureter. Before surgery, peristaltic waves could be seen at various levels of the ureter, but they were of low amplitude and ineffective. After surgery, peristaltic waves in the tapered lower 10 cm of ureter were excellent and effective but not in the persistently dilated ureteral segment 15 cm above the lower end of the ureter. In some cases, the upper ureter has been observed for a long time before being tapered because of continued dilation and poor emptying. In one case in which the upper ureter was repaired 8 years after the lower ureter was repaired, the upper tract hydronephrosis improved remarkably and creatinine clearance increased substantially.

## COMPLICATIONS

Surgical success without obstruction or reflux when reimplanting a normal-sized ureter into a normal bladder should approach 97%. The success rate of megaureter repair is not quite as high. Figure 119-9 shows the principal complications that can occur with repair of the megaureter.[30] When the orifice is too lateral, the tunnel too short, or the distal ureter too broad, reflux can result. A rare cause of reflux is a fistula at the top of the ureteral tunnel potentially caused by a stiff ureteral stent that can erode the ureter at the point at which it turns to exit the bladder. A soft No. 5 infant feeding tube should prevent this problem. The most common cause of persistent postoperative obstruction is by compression of the ureter at its new hiatus through the bladder wall often due to a hiatus that is located too far laterally on an unstable part of the bladder. This complication underscores the importance of having the new hiatus in the back wall of the bladder, not its side wall. In some cases, fixation of the bladder and hiatus with a psoas hitch is helpful to prevent this complication. A diverticulum is sometimes seen at the site of the new hiatus if it is left too large. The complication of fibrosis of the distal ureter can be avoided by meticulous handling and preservation of the blood supply to the ureter during mobilization, not making it too narrow when trimming it, and avoiding the temptation to taper so extensively that the blood supply to the lower ureter is jeopardized.

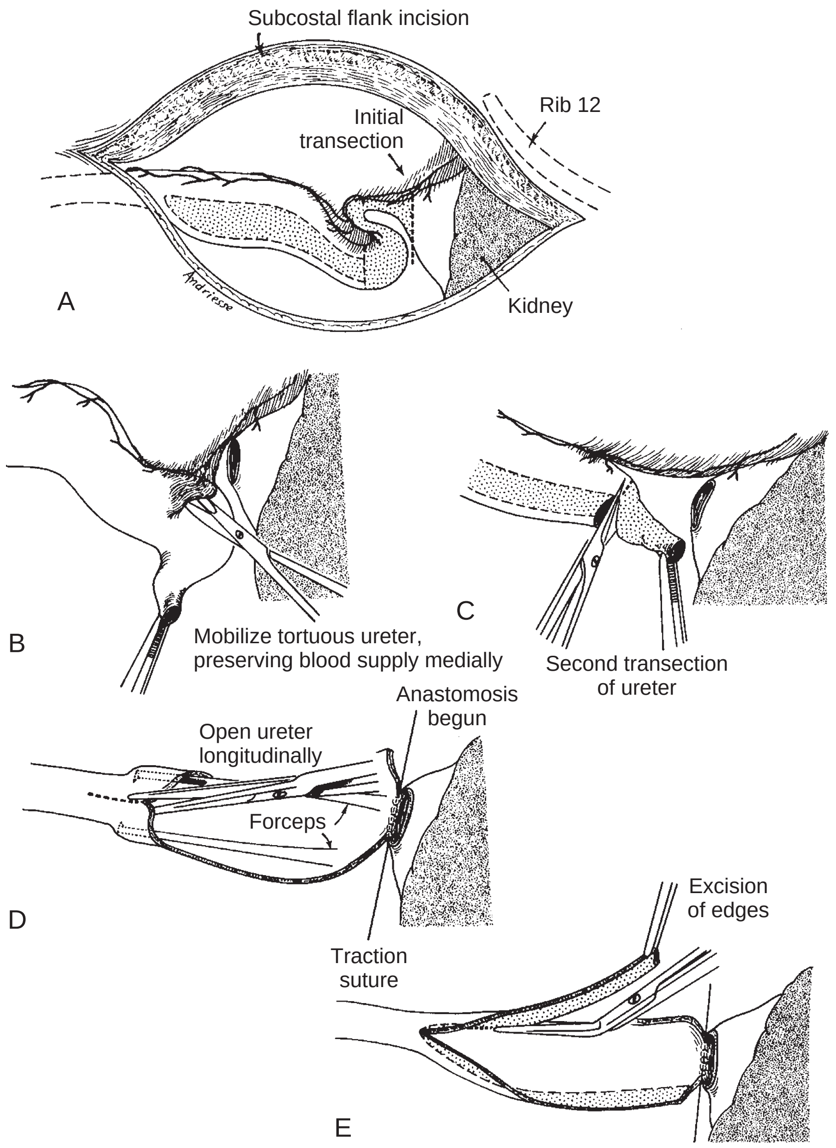

**FIGURE 119-7** Straightening and tapering of the upper part of the ureter. Trimming the upper ureter can improve its emptying and is performed in one quarter of cases in our experience, particularly those that remain tortuous and show evidence of obstruction, especially at the ureteropelvic junction. In some, the upper ureter remains dilated and does not empty well.

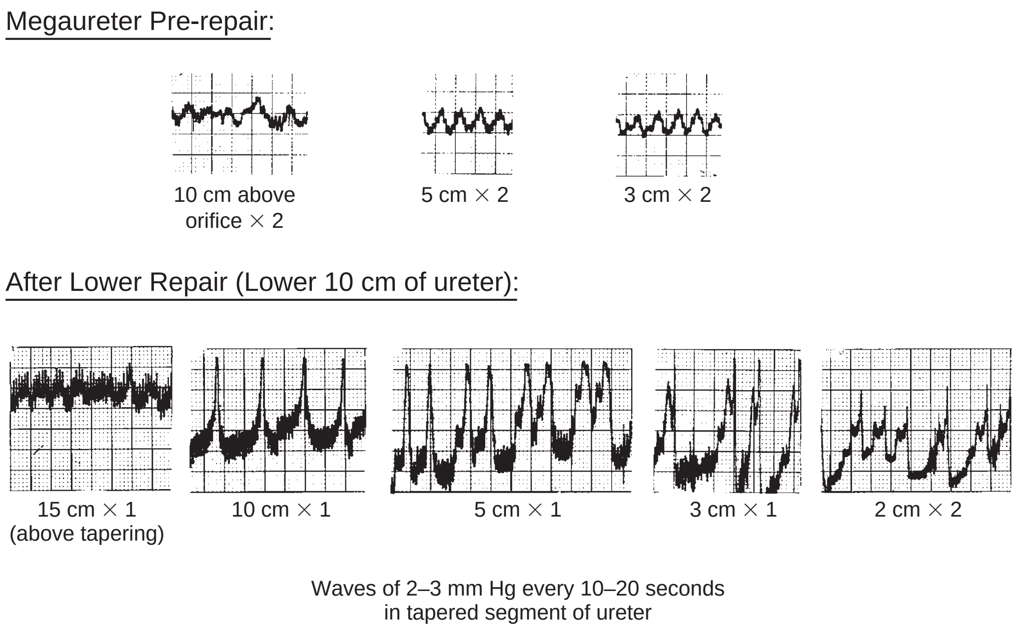

**FIGURE 119-8** Peristaltic study. Peristaltic waves in the lower ureter were ineffective before surgery but were excellent after the lower ureter was tapered. Peristalsis remained ineffective in the dilated upper ureter above the level of tapering at the time of this study.

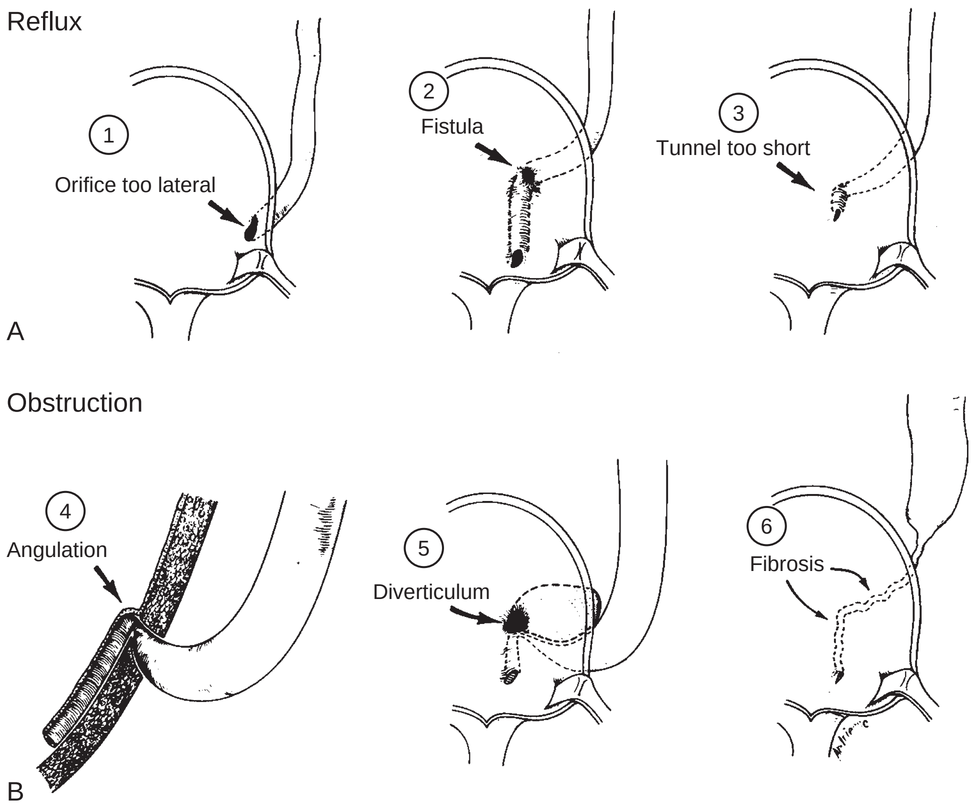

**FIGURE 119-9** The most common complications in failed surgery for megaureter.

In an experience with tapering 404 ureters in 294 patients (217 male and 77 female), which included 75 infants younger than 1 year of age, the success rate was 93% in obstructive megaureter but 83% when the problem was massive reflux. Success was higher with a normal bladder (130 patients) than with a markedly abnormal bladder (164 patients), such as in cases with urethral valves, neurogenic bladder, ureterocele, prune-belly syndrome, and exstrophy. Most patients who underwent a second operation on the ureter eventually achieved success (Fig. 119-10). Others have reported similar results,[12,19,31,32] and problems may occur whether excision or folding techniques are used. Consistently, problems with secondary reflux and obstruction have been noted more commonly after megaureter repair for reflux variants as compared with obstructive ones. Increased collagen deposition and abnormal collagen to muscle orientation have been noted in refluxing megaureters relative to obstructive ones above the distal adynamic segment.[33] Such intrinsic differences may be responsible for the difference in results for the two types.

## CONCLUSIONS

The function of the ureter is to transport urine from the kidney to the bladder at low pressure. It cannot do this effectively when the ureter is so dilated that its walls do not coapt with peristaltic waves. When ureters store urine rather than transport it, there is little question that stasis favors infection. This is particularly true if an inadequate ureterovesical junction allows reflux of urine. Megaureters may be repaired with consistent, good results. The large ureter should be handled minimally and mobilized carefully so as to preserve blood supply. The distal adynamic segment of ureter when obstructing should be completely excised. More proximal dilated ureter can then be tailored to normal size. We favor excisional tapering to achieve this, although folding techniques may be useful if the ureter is less dilated or thickened. The reconstructed ureter can then be reimplanted into bladder using the principles of standard antireflux surgery. The results of such repair are slightly more prone to complications of obstruction and, particularly, persistent reflux than are those done for reflux into a ureter that is not initially dilated. Those complications are also more likely to occur when repair is performed for reflux rather than obstruction. Longer follow-up and further experience at more centers should help define the role of endoscopic injection in the treatment of refluxing megaureters.[29]

# Prune-Belly Syndrome

Some of the most unusual and impressive megaureters are found in patients with the prune-belly syndrome, a term used by William Osler in 1901 to describe the appearance of the abdominal wall in patients with congenital deficiency of the abdominal wall musculature.[34] The skin usually has an irregularly wrinkled appearance similar to that of a prune. The condition has also been called the triad syndrome because there are three major features: deficiency of abdominal muscles, hydroureteronephrosis, and cryptorchidism.[35,36] Its cause is unknown. It has been suggested that early urinary tract obstruction[37] or urinary ascites[38] might be causative or that a primary mesodermal error might lead to the abdominal wall

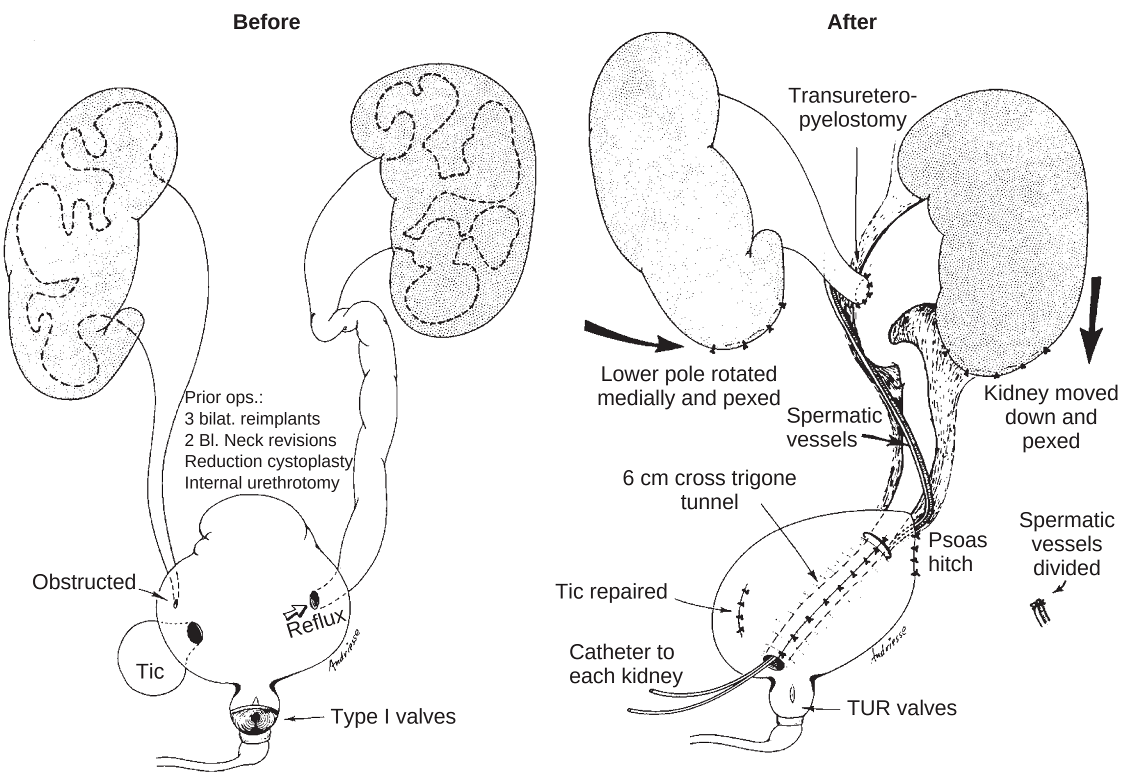

**FIGURE 119-10** A 14-year-old boy presented after three previous ureteral reimplantation operations but was left with a short obstructed megaureter on the right and massive reflux on the left. The left ureter was satisfactory for tapering and a fourth reimplant, and extra length was gained by sliding the kidney down and hitching the bladder upward.[81] Blood supply to that ureter was enhanced by maintaining the spermatic vessels with it. The right side was drained by transureteropyelostomy.

and genitourinary findings.[39] Almost all patients are male, but the condition has occurred in females.[40] We have cared for 48 patients with prune-belly syndrome since 1968, only 3 of whom were female. It has been described in a pair of twins,[41] one infant from a pair of twins, and in consecutive siblings with a mosaic chromosome abnormality.[42] Such cases suggest a genetic influence, but no clear pattern of inheritance has been identified. Like most pathologic entities, the prune-belly syndrome ranges from mild to severe in the degrees of both abdominal wall and urinary tract abnormality.

## ABDOMINAL WALL

The abdominal walls of four patients with the prune-belly syndrome are shown in Figure 119-11. In a typical case the abdominal wall is lax and protuberant, and close inspection shows coarse wrinkling of the skin. The abdominal wall may be so thin that loops of dilated ureter and intestine are easily visible and peristalsis can be seen or palpated. A protuberant abdomen and flaring rib margins are common, and the lower sternum is often depressed. As the child becomes older, the skin often becomes smoother; however, the lower abdomen may be remarkably protuberant in a potbellied appearance. Histologic examination of the abdominal wall has revealed both absence and hypoplasia of muscle, particularly in the lower, central area.[43] Normal relationships of muscle groups may be preserved, or they may be fused as a single fibrotic layer. Innervation does appear to be intact.[44] Poor support of the lower chest wall leads to an ineffective cough mechanism in many of these children and may make them more prone to respiratory infections. The lax abdominal wall may also contribute to poor bladder and bowel function. Interestingly, wound healing does not appear compromised and the appearance and function of the abdominal wall may be improved by surgical repair. The earliest and most simple techniques involved a midline incision and closure after trimming redundant skin and thinned abdominal wall from either side. Randolph and colleagues[45] described a nearly transverse incision extending from the tip of the lowest rib on either side to the symphysis pubis with central excision. Techniques reported by Ehrlich[46,47] and Monfort[48,49] (Fig. 119-12) preserve a central musculofascial strip, which is overlapped by better lateral fascia and skin. Both provide adequate exposure for orchiopexy or genitourinary reconstruction at the same time.

## KIDNEYS AND URETERS

Renal architecture and function vary widely in prune-belly syndrome. In some cases the kidneys are severely dysplastic and the infants die soon after birth of renal failure (Fig. 119-13).[50,51] At the other end of the spectrum are patients with relatively normal kidneys. Some element of renal dysplasia is found in more than half of patients with prune-belly syndrome,[51] and the severity is a major determinant of patient prognosis. The degree of dysplasia may vary greatly from side to side in the same patient. It tends to be worse in patients with bladder outlet obstruction (urethral atresia) and imperforate anus.[52]

This wide variability in severity is seen not only microscopically in the renal parenchyma but also in the collecting system

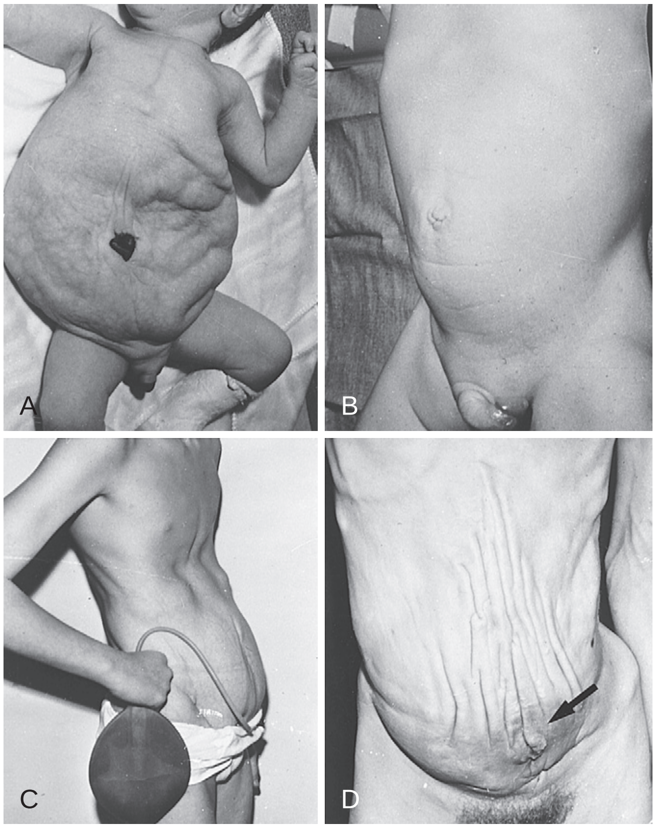

**FIGURE 119-11** Variable appearance of the abdominal wall in the prune-belly syndrome. **A,** Neonate with typical features of severe prune-belly syndrome. Note the sagging flanks and loops of bowel visible beneath extremely thin abdominal wall with deficient musculature. **B,** Mild case of prune-belly syndrome in an 8-week-old boy. Note the slight wrinkling of the skin of the lower abdomen and underlying distended bladder. The abdominal wall is lax but more developed than the patient shown in **A. C,** An 18-year-old patient with typical protuberant abdomen seen in prune-belly syndrome. Note inward protrusion of the lower sternum, which is common in these patients. A long-standing nephrostomy and cystostomy have been present since infancy. The urinary tract was subsequently reconstructed. **D,** A 16-year-old patient with severe wrinkling of the abdominal wall. The patient had long-standing end ureterostomies (*arrow*). Marked kyphoscoliosis is present. An undiversion operation was performed subsequently.

of the kidney, which can be dilated and have a peculiar dysmorphic appearance (Fig. 119-14). The ureters are characteristically dilated, elongated, and tortuous to a much greater degree than is seen in males with even high-grade obstruction from urethral valves. Some patients have scant muscle in the ureteral wall; others have well-developed muscle. In general, the upper ends of the ureters have better preserved architecture than do the lower ends.[53] Collagen is often increased and muscle mass decreased in the ureteral wall, especially when there is massive reflux.[54] In some patients the ureteropelvic junction is extremely tortuous but not obstructed. In others, ureteropelvic junction obstruction is present. Peristalsis is poor in some ureters and active but ineffective in others because the walls of the ureters cannot coapt. Repeat urinary infection can lead to inflammation and further fibrosis of the ureter, aggravating an already compromised situation. The hydronephrosis at the level of the kidney is often less remarkable than that of the distal ureter and bladder, and the parenchyma is sometimes better preserved than might be expected from the degree of distal dilation. Up to 85% of patients with prune-belly syndrome have vesicoureteral reflux.[55] The reflux may be difficult to grade because of the dysmorphism but often involves a massive volume of urine that may interfere with bladder dynamics and make the patient prone to urinary tract infection.

## BLADDER

In these patients the bladder usually has a large capacity. Most bladders feature a large diverticulum-like dome involving the area of the urachus (see Fig. 119-14). In those patients with urethral atresia, the dome may drain through a patent urachus at the umbilicus. Endoscopy shows that the wall of the bladder is usually smooth, not trabeculated. The ureteral orifices are often lateral and somewhat craniad. The orifices are often widely dilated, consistent with the massive reflux seen in most cases. The bladder neck is abnormally wide and funnels down into a dilated prostatic urethra. Grossly, the bladder wall is usually thick and quite vascular. The thickness of the bladder wall is not the result of hypertrophied muscle. Histologic examination reveals muscle and abundant collagen and fibrous tissue. The bladder will usually function as an adequate, if not enlarged, reservoir with good capacity and compliance, but it may not empty efficiently. Massive reflux, diminished detrusor contractility, decreased sensation of fullness, poor abdominal wall support, and diverticulum-like malformations at the dome all may serve to prevent normal emptying. Despite those problems, about half of such patients can void spontaneously.[56] Both spontaneous improvement and deterioration in the quality of voiding have been noted. Reducing the size of the bladder by excising the dome should be considered in some cases.[57,58] Domectomy can improve emptying and decrease postvoid residual urine in select cases.[80] Some children with prune-belly syndrome benefit from bladder emptying by intermittent catheterization.[56]

## URETHRA

In males with prune-belly syndrome, the dilation of the posterior urethra may be secondary to congenital deficiency of surrounding prostate tissue. The prostatic urethra appears heart shaped on voiding cystography. The external urethral sphincter is just below the apex. The narrowing of the prostatic urethra at the level of the external sphincter does not necessarily denote urethral obstruction, but some male patients have urethral atresia.[59] Those with urethral atresia who survive usually have a patent urachus that affords decompression of the urinary tract and allows for amniotic fluid needed for pulmonary development. Congenital urethral stenosis is also sometimes present. In the 45 males we have treated, true urethral valves were seen in 6; 20 had valvelike narrowing, usually at the level of a rudimentary verumontanum. Patients with poor bladder emptying may benefit from incision of such folds (Fig. 119-15). Besides atresia, the anterior urethra may be abnormal in the form of congenital megalourethra, the fusiform variant of which may distort development of all corpora in the phallus. Anterior urethral anomalies generally require surgical repair when present. Atresia may be repaired by open urethroplasty (Fig. 119-16), although progressive dilation may at times be effective.[60] Megalourethra is corrected by open tailoring of the urethral mucosa, which can be covered by the investing, periurethral tissue in several overlapping layers.

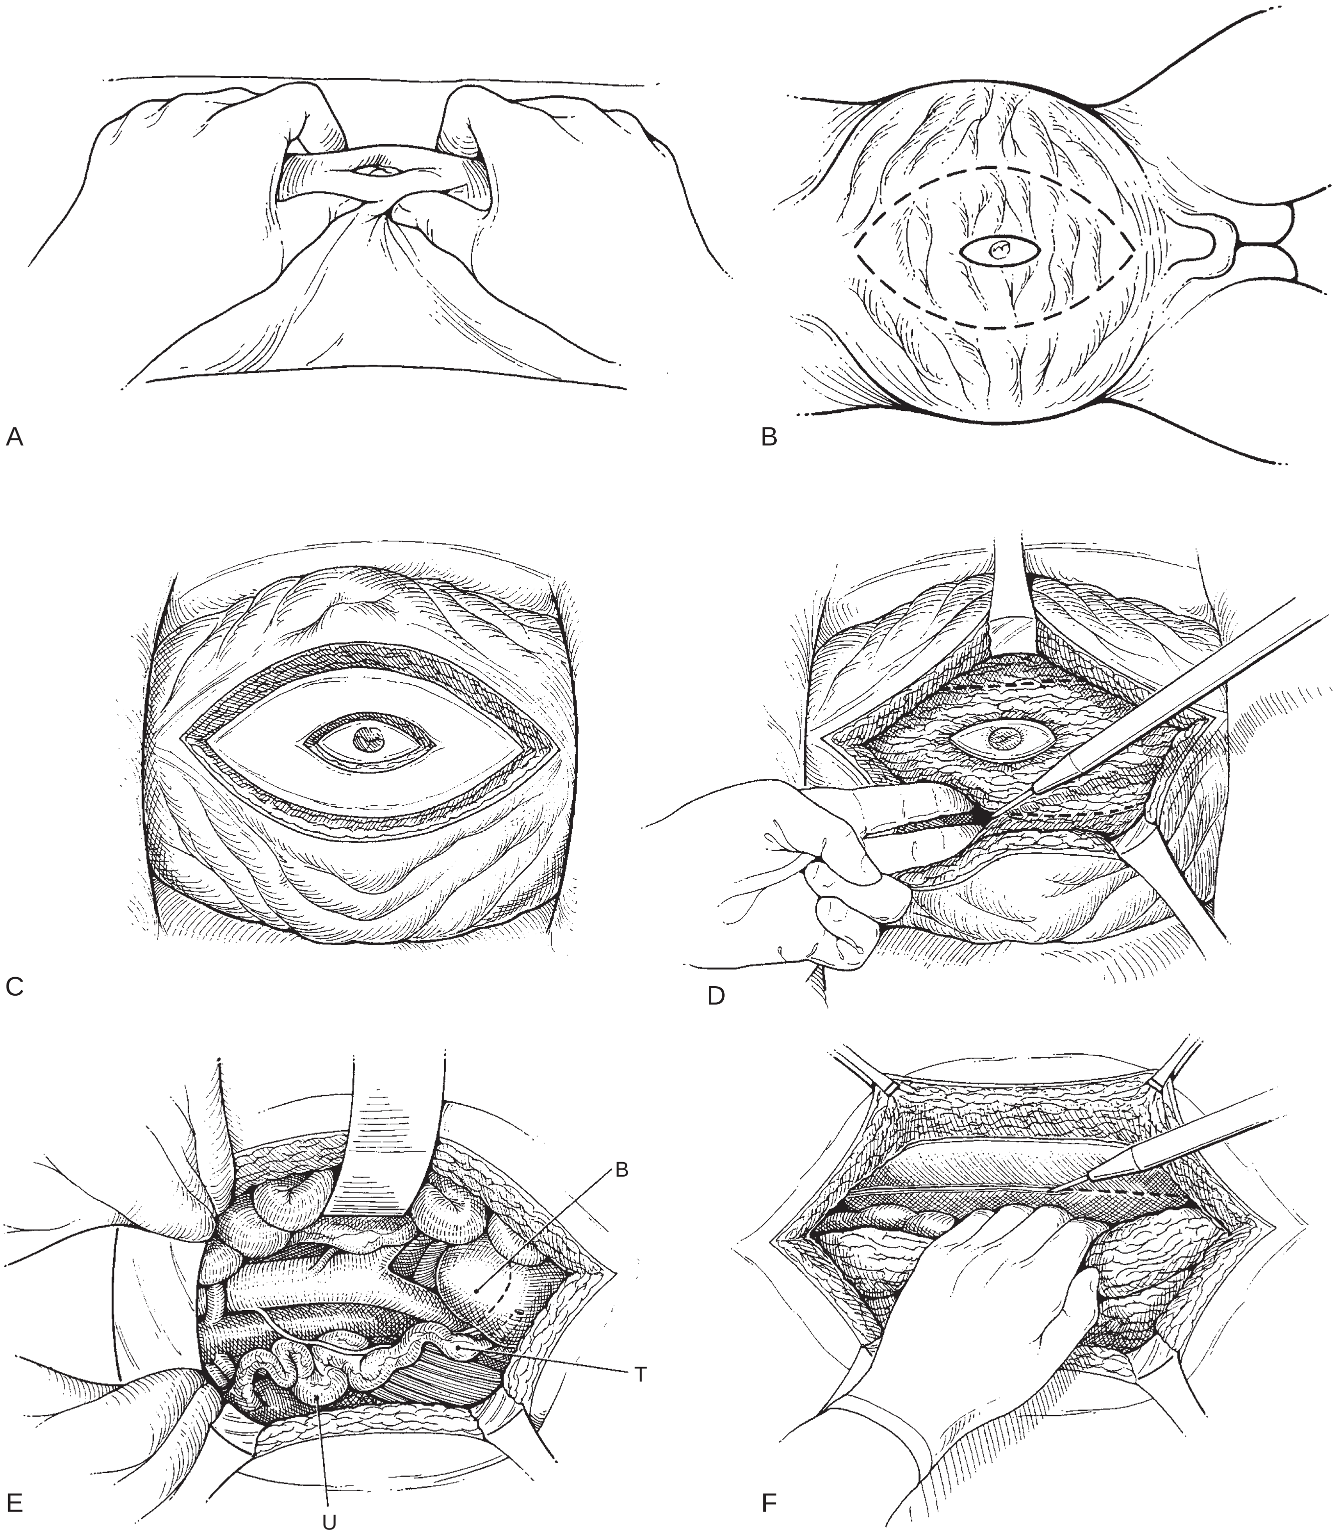

FIGURE 119-12 Surgical technique for Monfort abdominoplasty.[48,49] **A,** Delineation of redundancy by tenting up abdominal wall. **B,** Skin incisions are outlined with a separate circumscribing incision to isolate the umbilicus. **C,** Skin (epidermis and dermis only) is excised with electrocautery. **D,** Abdominal wall is incised at the lateral border of the rectus muscle on either side, creating a central musculofascial plate. **E,** Adequate exposure is provided for concomitant transperitoneal genitourinary procedures by retracting the central strip laterally. **F,** Completion of abdominoplasty by scoring of the parietal peritoneum underlying the lateral abdominal wall musculature with electrocautery.

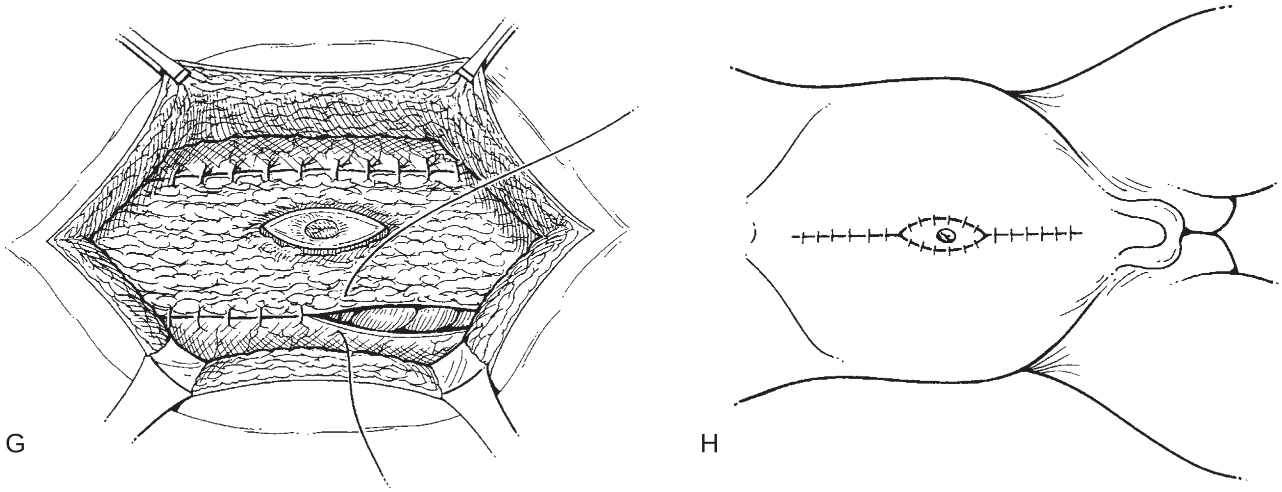

**FIGURE 119-12—CONT'D.** **G,** The edges of the central plate are sutured to the lateral abdominal wall musculature along the scored line. **H,** Lateral flaps are brought together in the midline, with closed suction drains placed between the lateral flaps and the central plate. Skin is brought together in the midline, enveloping the previously isolated umbilicus. (From Woodard JR, Perez LM: Prune-belly syndrome. In Marshall FF (ed): Operative Urology. Philadelphia, WB Saunders, 1996.)

## TESTES

Bilateral undescended testes lie in the abdomen in most males with prune-belly syndrome. The testes are usually smaller than normal and lie well inside the internal inguinal ring, much like ovaries in females. The spermatic vessels are shorter than normal, and there is often dysjunction of the epididymis from the testis. The vasa may be tortuous, and atresia of the vas is not uncommon. The pelvic peritoneum adjacent to the vas deferens usually has an abundant blood supply, which makes the Fowler-Stephens method of orchidopexy possible.[61] This technique involves dividing the spermatic vessels in the abdomen above the testis while mobilizing the testis with a broad strip of pelvic peritoneum and collateral blood supply surrounding the vas deferens. The goal of orchidopexy is to place the testes in the scrotum, where they can be monitored for development of malignancy and for psychologic reasons. Fertility has not been reported in these patients, although Leydig function leading to secondary sexual development with penile growth and libido is usually normal. Most surgeons have found that bringing a high testicle into the scrotum is easier in the young infant, in whom the relative distance is shorter.[62] Laparoscopic orchidopexy has been used for these patients[63] and may be particularly useful for a staged Fowler-Stephens technique. Access technique, insufflation pressure, and port stabilization may have to be modified because of the floppy abdominal wall.[64]

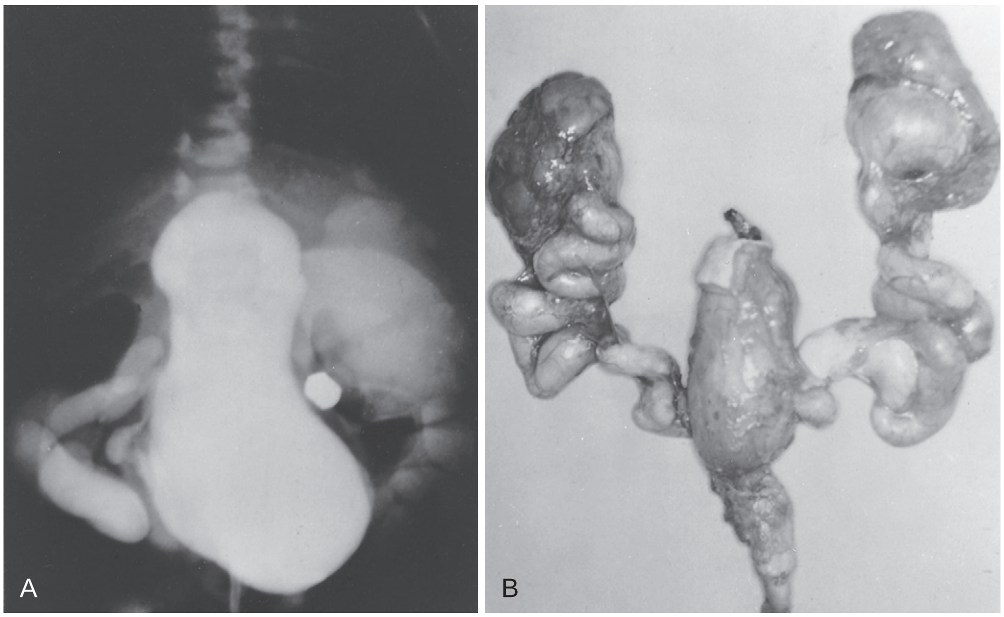

**FIGURE 119-13** Prune-belly syndrome in a neonate who died at 1 week of age with uremia. **A,** Cystogram showing large, elongated bladder with diverticulum-like dome, often seen in prune-belly syndrome. Massive reflux into dilated, convoluted ureters. **B,** Postmortem specimen of urinary tract. Note attachment of bladder to navel and cystic, dysplastic kidneys.

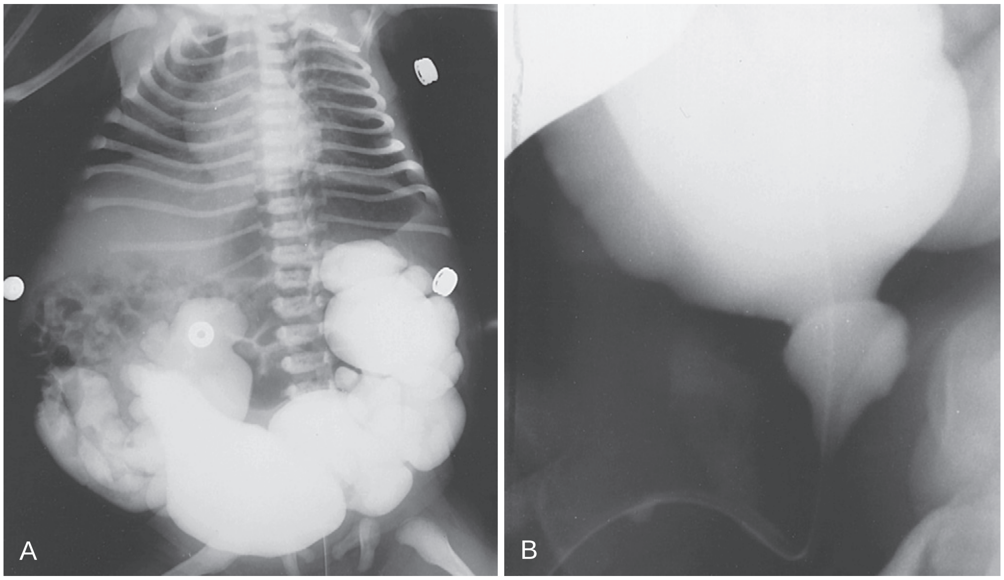

**FIGURE 119-14** Typical severe prune-belly case. **A,** Cystogram. Note large bladder, with appearance of an inverted light bulb and massive reflux into convoluted ureters. When straightened, the ureters were longer than the patient's legs. **B,** Cystourethrogram. Note smooth wall of bladder, open bladder neck, and heart-shaped urethra.

## OTHER ANOMALIES

Many patients with prune-belly syndrome have musculoskeletal or orthopedic abnormalities that require treatment.[65,66] Most of these patients have malrotation with nonfixation of the colon, but intestinal obstruction with midgut volvulus is extremely rare. Imperforate anus may be seen in prune-belly syndrome. All of the females we have treated for prune-belly syndrome have had cloacal malformations. Pulmonary hypoplasia is seen in some cases, and such severe cases are also prone to pulmonary infection. Pectus excavatum is common, and the abdominal wall musculature is weak. Various types of congenital heart disease may occur in association with prune-belly syndrome.

## CLINICAL MANAGEMENT

A newborn with prune-belly syndrome should be evaluated carefully because of the potential for sepsis. Any study that involves catheterization should be performed under cover of appropriate antibiotics and with meticulous aseptic technique. The dilated urinary tract, which may contain a large volume of urine and drain poorly, does not tolerate the introduction of bacteria. In some babies with poor renal function and dysplastic kidneys, early death from renal failure may be predestined due to associated pulmonary hypoplasia. Measurement of serum creatinine levels and, particularly, creatinine clearance identifies infants who have a reasonable measure of kidney function.

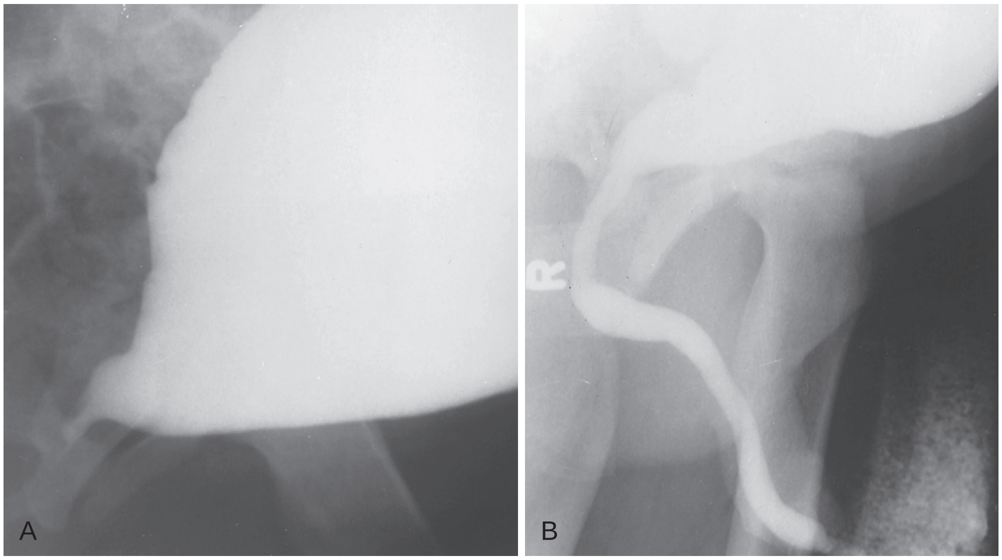

**FIGURE 119-15** Voiding urethrograms. **A,** Preoperative study showing typical dilated proximal urethra and wide bladder neck, with abrupt cutoff of contrast distal to rudimentary veru. There was a urethral valve. **B,** Postoperative study 7 months later showing free flow and normal caliber of the entire urethra.

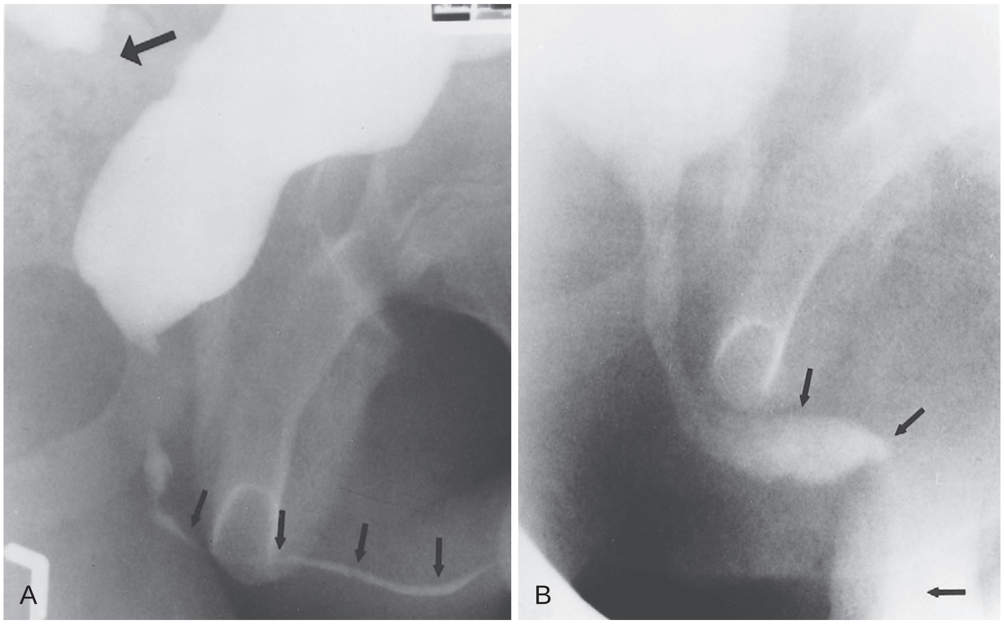

**FIGURE 119-16** Cystourethrograms. **A,** Preoperative. Note hypoplastic urethra (*small arrows*) and unusual obstruction of a megaureter by ureteral valve (*large arrow*). **B,** Postoperative study after long preputial patch graft to urethra.

Prune-belly syndrome in babies represents one of the most controversial conditions in pediatric urology. At one end of the therapeutic spectrum are those who advocate watchful waiting and minimal surgical intervention, citing a delicately balanced uropathy.[67–69] Others favor major reconstructive surgery when indicated.[8,57,70–76] It should be emphasized that reconstructive surgery in an infant with prune-belly syndrome should not be undertaken unless expert anesthesiology and medical support are available and the surgeon has extensive experience doing such surgery. Furthermore, a major reconstructive operation should not be considered unless the baby's overall status including pulmonary function and absence of established urinary tract infection is reasonable. Woodard and Zucker have suggested that an aggressive approach must be considered with caution because the surgery is difficult and the patients are vulnerable to pulmonary complications.[76]

Much of this controversy centers on the appropriate role for reconstruction of the urinary tract. There is little question that the intra-abdominal testes should be brought down by orchiopexy at an early age. Likewise, many patients and families will request reconstruction of the abdominal wall, for psychologic reasons if none other. It is our preference to perform such repairs at the same time as urinary tract reconstruction if necessary. If the patient will tolerate it from a pulmonary standpoint, we favor one longer reconstruction to repair everything rather than putting the same patient through multiple surgeries.

When initial evaluation demonstrates clear obstruction, correction should be performed whether it involves ureteropelvic junction, ureterovesical junction, or bladder outlet (Fig. 119-17). Most patients have some underlying renal dysplasia, and secondary insult from obstruction should not be allowed. It is our experience that most patients with this syndrome and vesicoureteral reflux eventually undergo repair. Classic grading systems for reflux may not apply to such patients; however, reflux in patients with prune-belly syndrome is often massive in volume. Early observation while the patient is on daily antibiotics to prevent infection may be appropriate and allow evaluation of bladder emptying or other issues. If reflux persists, correction is appropriate. When patients with reflux suffer breakthrough urinary tract infection or deterioration in renal function, repair of the reflux should be undertaken.

In considering the urinary system in patients with this syndrome, it may be useful to categorize them into three groups as described by Smith and Woodard.[77] The categories roughly correlate with the degree of renal dysplasia present. Group I patients usually have both severe renal dysplasia and pulmonary hypoplasia and do not survive. Urologic intervention will not rescue such patients. Group III patients generally have a mild or incomplete form of the syndrome and well-preserved renal function. Although some such patients may have impressive dilation of the urinary tract, little urologic intervention may be required if the patients do not suffer recurrent urinary tract infection. Definite indications for intervention in group II patients with intermediate degrees of dysplasia and renal dysfunction are less clear. These patients typically have full-blown features of the syndrome and a stagnant urinary system at best. Clearly, some such patients will progress to renal insufficiency with or without surgical intervention.[69,78] So many variables are present in patients with prune-belly syndrome that it remains difficult to predict the natural history for a given patient early in presentation. Careful surveillance is critical, and we favor surgical intervention in group II patients if they suffer from recurrent infection or deterioration of renal function. Those two problems often go hand in hand. We believe that correction of obstruction or reflux, optimizing bladder emptying, and avoidance of infection may prevent renal insufficiency in some patients with marginal function or, at least, prolong the time until they suffer insufficiency. It is clear that the scientific evidence to support such intervention, or argue against it, is largely anecdotal at this point.

We have performed reconstructive surgery on 40 patients with prune-belly syndrome; 12 were primary cases (Figs. 119-18 and 119-19), and 28 were secondary cases that had been previously treated with surgery elsewhere. Twenty-four of the latter 28 patients had undergone urinary diversion.[72,79] This illustrates how often urosepsis occurs in patients with prune-belly syndrome and has led to various types of surgery for diversion in the past (Fig. 119-20). We

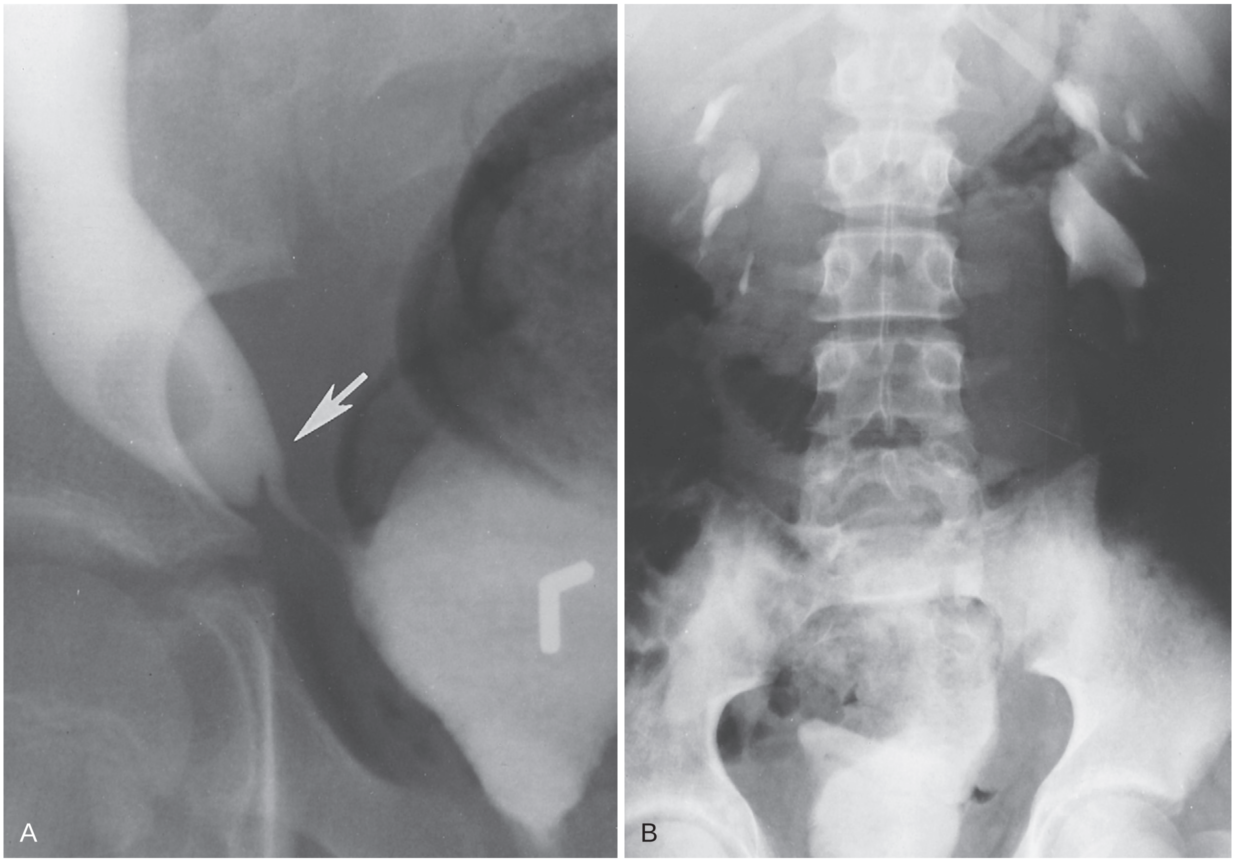

**FIGURE 119-17** Intravenous pyelograms from same patient shown in Figure 119-16. **A,** Ureteral valve in right megaureter (*arrow*). **B,** Intravenous pyelogram 3 years after extensive undiversion.

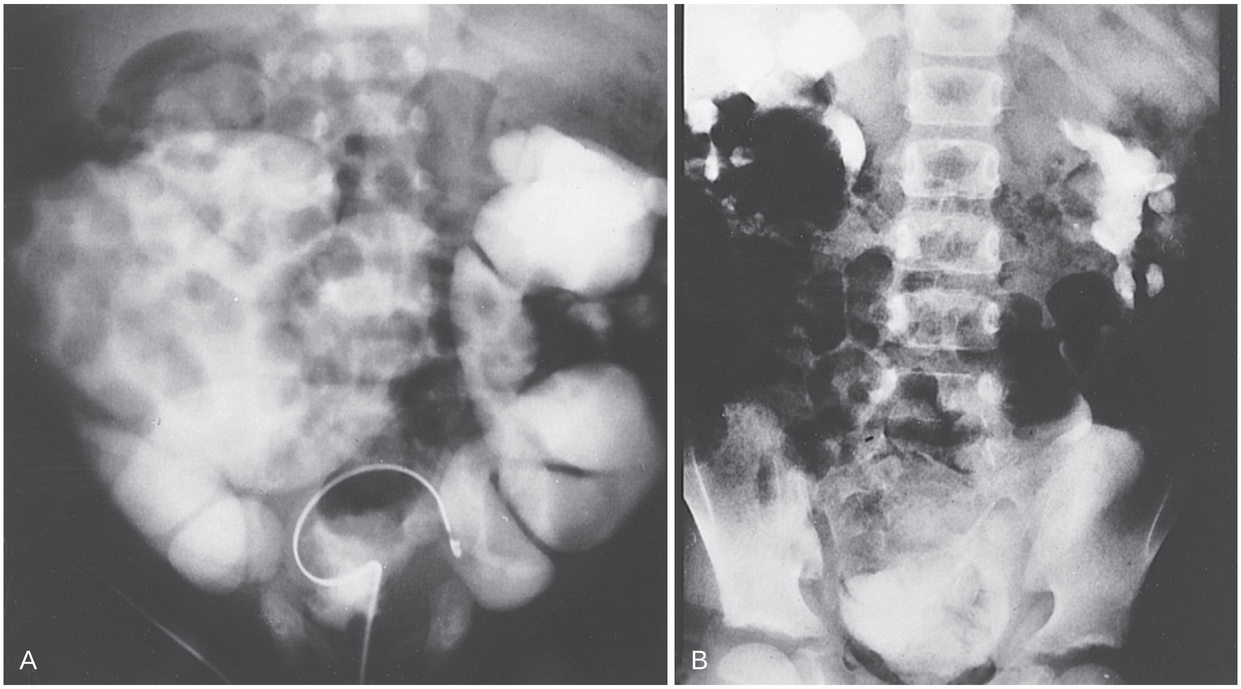

**FIGURE 119-18** Infant with prune-belly syndrome. **A,** Preoperative cystogram. There is massive bilateral reflux into elongated and tortuous ureters, especially on the right side. Note the dysmorphic collecting system of the left kidney. Total reconstruction was performed. **B,** Intravenous pyelogram at 7 years of age. The patient is well with no urinary tract symptoms. Note the contrast visible in the left ureter, which is of normal caliber. It is difficult to imagine that the great improvement in the appearance of the urinary tract does not equate with a better prognosis for the patient.

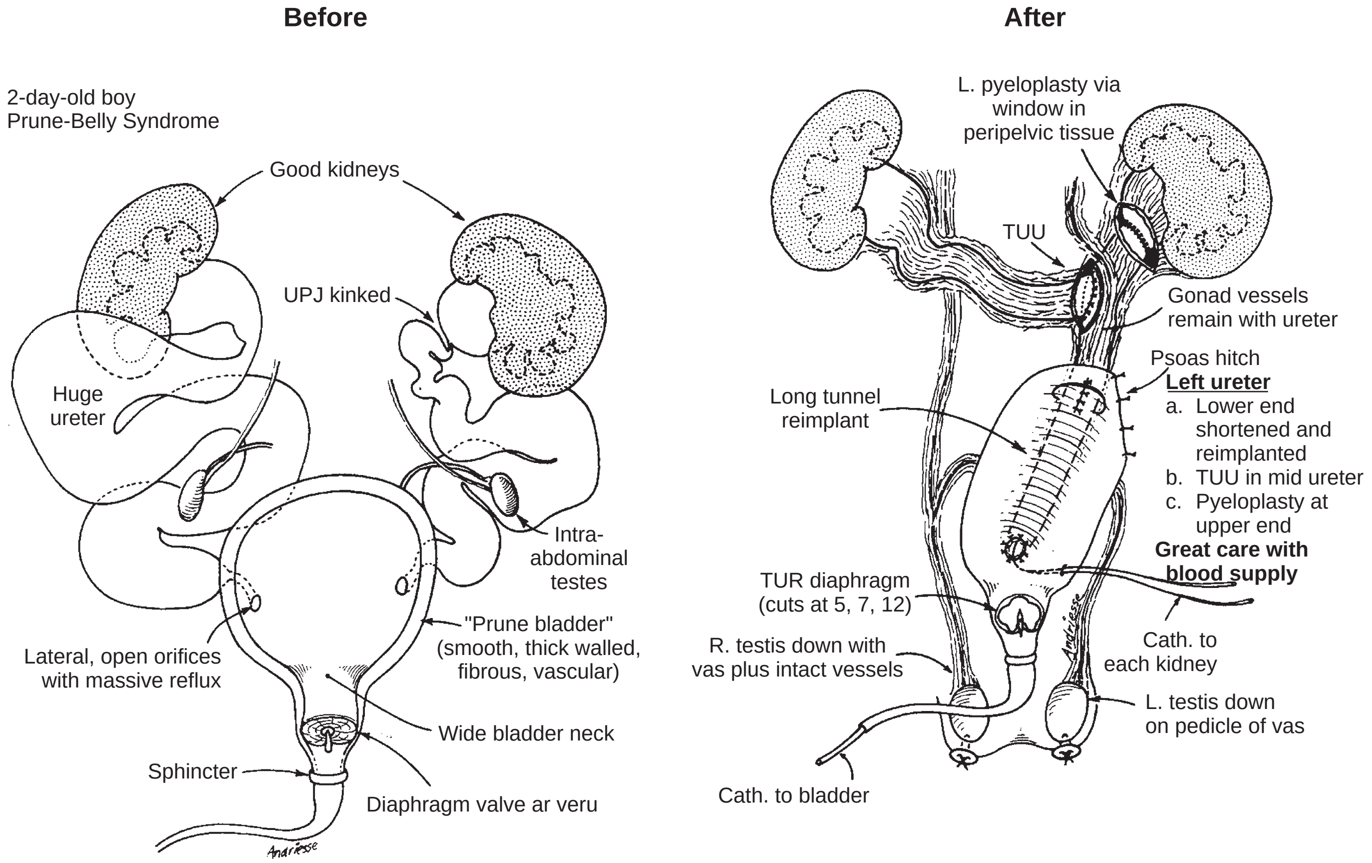

**FIGURE 119-19** Infant with prune-belly syndrome. Anatomy preoperatively and postoperatively.

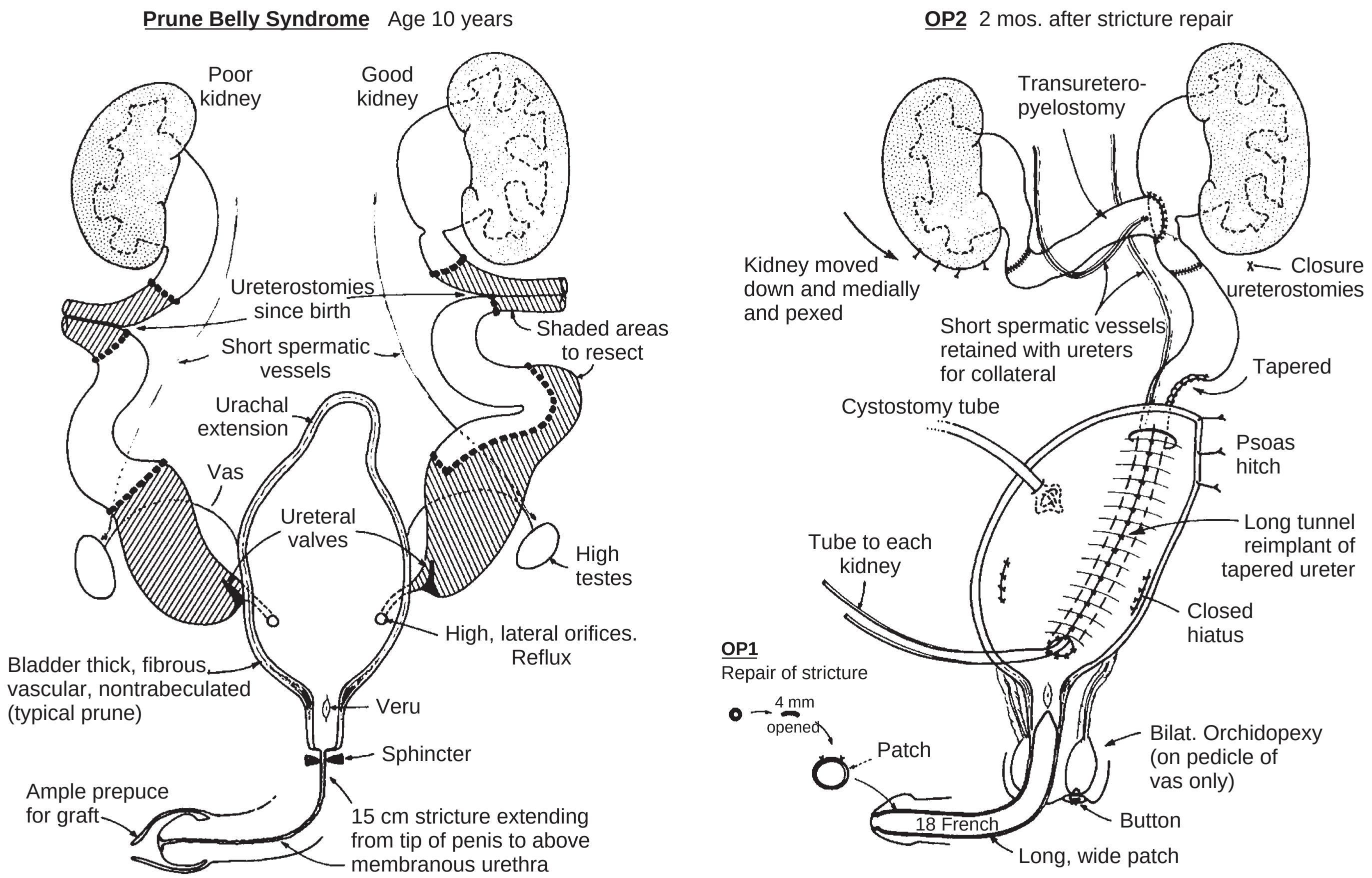

**FIGURE 119-20** 1-year-old boy with prune-belly syndrome, unusual anatomic findings, and long-standing ureterostomies. With operation 1, an extensive urethroplasty was performed with a long onlay of prepuce. Two months later, undiversion with urinary reconstruction and bilateral orchiopexies was performed. The patient voids normally and is continent. Renal function has been normal (serum creatinine 0.9 mg/dL and creatinine clearance 106 L/m$^2$ per day). Pyelograms are shown in Figure 119-17.

generally favor reconstruction over diversion in such patients as long as their general condition allows it. Twelve of these patients had only one kidney because of previous nephrectomy. Thirty-five of the 40 patients are alive (time since surgery, 1 to 27 years). Eight patients have had renal transplantation. Eight more will probably require renal transplantation, given their current renal function. Five patients have died. One infant died in the hospital because of blood loss secondary to hemophilia and inadequate monitoring. Another infant died at home 2 months after surgery of pulmonary aspiration. Three late deaths occurred: one 3 years after renal transplantation; another 10 years after successful transplantation, from an automobile accident; and one 11 years after reconstruction from septicemia during dialysis. It should be noted that this series is a select group and does not necessarily reflect rates of death from renal dysplasia in primary infants with prune-belly syndrome.

## Conclusions

Some of the most impressive megaureters are found in patients with prune-belly syndrome, and they are often then associated with other clinical problems. The philosophy of treating selective cases by aggressive surgical reconstruction is the opposite of the "watchful waiting" espoused by others. Surgical intervention is actually a conservative method in that it attempts to decrease stasis, urinary tract infection, and renal failure, the natural history of many patients with the syndrome. Reconstruction is demanding and technically difficult in these patients. It also requires extensive anesthesiology expertise to maintain metabolic hemostasis in a young child undergoing major reconstruction. This surgery should be performed in centers where surgeons concentrate on major reconstructive surgery and have access to all of the requisite back-up systems.

CHAPTER 120

# Bladder and Cloacal Exstrophy

Lynn L. Woo, John C. Thomas, and John W. Brock III

The authors would like to acknowledge Romano T. DeMarco and James A. O'Neill, Jr. for their previous contributions to this chapter.

## Bladder Exstrophy

Bladder exstrophy is a rare midline defect and exists as part of a larger spectrum of abdominal-pelvic fusion abnormalities, known collectively as the exstrophy-epispadias complex (EEC). Presentation of EEC can range from isolated glanular epispadias to cloacal exstrophy, in which several other organ systems may be affected. In the case of bladder exstrophy, the open bladder can be seen everting through a lower abdominal wall defect. This is accompanied by epispadias, a widened pubic diastasis, and an anus that is anteriorly displaced. Over the past 2 decades, continued improvements in the methods of functional bladder closure have dramatically increased reconstructive success rates; however, achieving the ultimate goals of adequate bladder capacity, urinary continence, and a good cosmetic outcome remain challenging.

### HISTORICAL PERSPECTIVES

The earliest account of bladder exstrophy can be found on Assyrian tablets, dating back to 2000 BC. Von Grafenberg first described the medical condition in 1597, and Mowat is credited with providing a complete description of bladder exstrophy in 1748. It was not until 1780, however, that Chaussier first coined the term "exstrophie."[1] Early management of bladder exstrophy included the application of an external urinary receptacle to the surface of the exposed bladder,[2] ureterosigmoidostomy,[3] transplantation of the bladder trigone into the rectum,[4] and coverage of the exposed bladder with lateral skin flaps.[5] These methods were fraught with continued urinary incontinence and/or urosepsis. Contributions by Coffey, Nesbitt, Leadbetter, and Clarke improved the technique of ureterosigmoidostomy; however, associated morbidities included infection, electrolyte abnormalities, and malignancy.[6] Complete urinary diversion into the colon or alternate conduit was preferentially used to provide continence and minimize infection, but the problems of anatomic reconstruction and sexual function persisted.

Paralleling efforts to develop improved methods of urinary diversion were attempts at successful bladder closure. Trendelenburg described bilateral sacroiliac osteotomies and the application of a pelvic sling to support bladder and abdominal wall closure in 1892.[7] The first case of successful closure and continence in a female patient with bladder exstrophy was not reported until 1942 by Young.[8] Michon subsequently reported successful reconstruction in a male patient 6 years later.[9] Despite these accounts of functional closure, a 1970 review of 329 cases by Marshall and Muecke concluded that only 19% of patients undergoing total reconstruction had fair-to-satisfactory results.[10] These unfavorable outcomes were reported by others, spurring efforts to improve methods of surgical repair.[11,12]

### EPIDEMIOLOGY

The incidence of bladder exstrophy is estimated at between 1 in 10,000 and 1 in 50,000 live births[13] with a higher male-to-female ratio of between 2.3:1 and 4:1.[14] Familial recurrence is approximately 1 in 100.[15] On the basis of a survey of 2500 indexed cases, familiar occurrence was found to be 1 in 275.[14] Multiple reports of bladder exstrophy among identical twins have demonstrated variability in involvement of one or both twins. Subsequent siblings and the offspring of individuals with bladder exstrophy may be at increased risk of being affected.[14,15] However, no clear pattern of inheritance has been characterized and no specific genetic or environmental factor that predisposes to bladder exstrophy has yet been identified.

### EMBRYOLOGY

The underlying embryologic defect shared by bladder exstrophy and other variants of the EEC is due to abnormal development of the cloacal membrane, a bilaminar structure composed of endoderm and ectoderm that overlies the cloacal cavity at the caudal end of the germinal disk.[16] In normal

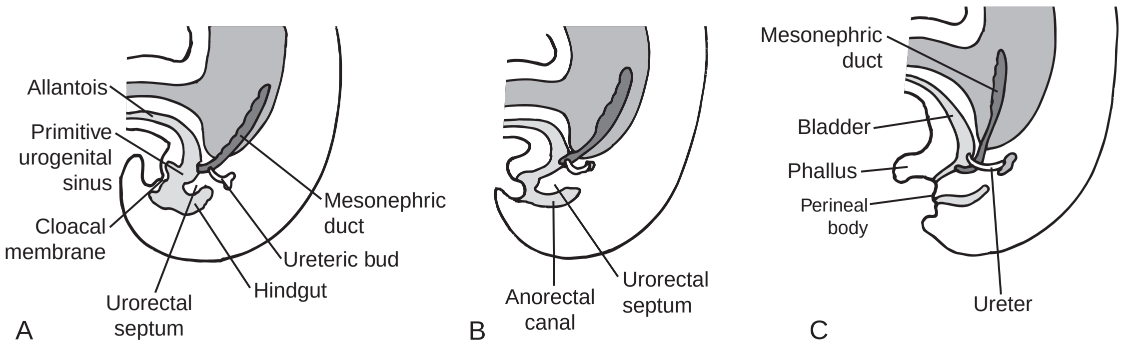

**FIGURE 120-1** Division of the cloaca in the urogenital sinus and rectum. **A,** At the end of the fifth week. **B,** At 7 weeks. **C,** At 8 weeks. (Modified from Sadler TW: Langman's Medical Embryology, 8th ed. Philadelphia, Lippincott Williams and Wilkins, 2000, p 316.)

development, lateral ingrowth of mesoderm occurs between the two layers of the cloacal membrane during the fourth and fifth weeks of gestation. This results in formation of the lower abdominal wall and pelvis. Subsequent caudal growth of the urorectal septum results in its fusion with the cloacal membrane, thus fully separating the cloaca into the bladder anteriorly and the rectum posteriorly (Fig. 120-1). The paired genital tubercles, which will give rise to the phallus, migrate medially to fuse in the midline. Normal perforation of the cloacal membrane occurs *after* fusion with the urorectal septum, at approximately the sixth week, resulting in formation of separate urogenital and anal openings.[17]

Migratory failure of the lateral mesodermal folds and abnormal overdevelopment of the cloacal membrane have both been proposed as potential causes of the prevention of normal mesodermal ingrowth to the cloacal membrane.[16,18] The lack of adequate mesodermal reinforcement is thought to result in *premature* rupture of the cloacal membrane, the timing of which determines the extent of the abdominal wall defect and degree/severity of urogenital tract involvement.[19] Rupture of the cloacal membrane after fusion with the urorectal septum results in bladder exstrophy, whereas rupture before fusion gives rise to the more severe presentation of cloacal exstrophy (see later discussion).

## CLINICAL PRESENTATION

In general infants with bladder exstrophy are born full term, without coexisting anatomic anomalies. At birth, an everted posterior bladder plate of varying size is seen in the midline of the lower abdomen. The mucosa of the exposed bladder in the newborn is typically smooth and pink. The umbilical cord exits from the superior-most border of the bladder plate, and a small umbilical hernia may be present (Fig. 120-2). In addition, there is significant widening of the pubic symphysis and the anus is anteriorly displaced. The levator ani complex is also divergent, leading to an inherent weakness in the pelvic floor and a tendency toward rectal prolapse and varying degrees of fecal incontinence. Associated inguinal hernias are common and have been reported in 82% of boys and 10% of girls.[20] The upper urinary tract is usually normal, though renal anomalies including ectopic, horseshoe, hypoplastic, dysplastic kidneys, and megaureters may be observed.[21] Vesicoureteral reflux occurs in the vast majority of children after bladder closure, secondary to an exaggerated lateral course of the ureters within the pelvis and lack of adequate submucosal tunnel in the bladder wall.[22] With continued exposure and chronic inflammation, the exstrophied bladder becomes thickened and polypoid (Fig. 120-3). Long-term exposure may eventually result in a fibrotic, rigid bladder plate that is ultimately unsuitable for closure.

## GENITAL DEFECTS—MALE

In the male infant, the open and everted urethral plate can be seen joining the exposed bladder. The penis is characteristically short with a flattened, everted glans. The prepuce is located on the penile ventrum (Fig. 120-4). The ejaculatory ducts are typically normal and exit at the exposed verumontanum in the posterior urethra. The base of the penis and scrotum are widely separated, with lateral displacement of the corporal bodies and neurovascular bundles. Historically it was believed that the individual corpora were of normal caliber and appeared shortened because of their attachment to the widened pubic diastasis and associated dorsal chordee.

**FIGURE 120-2** Typical findings of classic bladder exstrophy in a newborn male. The bladder plate is small, and a small hernia is evident at its superior border. The penis is foreshortened, with widely splayed corporal bodies and glanular separation. The urethral plate is short and located on the anterior surface of the split phallus.

FIGURE 120-3 When the bladder has been exposed for at least 1 week after birth and the mucosa is subjected to continued exposure and inflammation, polypoid excrescences typically appear, as in this female infant.

More recently, an MRI-based study by Silver and colleagues of adult men with exstrophy and age-matched controls found that although the length of the posterior corporal bodies was the same between groups, anterior corporal length in men with exstrophy was nearly 50% shorter than that of controls.[23] Therefore the penis appears shortened not only secondary to corporal divergence, dorsal chordee, and abnormal crural attachments to the corpora cavernosa but also because of an inherent deficiency of corporal tissue (Fig. 120-5). The testes may appear to be undescended, but in most cases they are actually retractile and will eventually reside in the scrotum without the need for formal orchiopexy. Should it be required, orchiopexy is performed in conjunction with inguinal hernia repair.

## GENITAL DEFECTS—FEMALE

The clitoris is bifid, with divergence of the mons pubis, labia, and clitoral halves (Fig. 120-6). The urethra and vagina are shortened, and the introitus is anteriorly displaced. The vaginal orifice is often stenotic. The uterus and adnexa are typically normal, though vaginal and uterine duplication have been reported.[24,25] Uterine prolapse occurs commonly in female patients, secondary to the inherent weakness in pelvic floor support.

## PELVIC DEFECTS

Some degree of widening of the pubic symphysis is present in all cases of bladder exstrophy and contributes to outward rotation and eversion of the pubic rami at their junctions with the ischial and iliac bones (Fig. 120-7). Using computed tomography (CT), Sponseller and colleagues further characterized the pelvic anatomy of a large group of exstrophy patients, noting a significantly increased distance between the triradiate cartilages (31%), external rotation of the anterior pelvis (18%), and 30% shortening of the pubic rami.[26] On the basis of three-dimensional models generated by CT, Stec and colleagues observed that among children with exstrophy, the levator ani muscles were more posteriorly positioned and outwardly rotated. Furthermore, the puborectal sling had a more flattened configuration and supported twice the body cavity area in exstrophy patients.[27] As mentioned previously, these pelvic floor defects predispose to pelvic organ and rectal prolapse in this patient population.

## PRENATAL DIAGNOSIS

The use of prenatal ultrasound (US) and MRI has improved the antenatal diagnosis of bladder exstrophy, allowing for appropriate parental counseling and planning of postnatal management. The prenatal diagnosis of bladder exstrophy may be suggested on US by failure to visualize the bladder in the presence of normal kidneys and amniotic fluid.[28–30] In a review of prenatal US studies from 25 women who delivered infants

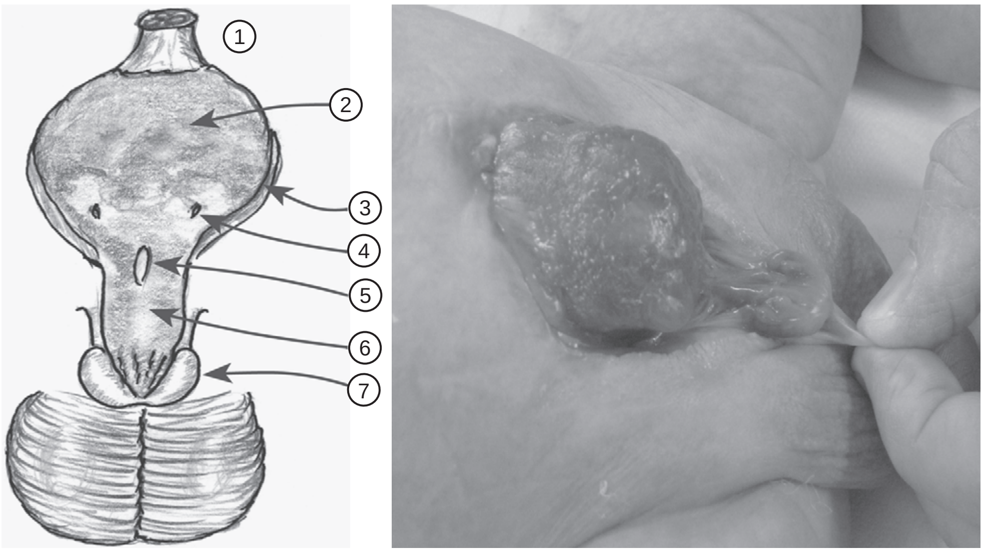

FIGURE 120-4 Classic exstrophy in the male. The penis is pulled downward to expose the dorsal aspect, revealing the urethral plate leading to the exposed bladder. *1,* umbilical cord; *2,* bladder mucosa; *3,* paraexstrophy tissues; *4,* left ureteric orifice; *5,* verumontanum; *6,* urethral plate; *7,* glans penis.

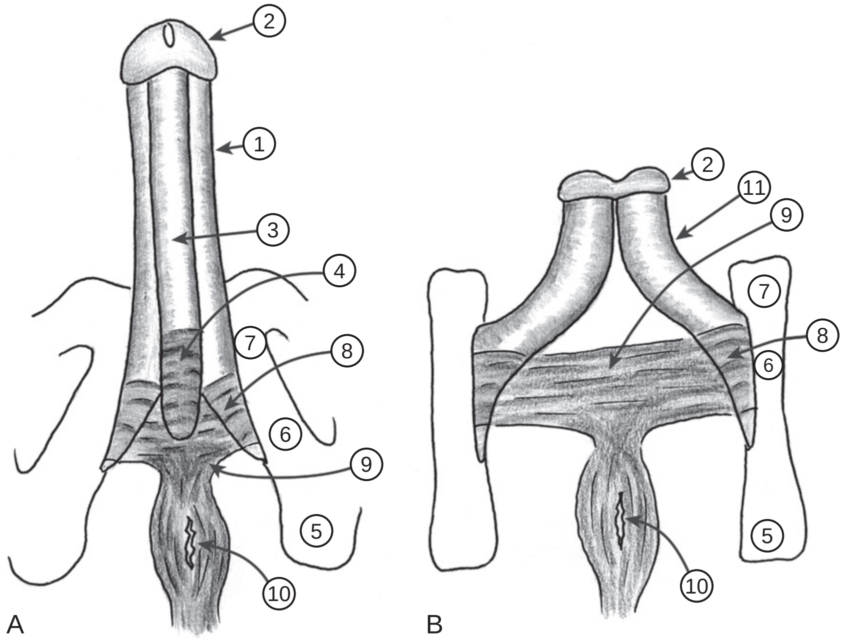

**FIGURE 120-5** Penile configuration in classic bladder exstrophy. Normal male perineum **(A)** and with bladder exstrophy **(B).** Note the loss of the normal triangular shape of the perineum and widening of the pubic symphysis. In the setting of exstrophy, the corpora cavernosa are widely separated and are intrinsically shorter. *1,* corpus cavernosum of the penis; *2,* glans penis; *3,* corpus spongiosum; *4,* bulbospongiosus muscle; *5,* ischium; *6,* ischiopubic ramus; *7,* pubis; *8,* ischio-cavernosus muscle and crus of penis; *9,* urogenital diaphragm; *10,* anus and external anal sphincter.

with exstrophy, Gearhart and colleagues observed the following features: absent bladder (71%), lower abdominal bulge (47%) and anteriorly displaced scrotum with small phallus in male fetuses (57%), low-set umbilical cord (29%), and abnormal widening of the iliac crest (18%).[31]

## SURGICAL RECONSTRUCTION

Surgical management of classic bladder exstrophy consists of functional closure of the native bladder, closure of the epispadic urethra and genitalia, and creation of a continence mechanism to allow for proper urine storage. Reconstruction may be accomplished in a multi- or single-stage (complete) repair. Multiple contemporary approaches including the modern staged reconstruction of exstrophy (MSRE) and complete primary reconstruction of exstrophy (CPRE) along with Warsaw,[32] Erlangen,[24] Mainz,[33] and Kelly[34] techniques have been published; however, for the purposes of this review, only the major principles of MRSE and CPRE are discussed.

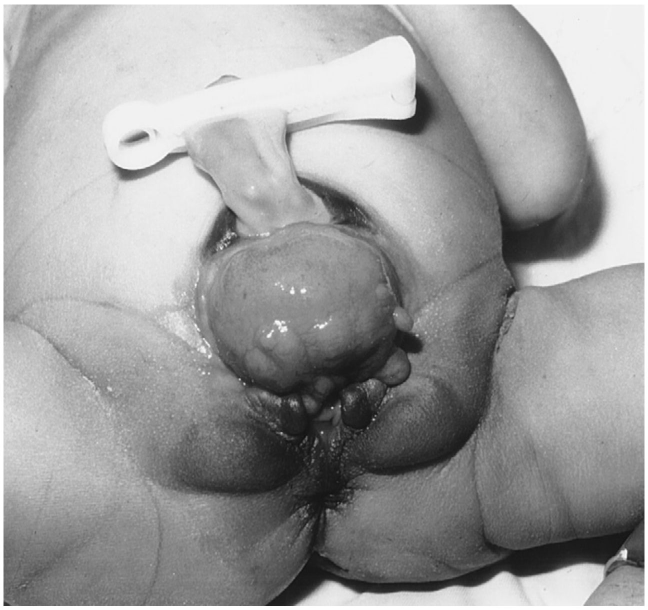

**FIGURE 120-6** Typical appearance of classic bladder exstrophy in a female. Note the widely divergent labia and anterior displacement of the vaginal introitus and anus.

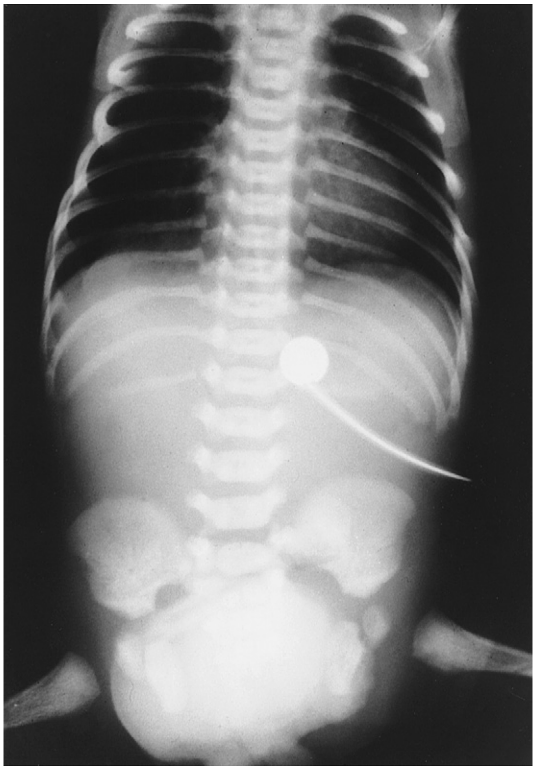

**FIGURE 120-7** Plain radiograph of a neonate with bladder exstrophy demonstrates the soft tissue mass effect of the exposed bladder, the wide diastasis of the symphysis pubis, and the posterior rotation of the acetabula.

## INITIAL MANAGEMENT

At birth, the umbilical cord should be ligated with a silk suture to avoid irritation of the bladder surface from the traditional plastic clip. The exposed bladder mucosa should be moistened with saline and protected with a nonadherent sheet of plastic wrap (e.g., Saran Wrap). A complete physical examination is performed to rule out associated anomalies and to assess the size of the bladder plate and extent of the genital defect. Renal US may be obtained to exclude hydronephrosis and/or other upper tract abnormalities. Prophylactic antibiotics should be administered.

## MODERN STAGED RECONSTRUCTION OF BLADDER EXSTROPHY

A three-stage approach for the treatment of bladder exstrophy was first pioneered by Jeffs and Cendron in the 1970s,[35,36] and continued improvements in technique have contributed to increased success of the procedure.[37–39] Stage 1 is performed at birth to protect the upper urinary tracts and assist later continent reconstruction. It consists of early closure of the bladder, posterior urethra, and abdominal wall with or without osteotomy. The primary objective of functional closure is to convert the bladder exstrophy into a complete epispadias.[40] Stage 2 is performed in later infancy and involves repair of the epispadias, with the goal of optimizing genital function and appearance, as well as increasing outlet resistance to promote bladder growth. Stage 3 is undertaken before school age and consists of bladder neck repair for continence and ureteral reimplantation for vesicoureteral reflux.

Primary functional closure is generally undertaken in the neonatal period, which offers several potential advantages. The pliability of the pelvic ring, in infants younger than 72 hours old, may obviate the need for osteotomy; early closure prevents further exposure and scarring of the bladder plate; there is theoretically less opportunity for bacterial colonization of the plate with decreased risk of postoperative infection. Alternatively, delayed closure in combination with pelvic osteotomy may be performed, allowing for patient growth and a period of time out of the hospital before reconstruction.

### Stage 1: Functional Closure

At the time of surgery, the patient should be prepped widely including the entire body anteriorly and posteriorly below the nipple line so that intraoperative turning is easier. Cardiopulmonary monitoring and adequate intravenous access are critical. Intraoperative and postoperative analgesia may be afforded by means of an epidural catheter. The most common technique of functional closure is based on descriptions by Jeffs and colleagues[36,41,42] and Duckett and Caldamone.[43] Figure 120-8 depicts the initial incisional template for bladder closure in the female infant, and Figure 120-9 details the complete sequence of stage 1 closure in the male. Traction sutures are placed into the glans penis, and ureteral catheters are secured in each ureteral orifice. An incision is made around the periphery of the exstrophic bladder plate, and a plane of dissection is established between the rectus fascia and bladder. The umbilical cord is excised, and umbilicoplasty may be performed during or after the initial procedure. Dissection is continued toward the pubis, and the incision is then extended

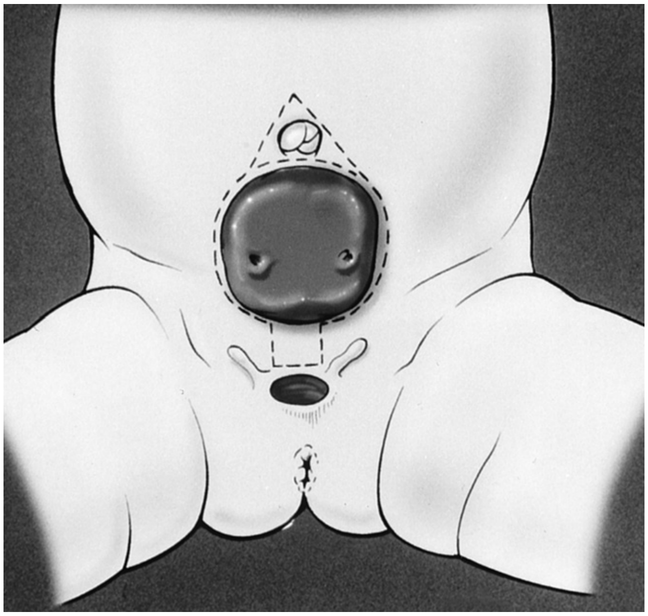

FIGURE 120-8 Typical findings of classic bladder exstrophy in a female and the incision template used for repair.

distally to the verumontanum on both sides of the prostatic urethra, leaving a wide strip of bladder neck and urethral plate.

A major objective of primary closure in the male patient is to place the bladder and prostate deep within the pelvis to achieve a more normal anatomic position.[44,45] In some boys, this maneuver results in inadequate length of the urethral plate for subsequent penile reconstruction. Duckett therefore proposed transection of the urethral plate, distal to the verumontanum, with the development of lateral paraexstrophic skin flaps, which could be then rotated medially to bridge the gap between the transected edges of the urethra.[46] Although this technique allows for better mobilization of the bladder, Gearhart and colleagues[41,47] reported a 40% complication rate associated with the use of paraexstrophy flaps. Urethral stricture is the most common complication and may be secondary to local tissue ischemia. The routine use of such flaps appears to be decreasing, though their application remains a viable option when a short urethral plate prohibits adequate bladder mobilization.[48]

If the urethral plate is left intact, it should be mobilized to the level of the prostate to create as much urethral length as possible. Following complete mobilization of the bladder, the corpora cavernosa are dissected off the inferior pubic rami bilaterally, taking care to preserve the neurovascular bundles and avoid penile devascularization. This maneuver aids in penile lengthening, primarily through release of dorsal chordee.[23] After placement of a Malecot suprapubic tube and exteriorization of the ureteral catheters, the bladder is closed anteriorly in the midline and the urethra tubularized over a 10- to 12-Fr sound. The first-stage repair thus results in an isolated penopubic epispadias, which is generally incontinent.

Closure of the pelvic ring is required to assist in abdominal wall closure. Pubic approximation without ancillary osteotomy may be possible in the immediate newborn period, when the bones are still malleable; however, osteotomy is generally required after 3 days of age. Although multiple techniques are

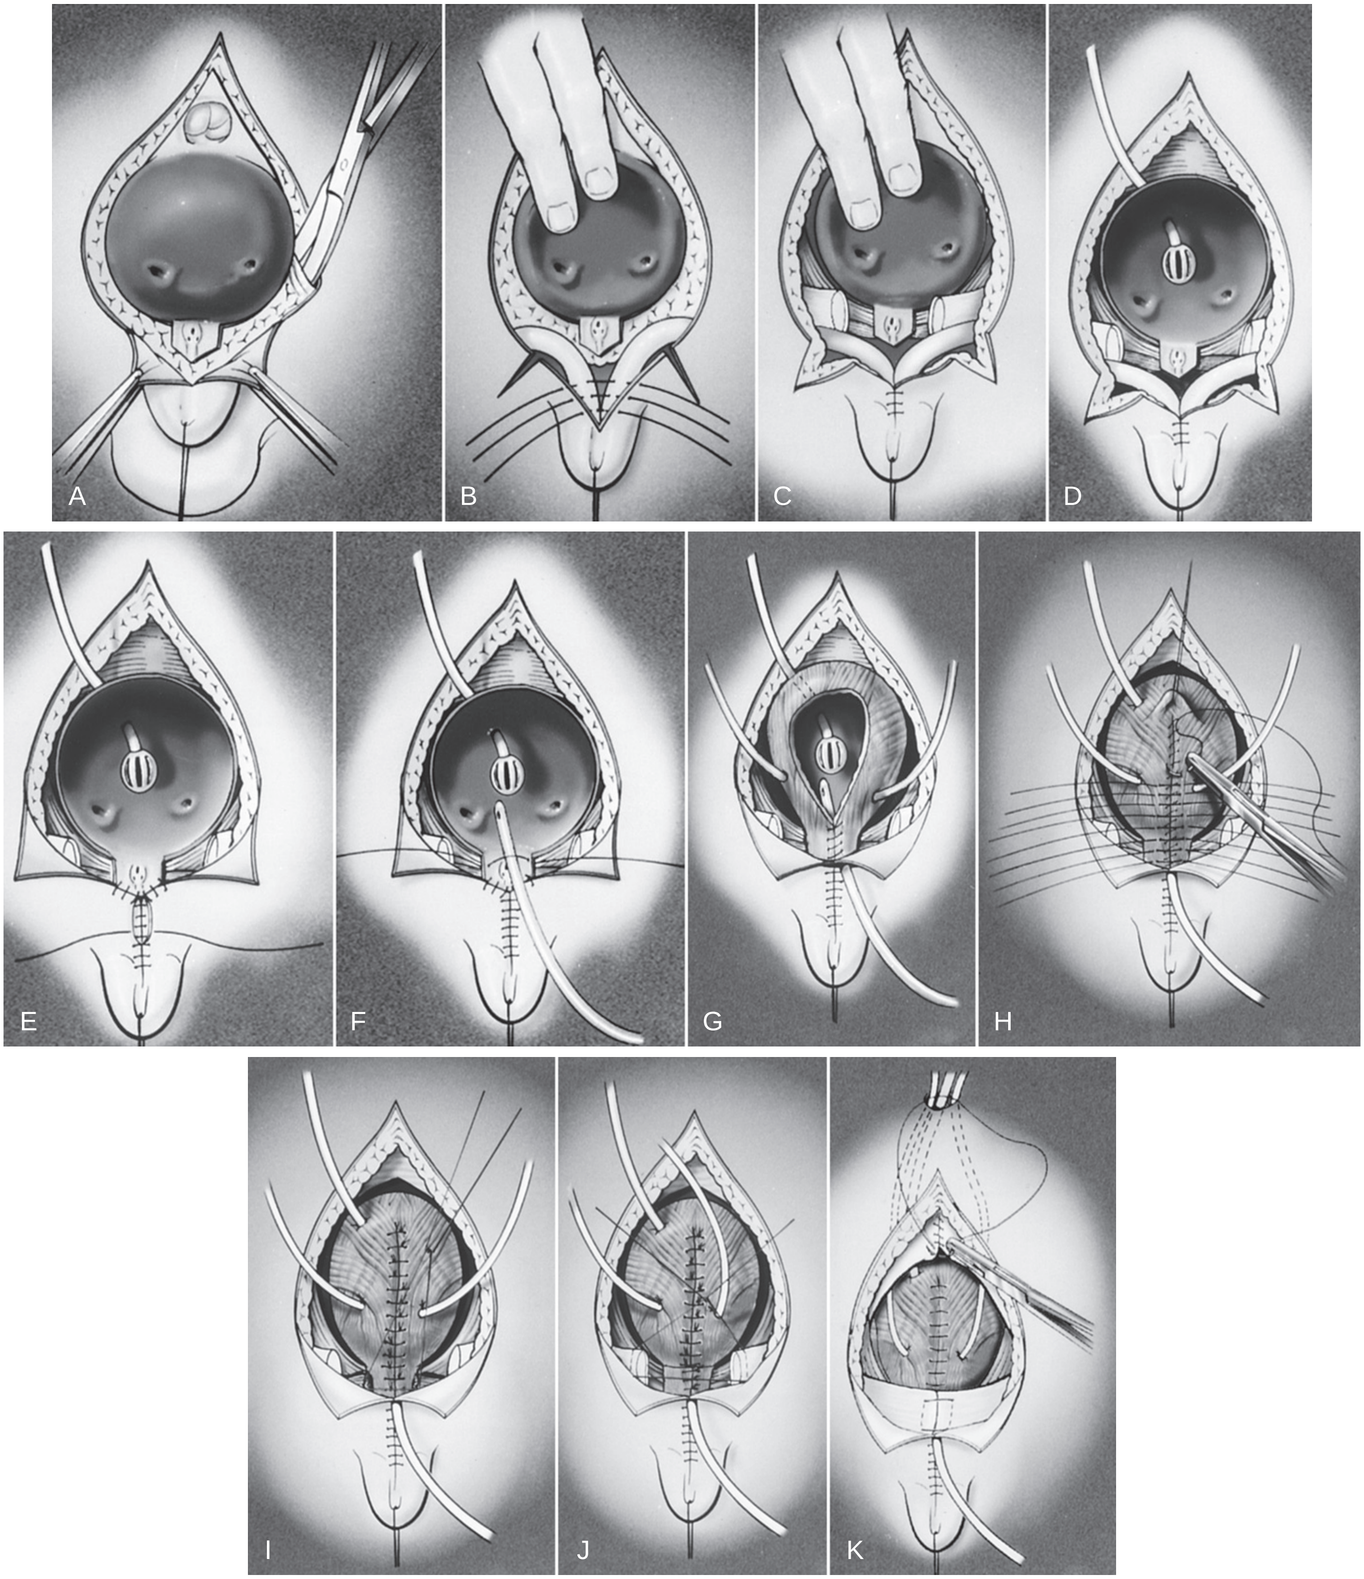

**FIGURE 120-9** Sequence of repair of bladder exstrophy in a male. **A**, Completion of the dissection around the periphery of the bladder and the urethral plate. **B**, Inversion of the bladder plate and approximation of the corpora as a first stage in epispadias repair. Also note the inferior paraexstrophy incisions. **C**, Further closure of the skin over the corpora and their partial freeing from the pubis. **D**, Placement of a suprapubic drainage tube. **E**, Further closure of the skin inferiorly, with approximation to the urethral plate. Creation of the paraexstrophy flaps is now evident. **F**, The urethral plate is prepared for tubularization over a catheter. **G**, The urethral plate is now tubularized, and ureteral catheters are placed bilaterally and brought out on each side of the bladder. The bladder is also in the process of being tubularized. **H**, Completion of tubularization of the bladder and urethra, and location of the various drainage tubes. **I**, After two-layer closure of the bladder and urethral plate, the bladder is reduced into the pelvis and fixed with sutures. **J**, Sutures are placed to encourage approximation of the pubic halves. **K**, Drainage tubes are brought out superiorly, and fascia, subcutaneous tissue, and skin are approximated. Approximation of the pubis helps protect the bladder closure and the abdominal wall closure.

described, combined bilateral anterior innominate and vertical iliac osteotomy is most frequently used to assist symphyseal approximation and medial rotation of the pelvic bones.[49] Fixator pins are then placed into the iliac wings and lower osteotomized segments. Our group generally used bilateral anterior iliac osteotomies (Fig. 120-10). Closure of the pelvic ring is performed using a large-sized, monofilament suture, taking care to place the knot anteriorly to avoid erosion into the soft tissue below. The newly closed bladder and urethra can now be covered by reapproximation of the rectus fascia and skin, with externalization of tubes and drains. External fixators are applied to the pins to hold the pelvis in the correct configuration. Lower extremity traction is applied to keep the legs still and prevent destabilization of the pelvis (Fig. 120-11). The external fixator remains in place for 4 to 6 weeks after surgery, allowing for callus formation at the osteotomy sites. As an alternative to external fixation, immobilization may also be accomplished through the application of a spica cast, which envelops the hips and lower extremities. The cast remains in place for 4 to 6 weeks.

The technique for initial closure in a female patient is similar to that described previously. The traction suture is initially placed anterior to the vagina, which is fully mobilized, as the neourethra is tubularized. The vagina is then repositioned to create a more caudal angle of entry.

Postoperatively, the patient is maintained on antibiotic prophylaxis. Parenteral nutrition may be used initially in order to avoid abdominal distension. Close attention must be given to patient positioning and fixator pin sites to minimize the risk of skin ulceration and nerve injury.

### Stage 2: Epispadias Repair

The second stage of repair is generally undertaken between 6 and 12 months of age. It centers on reconstruction of the phallus, with repair of epispadias and urethroplasty. This may further optimize bladder capacity, through an increase in outlet resistance.[50] Although many techniques have been used, the method described by Cantwell and later modified by Ransley has been shown effective in accomplishing urethral relocation to the penile ventrum, correction of chordee, and a

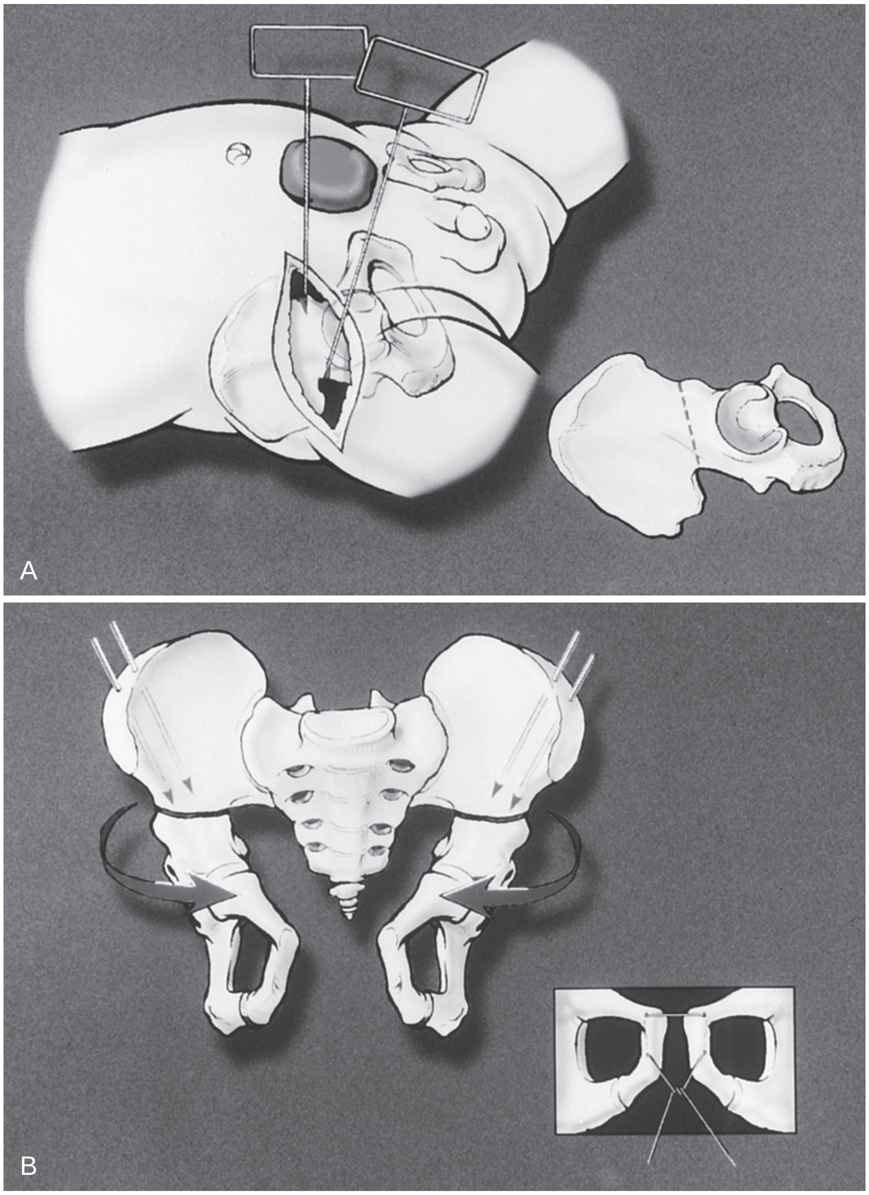

**FIGURE 120-10** **A,** If the pubis cannot be approximated in a newborn or if the procedure is undertaken later, when the pelvis is less flexible, pelvic osteotomy is required. The location of an anterior iliac osteotomy is shown. **B,** External fixator pins are used to hold the pelvis, and the pubic halves are brought together in the midline.

**FIGURE 120-11** An infant in Bryant's traction. The patient must remain immobilized for 4 to 6 weeks postoperatively.

low fistula rate (Fig. 120-12).[51,52] This technique involves full mobilization of the corpora and dorsal urethral plate, which is dissected free and tubularized. Correction of dorsal chordee is achieved by incising each corpora transversely, creating diamond-shaped defects and anastomosing their dorsal medial aspects over the tubularized urethra. A ventral meatotomy is then performed at the tip of the glans to produce a more anatomically normal meatal position.[53] Other described modifications of the Cantwell-Ransley technique include full detachment of the urethral plate from the corporal bodies, leaving only the distal-most 1 cm of urethra attached to the glans tip. The urethra is then tubularized, the corpora are incised transversely at the point of maximum dorsal curvature, and the corporocavernostomy defects sutured together, thus covering neourethra. This maneuver places the urethra ventrally between the corporal bodies, causes downward deflection of the penis, and also provides extra length. If chordee is correctable by simple corporal rotation, bilateral corporotomies are not required. The glansplasty is completed in two layers, resulting in a ventrally placed neourethra.[54] Further modifications to the technique of epispadias repair include the use of full penile disassembly described by Mitchell and Bagli (Fig. 120-13).[55]

### Stage 3: Bladder Neck Reconstruction and Ureteroneocystostomy

The final stage of exstrophy repair involves the construction of a urinary continence mechanism and is generally undertaken around 4 years of age.[56] During this interval, the patient is monitored periodically with renal US to evaluate the adequacy of upper tract drainage. Bladder capacity is also assessed before bladder neck surgery. Jeffs and colleagues[57] reported that a bladder capacity of greater than 60 mL typically allows for adequate functional storage capacity without the need for concomitant bladder augmentation, although others have reported median capacities of greater than 85 mL to be more predictive of achieving continence.[58] Regardless, it is generally agreed that continence is highly dependent on the size of the original bladder plate, successful initial bladder closure, and an adequate preoperative bladder capacity.

The Young-Dees-Leadbetter technique of bladder neck repair remains the most common approach to bladder neck reconstruction (Fig. 120-14). After opening the bladder, the ureters are first mobilized and reimplanted into a more cephalad position by either cross-trigonal or cephalotrigonal ureteroneocystotomy.[22,59] This procedure not only corrects vesicoureteral reflux, which occurs in virtually all cases of closed bladder exstrophy, but also allows for creation of posterior bladder plate flaps for the bladder neck reconstruction. A recent report by Braga and colleagues also describes

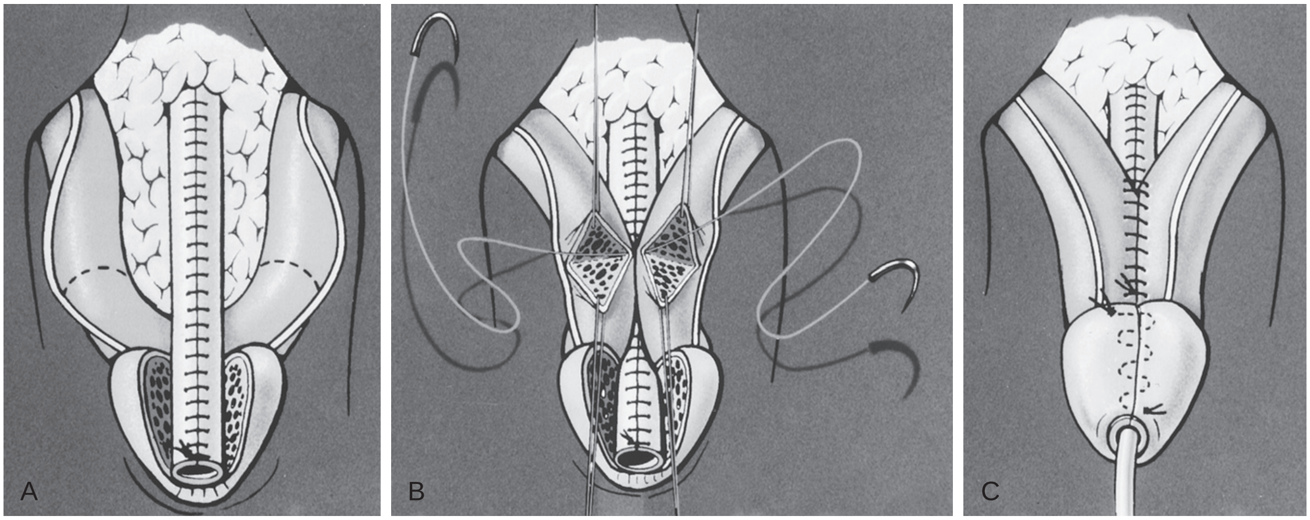

**FIGURE 120-12** Steps in the Cantwell-Ransley epispadias repair. **A,** The urethral plate is dissected from the corpora and is tubularized, taking care to preserve the lateral blood supply of the urethra and the neurovascular bundles**. B,** Corporotomies are created at the midphallus, and the urethra is transposed to the ventral surface. **C,** The corpora cavernosa are rotated medially and reapproximated at the corporotomy sites, pulling the corporal bodies inward and providing coverage of the neourethra. This procedure permits further urethral lengthening, approximation of the corpora with preservation of the blood supply, and full coverage of the urethra.

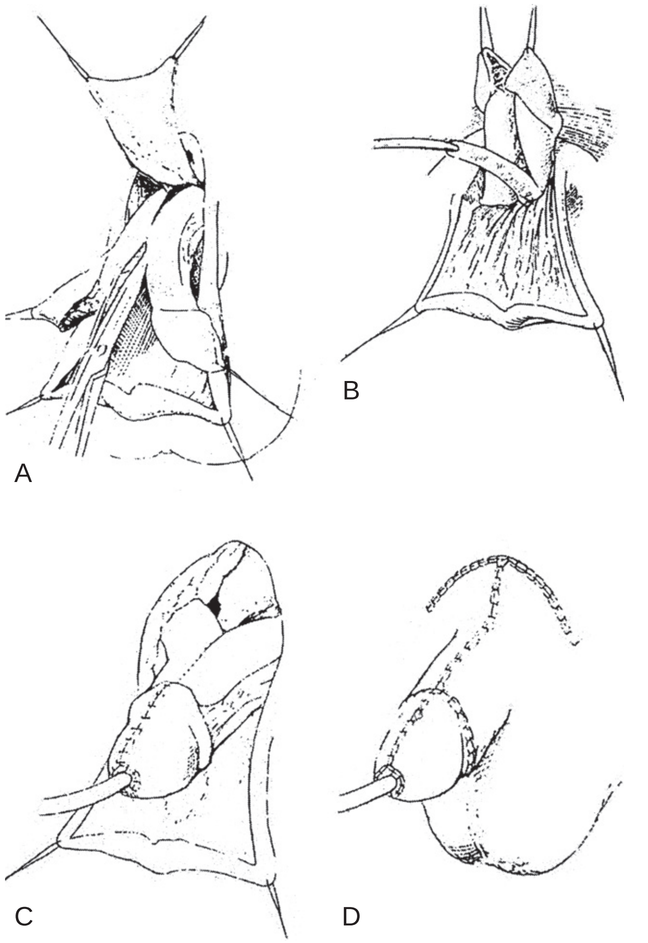

**FIGURE 120-13** Complete penile disassembly technique. **A,** The corporal bodies and the hemiglans are separated. **B,** The urethra is tubularized and moved ventrally. **C,** The corpora are reapproximated dorsally. **D,** Glans closure is performed distally to complete the repair. successful bilateral ureteral reimplantation at the time of primary bladder closure.[33]

A strip of posterior bladder plate 2 cm × 4 cm is marked off, and the triangles of bladder laterally are demucosalized. The strip of bladder is tubularized, and the triangles of denuded muscle are mobilized laterally to provide coverage of the neourethra. If prior urodynamic evaluation has demonstrated inadequate bladder capacity, augmentation cystoplasty with a bowel segment may be performed at this setting.

## SINGLE-STAGE RECONSTRUCTION: COMPLETE PRIMARY REPAIR OF EXSTROPHY

Recently, Mitchell and Grady minimized the number of required operations by combining bladder closure with epispadias repair at birth in a technique known as *complete primary repair.*[60] Major potential benefits of this approach include the earlier creation of bladder outlet resistance, theoretically leading to normal cycling and improved bladder capacity and functionality as the patient grows. Major principles of CPRE include total penile disassembly and division of the intersymphyseal band, which enables posterior positioning of the bladder, bladder neck, and urethra. As described by Grady and Mitchell,[60] CPRE begins with intubation of each ureteral orifice with ureteral catheters. Traction sutures are placed into each hemiglans, the bladder plate is circumscribed, and dissection is continued inferiorly along the ventral aspect of the penis. The urethral plate is mobilized off the penis, which is fully disassembled into separate right and left corporal bodies and the spongiosum-containing urethra. The intersymphyseal band is incised (Fig 120-15), which allows the bladder unit to be positioned deep within the pelvis. A suprapubic tube is left in place, the ureteral catheters are externalized, and the bladder is closed. Similar to the staged approach, pelvic osteotomy may be required for abdominal closure. The pubic symphysis is approximated using PDS sutures, and the abdominal wall is closed. The urethral plate is tubularized and transposed to the penile ventrum, and the corporal bodies are rotated medially and reapproximated (Fig. 120-16). Because of the new posterior positioning of the bladder unit, urethral length is often inadequate to reach the glans, and a hypospadiac meatus is left for future reconstruction (Fig. 120-17). Penile shaft coverage is achieved through the use of ventral rotational penile skin flaps. Postoperatively, the patient remains immobilized as previously described in the technique of staged closure. Additional procedures to correct for residual hypospadias, vesicoureteral reflux, and incontinence may be required as the child grows.

## URINARY DIVERSION

Urinary diversion, in the form of a bowel conduit or reservoir, may ultimately be required for patients with insufficient bladder plate or after reconstructive efforts have been unsuccessful and is discussed in Chapter 118.

## OUTCOMES AND COMPLICATIONS

The most devastating complication of bladder closure is dehiscence. Major contributing factors include wound infection, abdominal distension, bladder prolapse, and loss of ureteral and/or suprapubic catheters within 6 days of closure.[61] Urinary diversion, reclosure of the bladder as a urethral tube for later augmentation, or delayed repair of the bladder may be performed. If not performed in the initial setting, pelvic osteotomy is frequently necessary for successful reclosure.

Urinary incontinence remains a significant problem for up to 30% of bladder exstrophy patients. In the case of bladder neck incompetence, injectable bulking agents, bladder neck sling or artificial urinary sphincter have all been applied. Bladder neck reconstruction or formal closure of the bladder neck, with the creation of a catheterizable channel, can also be performed. In cases where incontinence is secondary to insufficient bladder capacity, augmentation cystoplasty remains the most viable treatment option.

Following epispadias repair, the most common complication is urethrocutaneous fistula, which ranges from 2% to 26% in modern series.[51,54,62]

The incidence of adenocarcinoma of the bladder in adults with bladder exstrophy has been estimated to be 250 times that of the normal population and is likely due to chronic inflammation, infection, and metaplasia of an exposed bladder plate.[63] A series by Woodhouse and colleagues, however, recently documented an 800-fold risk in the incidence of bladder

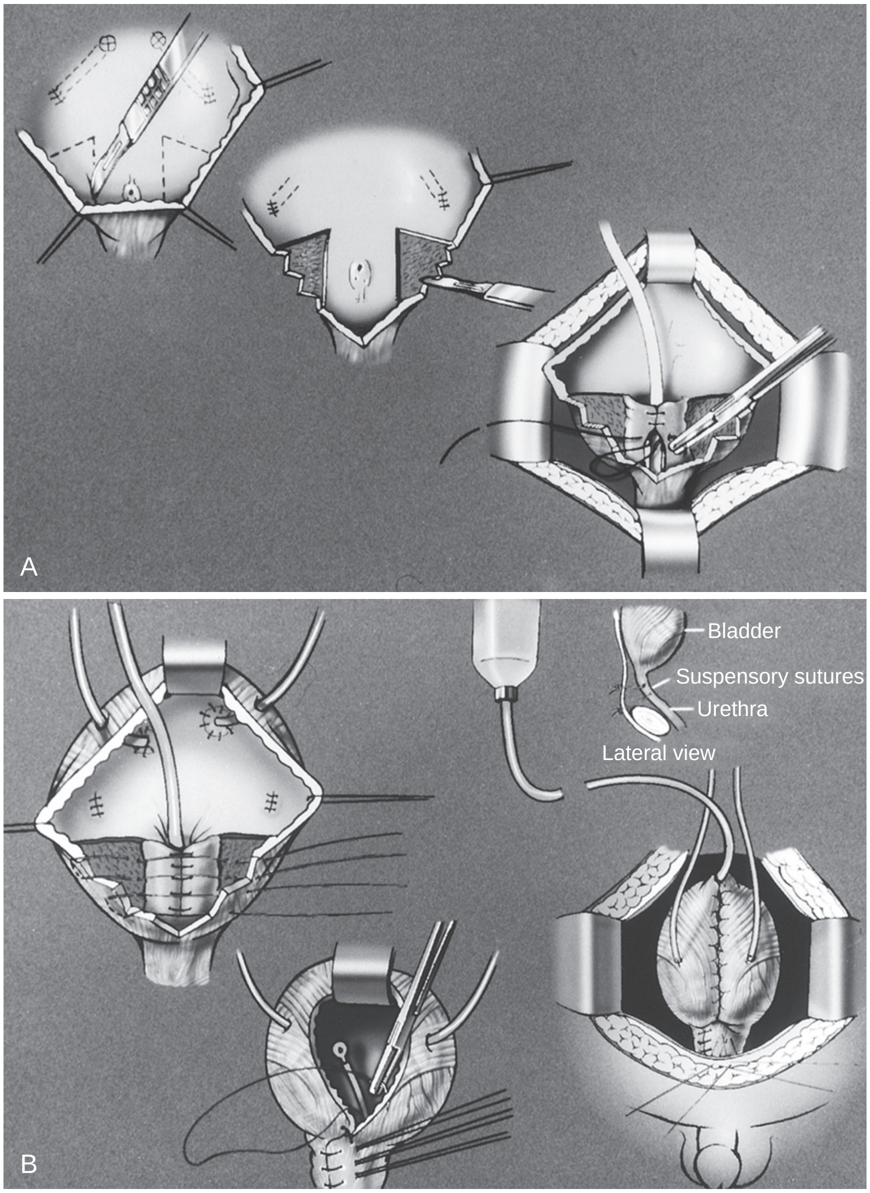

**FIGURE 120-14** Young-Dees-Leadbetter procedure for bladder exstrophy repair. **A,** The ureters are appropriately reimplanted to avoid reflux. Triangular areas at the bladder base are then denuded, and the remaining muscle is tubularized over a catheter. This serves to lengthen the urethra and provides sufficient pressure to encourage the development of improved bladder capacity without causing urethral obstruction. **B,** The bladder is reclosed, and the bladder neck is further supported by sutures, which secure it to the pubis anteriorly.

malignancy among those with a history of bladder exstrophy by age 40.[64] The development of adenocarcinoma and transitional cell carcinoma of the bladder is also a potential risk in those patients who have undergone augmentation cystoplasty.[65,66]

Fertility in patients with bladder exstrophy and epispadias was studied by Shapiro and colleagues,[14] who surveyed 2500 patients. Among these, 38 men had successfully fathered children and 131 women had given birth. Diminished fertility rates among males may be secondary to retrograde ejaculation, though libido and erectile function appear to be normal according to a report by Woodhouse and colleagues.[67] Female patients face a significant risk of uterine prolapse.

### CONCLUSION

Contemporary reconstructive techniques for the repair of bladder exstrophy have resulted in acceptable function and cosmesis for the majority of patients with classic bladder exstrophy. Overall continence rates range from 70% to 80%. Bladder augmentation is preferred in patients without adequate bladder capacity, and bladder neck closure with creation of a continent catheterizable stoma may be performed when other continence procedures have failed.

## Cloacal Exstrophy

Cloacal exstrophy is a rare condition occurring in 1 of 200,000 to 400,000 live births[68] and comprises the most severe deformation along the EEC spectrum, which includes both epispadias and classic bladder exstrophy. Cloacal exstrophy is also referred to as the *OEIS complex* (omphalocele, exstrophy, imperforate anus, and spinal defect) when other malformations of the urogenital, gastrointestinal, skeletal, and neurospinal axis are present.

Although first described by Littre in 1709, historic survival rates were dismal secondary to sepsis or fluid, electrolyte, and nutritional derangements from short gut syndrome or

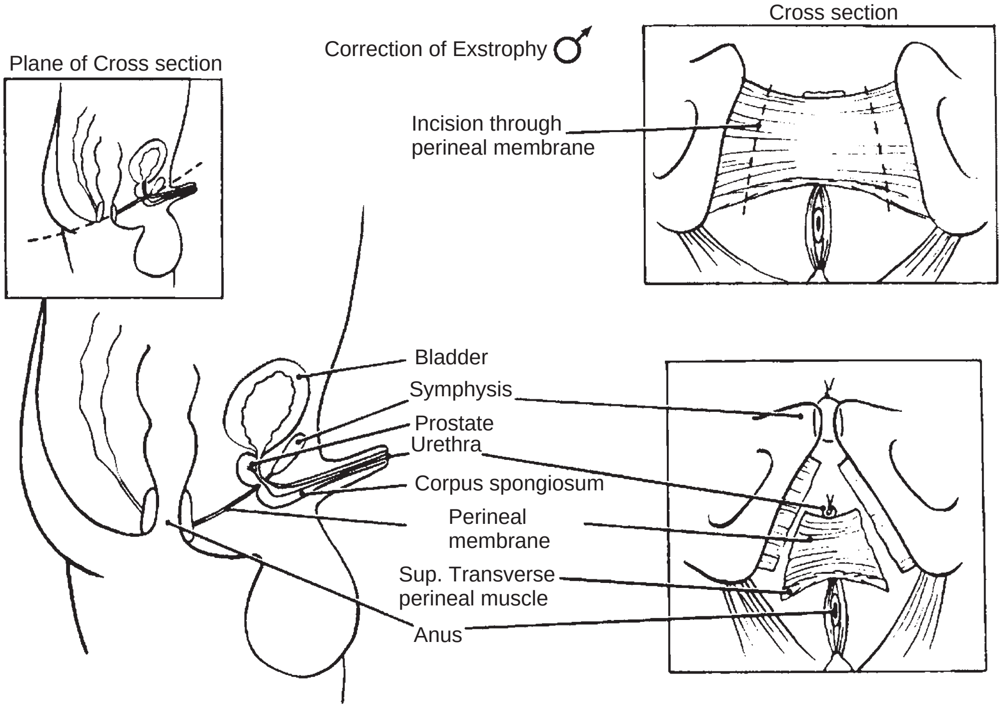

**FIGURE 120-15** Pelvic view of male exstrophy repair as described by Grady and Mitchell. Aggressive dissection along each side of the urethra and division of the intersymphyseal band allow posterior positioning of the bladder in the pelvis. (Modified from Grady RW, Mitchell ME: Complete primary repair of exstrophy. J Urol 1999;162:1416.)

intestinal obstruction.[69] The first successful repair was reported in 1960 by Rickham, who recommended staged surgeries for reconstruction.[70] Advances in neonatal care and surgical technique have resulted in present-day survival rates that exceed 90%, and principle goals of treatment are now directed toward improving quality of life in these patients.[68,71–75]

## EMBRYOLOGY AND GENETICS

The underlying defect in cloacal exstrophy is thought to be related to abnormal development and premature rupture of the cloacal membrane, as described earlier in the bladder exstrophy section. In the setting of cloacal exstrophy, it has been postulated that membrane rupture occurs within the first 8 weeks of gestation. Confirmation of this theory is difficult, however, given no embryologic stage similar to cloacal exstrophy exists in normal development.[76] Disruption of the cloacal membrane, as the principle underlying abnormality, has been supported by surgically induced exstrophy in animal models.[19,77] The prevailing developmental theories are further clouded by several recent reports documenting rupture as late as 26 weeks.[78,79] Rupture at 5 weeks gestation, as traditionally postulated, would cause anterior herniation of the bladder and small bowel, which would prevent normal midline fusion of the hindgut, bladder plate, genital tubercles, and müllerian ducts, thus resulting in the typical anatomic presentation of two open bladder halves separated by a strip of exstrophied cecum, hemiphallic halves with a widely separated pubic diastasis, an underdeveloped and blind-ending distal hindgut with imperforate anus, and an omphalocele of varying size (Fig. 120-18).

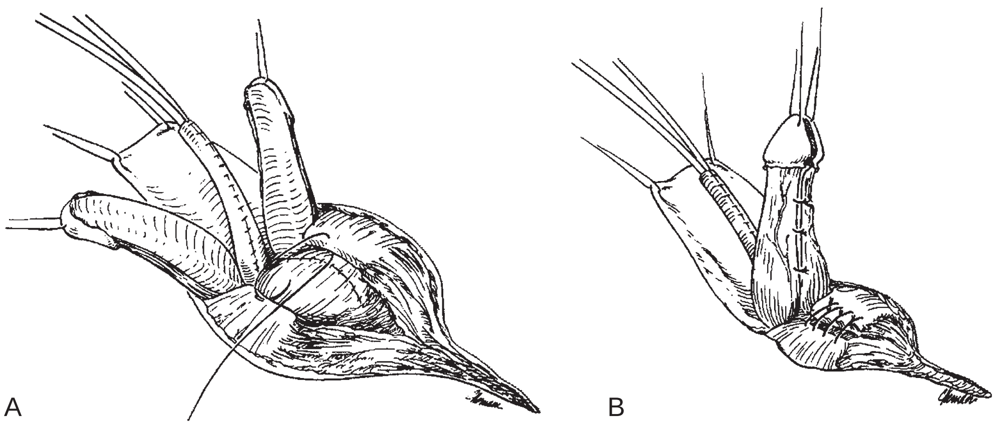

**FIGURE 120-16** **A,** Closure of the urethral plate and bladder as a continuous unit. **B,** Placement of the urethra ventral to the corporal bodies by positioning the bladder, bladder neck, and urethra posteriorly in the pelvis. (Modified from Grady RW, Mitchell ME: Complete primary repair of exstrophy. J Urol 1999;162:1417.)

FIGURE 120-17 At completion of complete primary closure, placement of the bladder and urethral units deeper within the pelvis along with ventral transposition of the urethra may result in a hypospadiac meatus, which can later be reconstructed with formal urethroplasty.

No single environmental exposure or consistent genetic defect in the etiology of cloacal exstrophy has yet been identified. Thauvin-Robinet and colleagues recently identified an unbalanced translocation between chromosomes 9q and Yq, and other studies have implicated mutations in homeobox genes such as HLXB9 and HOX, which are involved in the development of embryonic mesoderm.[80–82] Although there have been multiple reports of cloacal exstrophy among members of the same family, these are generally anecdotal and have involved multigenerational relatives or nontwin siblings.[83–85] Multiple instances of affected monozygotic twins have been reported, however, which lends support to an underlying genetic cause.[76,86–88]

## ASSOCIATED ANOMALIES

Unlike classic bladder exstrophy, cloacal exstrophy is typically associated with a variety of other anatomic defects (Table 120-1).

## GASTROINTESTINAL

Ileocecal exstrophy with an associated omphalocele, hindgut remnant, and imperforate anus is the most common clinical presentation.[54] Omphaloceles are present in 88% to 100% of infants and generally contain portions of small bowel and/or liver.[54,89] Other findings include intestinal duplication anomalies, gastroschisis, ectopic anus, colonic exstrophy, and malrotation.[90,91] Short gut syndrome may be a significant source of morbidity among patients with cloacal exstrophy and is observed in 25% of cases.[71] The risk of short gut syndrome is markedly increased in patients subjected to ileostomy placement as the initial intestinal diversion procedure.[92,93] Furthermore, the phenomenon may occur even in the presence of normal bowel length, implicating an inherent absorptive abnormality of the intestine.[71,72,90]

## GENITOURINARY

Abnormalities of the upper urinary tract have been reported in 41% to 66% of cases.[72,89] Unilateral renal agenesis, pelvic kidney, and/or hydronephrosis were observed in up to 33% in Diamond's 1990 series.[89] Less commonly reported findings include horseshoe kidney, fusion anomalies, and ureteral abnormalities.[72,89,90] Complete separation or even absence of the phallic/clitoral halves may be observed, and the scrotum/labia are widely separated. Male infants frequently have undescended testes with associated bilateral inguinal hernias, whereas failure of müllerian duct fusion in females results in varying degrees of uterine and vaginal duplication anomalies in the majority of patients.[72,89]

## CENTRAL NERVOUS SYSTEM

Some form of spinal dysraphism including tethered cord, myelomeningocele, or lipomyelomeningocele is present in nearly all patients, with recent reports ranging from 64% to 100%.[74,84,91,94] Neurologic impairment is variable and may affect bladder function, urinary continence, lower extremity movement, and erectile function. Detailed postmortem microdissection studies have demonstrated both aberrant origin and vascular supply of the pelvic autonomic nerves,[95] and these nerves are at additional risk of iatrogenic injury during operative repair. Other reported abnormalities include periventricular leukomalacia, hydrocephalus, hypoplastic cerebellum, and Chiari malformation.[84]

## SKELETAL

Abnormalities of the spine, pelvis, and limbs have all been observed in the setting of cloacal exstrophy. Spinal anomalies, excluding myelodysplasia, have been reported in 22% to 60% and consist mainly of absent or extra vertebrae, scoliosis, and kyphosis.[90,96,97] The pelvic deformity is similar to that of classic bladder exstrophy but typically more severe with significant widening of the pubic diastasis, external angling of the posterior and anterior segments, and external rotation and abduction of the iliac wings.[70] A review by Jain and Weaver found a 17% to 26% incidence of associated lower limb abnormalities.[98] Certain limb malformations like club foot and equinovarus deformities can be seen in association with myelomeningocele, which often accompanies cloacal exstrophy; however, a variety of true limb malformations including hypoplasia, absence, split foot, and ectopic or additional digits have also been observed.[98]

## PRENATAL DIAGNOSIS

Early prenatal diagnosis allows time for thorough parental counseling and allows for consideration of pregnancy termination. Prenatal diagnosis was first reported by Meizner and Bar-Ziv in 1985,[99] and since then, several authors have proposed criteria for the prenatal diagnosis of cloacal exstrophy. Principle findings include failure to visualize the urinary bladder along with a large midline anterior abdominal wall defect and/or lumbosacral myelomeningocele.[87,100–102] The prolapsed ileal segment, which may appear as an "elephant trunk–like" mass on US, has also been reported as a pathognomonic finding.[103] From a review of 22 cases, Austin and colleagues[102] developed a list of major and minor criteria for prenatal US diagnosis on the basis of the frequency with which abnormalities were observed. Major criteria were those seen in greater than 50% of cases and included nonvisualization of the bladder (91%); a large, midline, infraumbilical anterior abdominal wall defect or cystic anterior abdominal wall structure (82%); omphalocele (77%); and myelomeningocele (68%). Minor criteria were observed in less than 50% and consisted of lower extremity defects (23%), renal anomalies (23%), ascites (41%), widened pubic arches (18%), narrow thorax (9%), hydrocephalus (9%), and single umbilical artery (9%).[102]

## SURGICAL REPAIR

### Immediate Postnatal Management

After delivery and stabilization of the newborn, exposed organs and mucosal surfaces including the omphalocele, bladder, intestine, and myelomeningocele should be protected by enclosing the infant's lower torso in a bowel bag or by first moistening surfaces with saline and covering with sterile plastic wrapping.[90] Urologic examination should attempt to note genetic sex and size of hemibladder plates. Baseline renal function, electrolyte, and hematologic status should be determined. Karyotyping can be performed if gender has not been previously determined or is not obvious on examination. Initial imaging should include plain films of the chest and spine along with head, abdominal, renal, and spinal US. In the absence of obvious spinal dysraphism, magnetic resonance imaging (MRI) may be advisable for detection of occult lesions. Consultation should also be made to general surgery, neurosurgery, and orthopedics for operative planning. Once the initial evaluation has been completed, discussion may be had with the parents regarding gender assignment, surgical reconstruction, potential functional deficits, and overall expected quality of life.

### Principles of Repair

The surgical management of cloacal exstrophy is typically undertaken in the newborn period (48 to 72 hours) as a combined effort between pediatric surgery and urology. In the setting of associated spinal dysraphism, neurosurgical consultation and closure should be undertaken as soon as the infant is medically stable. Early operation minimizes bacterial colonization of exposed viscera and may decrease the need for pelvic osteotomy.[68,104] The traditional approach of staged repair has been thoroughly described by Gearhart and Jeffs.[40,94] Complete primary repair has also been reported by Howell and colleagues,[68] Zderic and colleagues,[105] Hendren,[106] and most recently by Mitchell and Plaire.[75] It is generally agreed that an individualized approach toward reconstruction, whether in a single-staged or multistaged procedure, results in the best long-term outcomes.[107] The main goals of reconstruction include secure abdominal wall and bladder closure, preservation of renal function, prevention of short gut syndrome, creation of functionally and cosmetically acceptable genitalia, and attainment of urinary and fecal continence.[73,94]

Although various operative algorithms have been published, all approaches begin with initial separation of the intervening cecal plate from the two bladder halves, closure of the omphalocele, and hindgut preservation (Fig. 120-19).[68,71,72,75,107] In the past, the bowel was initially diverted through the creation of loop or end-ileostomies, and the hindgut segment was uniformly discarded. This practice has since fallen out of favor in order to maximize the absorptive capabilities of the intestinal tract.[72,74] Currently, after tubularization of the exstrophied cecum, it is recommended that the hindgut segment be brought out as an end-colostomy.[92] In the rare instance when the hindgut remnant is not used, it may be left as a mucous fistula for use in future urologic or vaginal reconstruction.[90]

The omphalocele is reduced to assist abdominal wall closure; however, in cases of large omphaloceles, complete initial reduction may not be possible. In this setting, a silo device

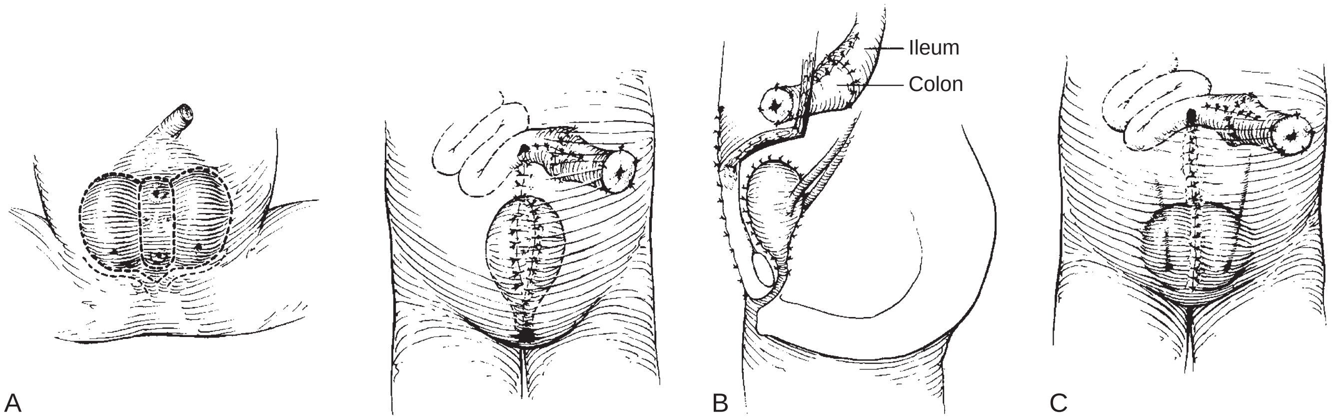

**FIGURE 120-19** Repair of cloacal exstrophy. **A** and **B,** The bowel and bladder mucosa are separated, and the ileocecal junction is tubularized and brought out as an end-colostomy. The bladder halves are turned in, as in a complete exstrophy repair, with approximation of the pubic rami. **C,** Alternatively, the bladder halves are approximated in the midline and left open for staged repair if tubularization is not possible. The omphalocele is also closed.

may be used or the omphalocele may be allowed to re-epithelialize, converting it to a ventral hernia, which may be repaired at a later time (Fig. 120-20).[94]

The hemibladders are dissected and then reapproximated in the midline. In infants with few other associated malformations and who are medically stable, complete closure of the abdominal wall, bladder, and phallic halves may be undertaken at this point in a single-stage procedure with or without pelvic osteotomy. If this is not possible at the initial setting, the two bladder halves can first be joined in the midline, recapitulating the appearance of classic bladder exstrophy, which can then be repaired in a staged fashion as described in the previous section.

Genital reconstruction consists of bringing the phallic halves together to create an appearance congruent with the assigned gender. In the male infant with cloacal exstrophy, the phallic halves are characteristically diminutive, widely separated, and asymmetric. Historically, genetically male infants were routinely assigned to female gender at the time of initial closure, undergoing orchiectomy and feminizing genitoplasty.[108] Recent data regarding gender identity outcomes in gender-reassigned cloacal exstrophy patients has suggested an inherent preference toward male behaviors and sexual identities in these patients.[75,105,109] It remains a topic of continued study and debate. Gender reassignment has since been largely abandoned in the current management of cloacal exstrophy, though functional and aesthetic phallic reconstruction remains challenging. Vaginal reconstruction is necessary in females and in gender-reassigned males and is accomplished through the use of bowel or skin grafts.

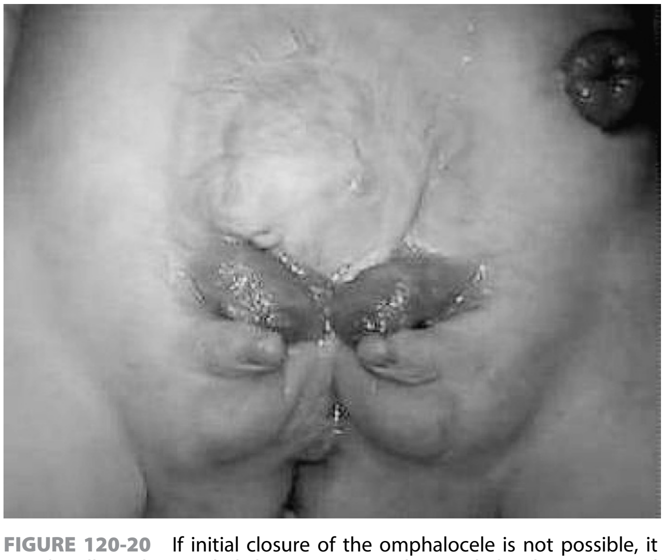

**FIGURE 120-20** If initial closure of the omphalocele is not possible, it may be allowed to epithelialize, converting the omphalocele to a ventral hernia, which can be repaired at a later time.

Gastrointestinal reconstruction, in the form of a pull-through procedure, may be performed in select patients, some time after initial diversion and abdominal closure. The decision is based on the potential for fecal continence and may be influenced by colonic length, ability to form solid stool, and the presence of anal stenosis versus imperforate anus.

Like those with classic bladder exstrophy, these patients will also require the creation of antireflux and urinary continence mechanisms. The presence of myelodysplasia in these patients usually necessitates augmentation cystoplasty with a bowel segment and intermittent catheterization in order to achieve continence. Continence procedures include creation of a neourethra, construction of a catheterizable abdominal stoma with concomitant bladder augmentation, and/or bladder neck closure, the selection of which is influenced by the presence of short gut syndrome, manual dexterity, degree of mobility, and patient motivation.[94]

## POSTOPERATIVE CONSIDERATIONS

Given the high incidence of short gut syndrome, fluid and nutritional status must be carefully monitored and the initial use of total parenteral nutrition (TPN) is advocated.[110] The keys to postoperative success are similar to those for repair of classic bladder exstrophy. Patients are immobilized in some type of traction device. In the setting of pelvic osteotomy, an external fixator is left for 4 to 6 weeks postoperatively. Broad-spectrum antibiotics are administered to minimize risk of wound infection and urosepsis. In contrast to patients with classic bladder exstrophy, the presence of associated myelodysplasia in cloacal exstrophy generally precludes use of an epidural catheter. Pain control in cloacal exstrophy patients can be challenging, and the involvement of the pediatric pain service is recommended. Finally, the importance of limiting abdominal distension to ensure successful abdominal closure and

adequate drainage of both ureteral and bladder catheters cannot be understated.[61,111,112] Following repair, close monitoring of the upper tracts by US is mandatory to observe for adequate renal growth and to detect evidence of obstruction or VUR, which has been reported in 50% to 60% of cloacal exstrophy patients after staged or complete primary repair.[60,107]

## CONCLUSION

For the past 20 years, survival among patients with cloacal exstrophy has exceeded 90%.[68,72,74,105] Death is typically related to complications related to extreme prematurity, renal agenesis, or other complex malformations that are incompatible with life. It is interesting to note that cardiovascular anomalies are rarely observed in the setting of cloacal exstrophy. The various complications related to the management of patients with cloacal exstrophy are similar to those of patients with classic bladder exstrophy, as described in the previous section. Compared with those with classic exstrophy, however, cloacal exstrophy patients face additional challenges of achieving bowel and bladder continence secondary to the need for anal reconstruction and the associated defect of spinal dysraphism. It must be stressed that multiple operations are the rule, and these patients will likely face significant medical, psychologic, and social challenges throughout their lives. Advancements in medical and surgical management continue to improve functional and quality of life outcomes in these patients, but it is important that these individuals remain under the care of a multidisciplinary team of providers who can offer medical care, psychologic support, and lifelong follow-up.

CHAPTER 121

# Hypospadias

Laurence S. Baskin

Hypospadias is one of the most common congenital anomalies, occurring in approximately 1 in 250 newborns, or roughly 1 in 125 live male births.[1,2] Hypospadias can be defined as an arrest in normal development of the urethra, foreskin, and ventral aspect of the penis.[3] This results in a wide range of abnormalities; the urethral opening can be anywhere along the ventral shaft of the penis, within the scrotum, or even in the perineum (Fig. 121-1). Hypospadias is also associated with a ventral curvature of the penis, or chordee. Left uncorrected, patients with severe hypospadias may need to sit down to void and tend to shun intimate relationships because of fears related to abnormal sexuality. Babies born with severe hypospadias and penile curvature may have "ambiguous genitalia" in the newborn period, making an immediate and accurate sex assignment difficult.

Hypospadias is classified by the location of the urethral meatus (Fig. 121-2). Mild (distal) hypospadias may be glanular (meatus on the ventral surface of the glans penis), coronal (meatus in the balanopenile furrow), or distal (in the distal third of the penile shaft). Moderate hypospadias is along the middle third of the penile shaft. Severe (posterior) hypospadias extends through the proximal third of the penile shaft to the perineum and may be described as posterior penile (at the base of the shaft), penoscrotal (at the base of the shaft in front of the scrotum), scrotal (on the scrotum or between the genital swellings), or perineal (behind the scrotum or behind the genital swellings). Classifying hypospadias is not necessarily useful in determining surgical approach, and these classifications do not take into account the associated penile curvature (Fig. 121-3). A patient with severe curvature and an anterior urethral meatus may require more extensive surgery to correct both anomalies.

## Historical Notes

Throughout Greek culture, there was high appreciation for the goddess Hermaphrodite, who was half man and half woman. Many statues reflect hypospadiac genitalia, perhaps indicative of admiration for this condition. It is, therefore, understandable why it was not until the first and second centuries AD that the Alexandrian surgeons Heliodorus and Antyllus attempted to correct this anomaly by amputation of the distal curved portion.[4] Sexually, the dystopia of the meatus may cause impotentia generandi. Henry II of France was known to have hypospadias, as recorded by his physician Fernal. Henry's marriage with Catherine de Medici was infertile until Fernal "advised his patient that in such cases *coitus more ferarum* permitted him to overcome the difficulty."[5] Henry II went on to sire three kings of France, along with seven other children.

## Embryology

Formation of the external male genitalia is a complex developmental process involving genetic programming, cell differentiation, hormonal signaling, enzyme activity, and tissue remodeling.[6,7] By the end of the first month of gestation, the hindgut and future urogenital system reach the ventral surface of the embryo at the cloacal membrane.[8] The urorectal septum divides the cloacal membrane into a posterior, or anal, half and an anterior half, the urogenital membrane. Three protuberances appear around the latter. The most cephalad is the genital tubercle. The other two, the genital swellings, flank the urogenital membrane on each side. Up to this point, the male and female genitalia are essentially indistinguishable. Under the influence of testosterone and dihydrotestosterone in response to a surge of luteinizing hormone from the pituitary, masculinization of the external genitalia takes place (Fig. 121-4). One of the first signs of masculinization is an increase in the distance between the anus and the genital structures, followed by elongation of the phallus, formation of the penile urethra from the urethral groove, and development of the prepuce.[9,10]

At 8 weeks' gestation, the external genitalia remain in the indifferent stage (see Fig. 121-4). The urethral groove on the ventral surface of the phallus lies between the paired urethral folds (Fig. 121-5). The penile urethra forms as a result of fusion of the medial edges of the endodermal urethral folds. The ectodermal edges of the urethral groove fuse to form the median raphe. By 12 weeks, the coronal sulcus separates the glans from the shaft of the penis. The urethral folds have completely fused in the midline on the ventrum of the penile shaft. During the 16th week of gestation, the glanular urethra appears. Two possible explanations for formation of the glanular urethra have been proposed (see Fig. 121-5): (1) endodermal cellular differentiation or (2) primary intrusion of ectodermal tissue from the glans (Fig. 121-6).

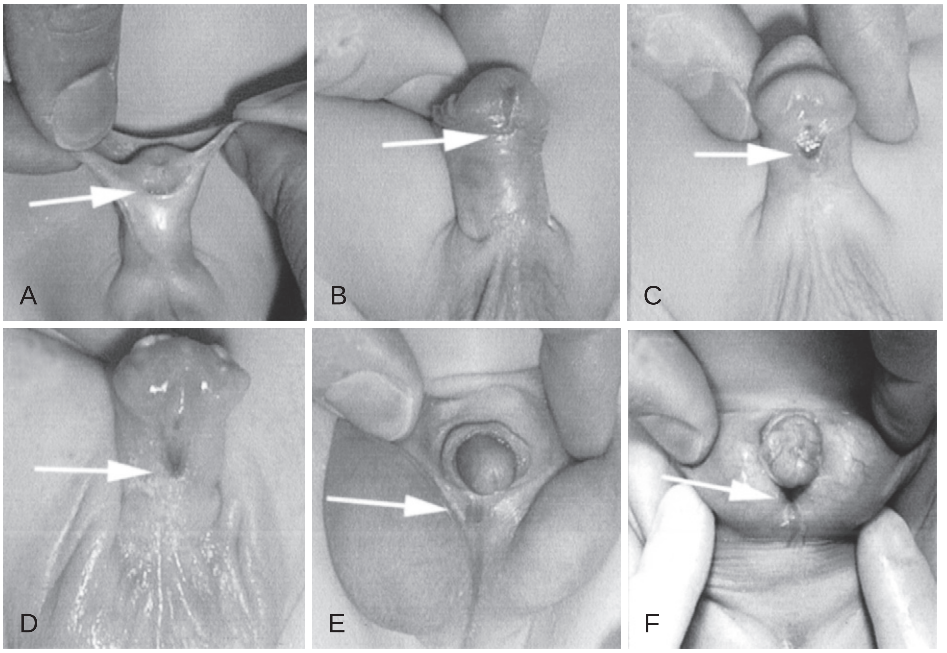

FIGURE 121-1 Mild to severe hypospadias. **A,** Mild hypospadias with the urethral opening on the glans. **B,** Mild hypospadias with the urethral opening at the coronal margin. **C,** Moderate hypospadias with the urethral opening on the distal penile shaft. **D,** Moderate hypospadias with the urethral opening on the midpenile shaft. **E,** Severe hypospadias with the urethral opening at the penoscrotal junction. **F,** Severe hypospadias with the urethral opening in the scrotum (the *arrows* indicate the opening of the hypospadiac urethral meatus). Note that the foreskin is absent on the ventral surface of the penis and excessive on the dorsal aspect. The more severe forms of hypospadias are associated with penile curvature. (From Baskin LS: Hypospadias and urethral development. J Urol 2000;163:951-956.)

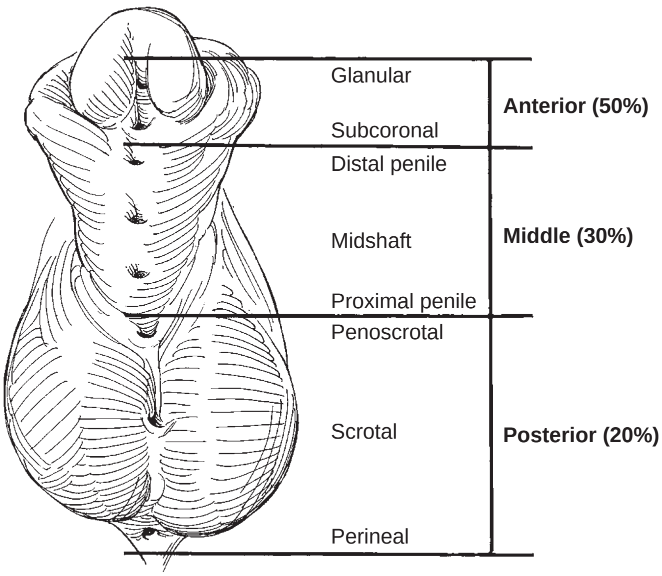

FIGURE 121-2 Classification and incidence of hypospadias: distal (anterior), moderate (middle), and posterior.

Anatomic and immunohistochemical studies advocate the theory of endodermal differentiation on the basis of evidence that the epithelium of the entire urethra is of urogenital sinus origin.[11] The entire male urethra including the glanular urethra is formed by dorsal growth of the urethral plate into the genital tubercle and ventral growth and fusion of the urethral folds. Under proper mesenchymal induction, urothelium has the ability to differentiate into a stratified squamous phenotype with characteristic keratin staining, thereby explaining the cell type of the glans penis.[12] There is no evidence of ectodermal ingrowth, as proposed under the second theory.[13]

The future prepuce is forming at the same time as the urethra and is dependent on normal urethral development. At about 8 weeks' gestation, low preputial folds appear on both sides of the penile shaft, which join dorsally to form a flat ridge at the proximal edge of the corona. The ridge does not entirely encircle the glans because it is blocked on the ventrum by incomplete development of the glanular urethra (see Fig. 121-5, *A*). Thus the preputial fold is transported distally by active growth of the mesenchyma between it and the glanular lamella. The process continues until the preputial fold (foreskin) covers all of the glans (see Fig. 121-5, *C*). The fusion is usually present at birth, but subsequent desquamation of the epithelial fusion allows the prepuce to retract. If the genital folds fail to fuse, the preputial tissues do not form ventrally; consequently, in hypospadias, preputial tissue is absent on the ventrum and is excessive dorsally (see Fig. 121-1).

At the molecular level, testosterone must be converted to $5\alpha$-dihydrotestosterone (DHT) by the microsomal enzyme type 2 $5\alpha$-reductase for complete differentiation of the penis with a male-type urethra and glans.[14–16]

## Incidence

Several European countries including Norway, Sweden, England, Wales, Hungary, Denmark, Finland, Italy, France, and the United States published independent reports of increasing rates of hypospadias during the 1960s, 1970s, and 1980s.[2,17] More recently, data from the International

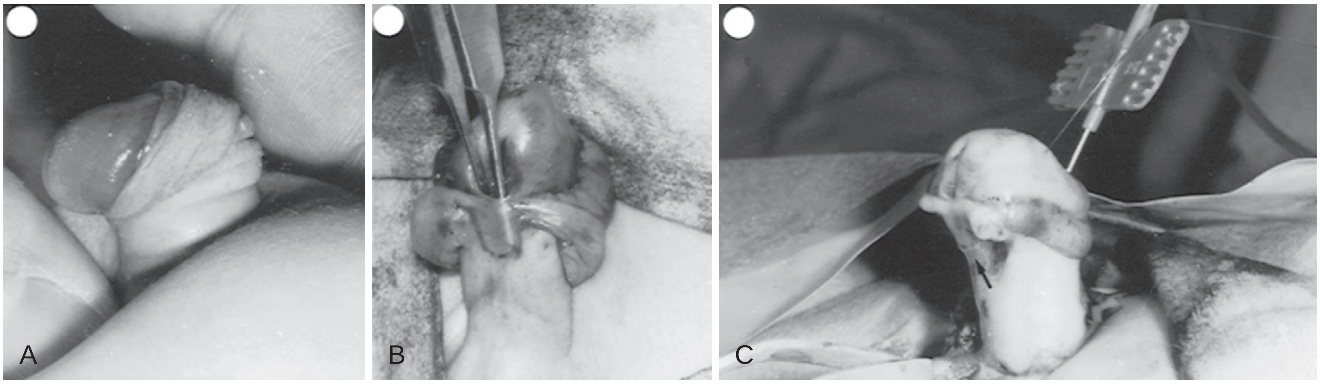

FIGURE 121-3 **A,** Coronal hypospadias with penile curvature. **B,** The thin ventral skin is not suitable for a parameatal-type procedure. **C,** After release of the skin and dartos fascia (straightening the penis), the meatus (*arrow*) is cut back to remove thin urethral skin in preparation for an onlay island flap urethroplasty. (From Baskin LS, Duckett JW, Ueoka K, et al: Changing concepts of hypospadias curvature lead to more onlay island flap procedures. J Urol 1994;151:191.)

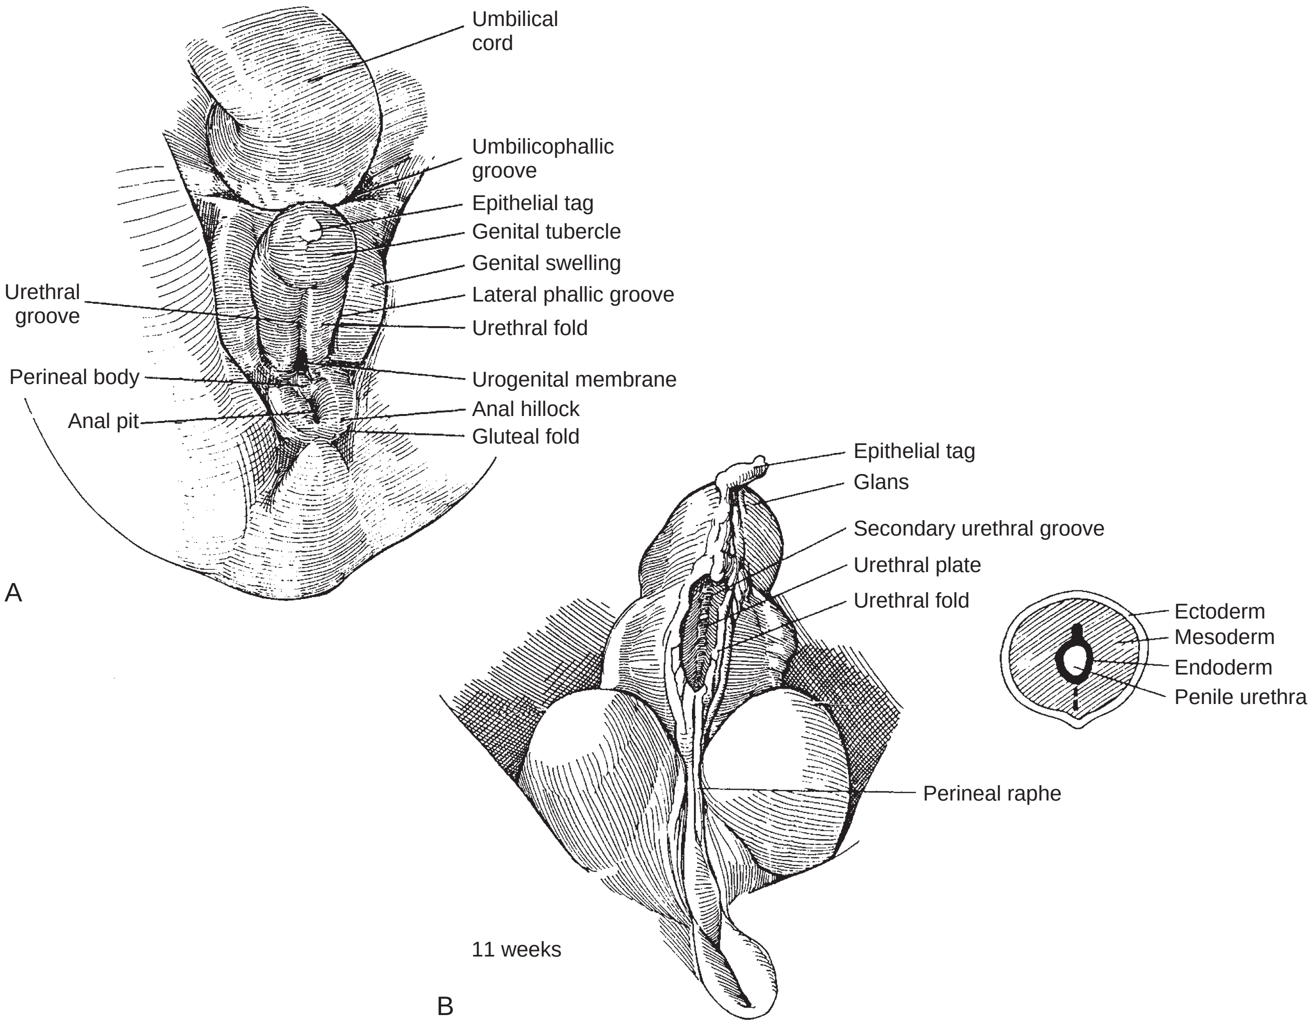

FIGURE 121-4 Development of the penis and urethra. **A,** Indifferent stage at about 8 weeks. Note that the primitive urethral groove forms on the caudal slope of the genital tubercle. Paired genital (labioscrotal) swellings arise on either side of the urogenital membrane above the anal pit and the perineal body. **B,** Enclosure of the urethra at 11 weeks. Beginning near the anus, the adjacent ectodermal urethral folds fuse over the urethral plate to form the penile urethra, with the distal urethra at the coronal sulcus being the last to close.

*Continued*

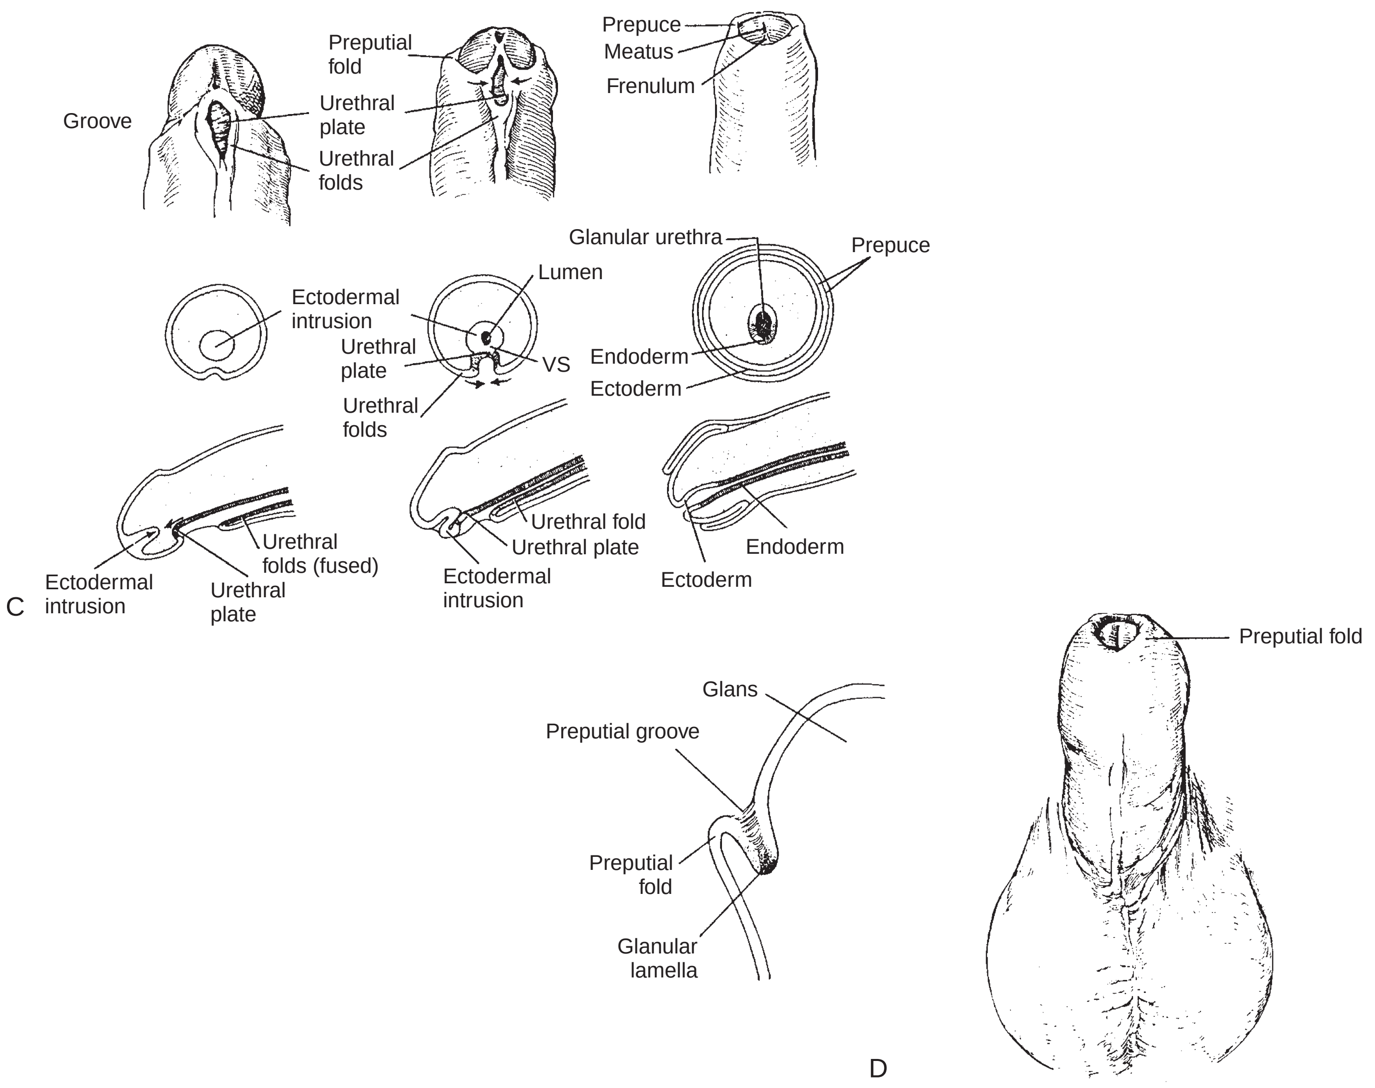

**FIGURE 121-4—CONT'D** **C,** Formation of the glanular urethra and fossa navicularis occurs late in gestation. A plug of ectoderm from the tip of the glans invades the mesenchyma as an ectodermal intrusion. The floor of the ectodermal intrusion makes contact with the end of the urethral plate that forms the roof of the advancing urethra, and the intervening double wall breaks down. **D,** The prepuce forms by the differentiation of the epithelial cells of the glanular lamella, which forms a groove between the preputial folds and the glans. (From Hinman F Jr: Surgical Anatomy of the Genitourinary Tract. Philadelphia, WB Saunders, 1994, pp 418-470.)

Clearinghouse for Birth Defects Monitoring Systems (ICBDMS) were analyzed to determine whether these increases were worldwide and continuing and whether they had any geographic pattern.[2] The ICBDMS data suggested that the increased incidence of hypospadias was not a worldwide trend; it was most notable in the United States, Norway, and Denmark. Also, it was determined that the incidence was not increasing in the less affluent and less industrialized nations (on the basis of gross domestic product) for which data were available. Increasing trends in England, Canada, and northern Netherlands appear to have leveled off since 1985.

Data from the Metropolitan Atlanta Congenital Defects Program showed that the incidence of severe hypospadias increased between 1968 and 1990.[1] The Birth Defects Monitoring Program (BDMP), which gathers diagnoses recorded on newborn discharge summaries from hospitals nationwide, also reported an increase in hypospadias. However, more recent studies in the New York area question whether the incidence is actually changing.[18]

## Associated Anomalies

Undescended testis and inguinal hernia are the most common anomalies associated with hypospadias. In one series, 9.3% of hypospadias patients had an undescended testis; the incidence was 32% with posterior hypospadias, 6% for moderate, and 5% with distal.[19] The same investigators found the overall incidence of inguinal hernia to be 9%, with 17% of those cases associated with posterior hypospadias. A utriculus masculinus (utricle) is more often found in cases of severe hypospadias.[20,21] Combining two large studies in severe hypospadias, there was an 11% incidence of a utricle. Usually, the only complications caused by the presence of a utricle are difficulty passing a catheter and rarely infection.[22]

It is not surprising that urinary tract anomalies are infrequent because the external genitalia are formed after the supravesical portion of the urinary tract. McArdle and Lebowitz found only 6 genitourinary anomalies among

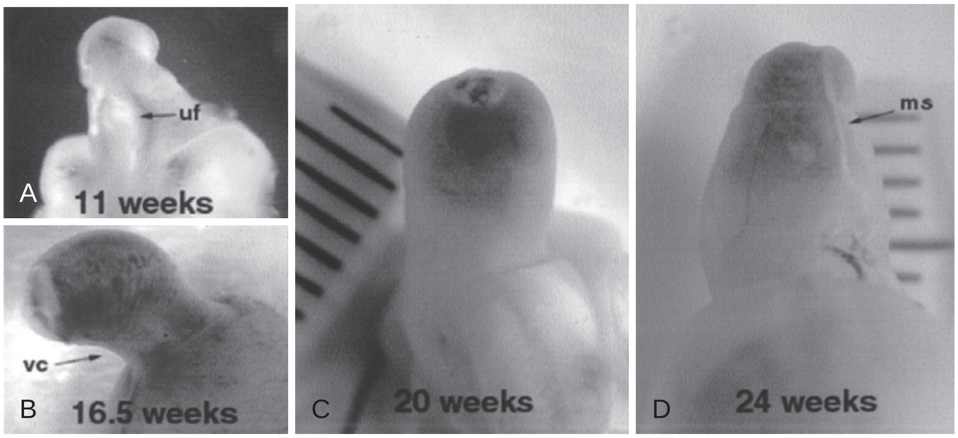

**FIGURE 121-5** Normal human male genitalia development at 11, 16.5, 20, and 24 weeks' gestation. **A,** Note the open urethra and prominent urethral folds (*uf*). **B,** Note the natural phase of penile curvature that occurs during development. **C,** The foreskin is completely formed, and the curvature has resolved. **D,** Continued growth with visualization of the midline skin seam (*ms*).

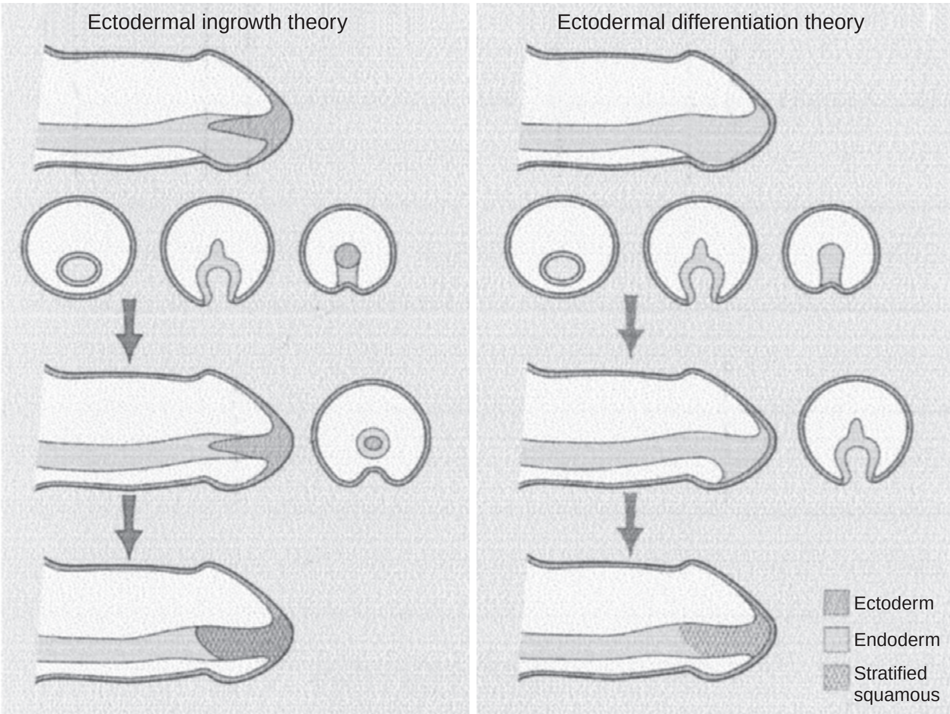

**FIGURE 121-6** Two theories of urethral development: the older theory of ectodermal intrusion and the newer theory of endodermal differentiation. (From Kurzrock EL, Baskin LS, Cunha GR: Ontogeny of the male urethra: Theory of endodermal differentiation. Differentiation 1999;64:115-122.)

200 patients with hypospadias (3%).[23] Cerasaro and colleagues[24] found that 1.7% of patients (4 of 233) had significant anomalies. On the basis of a review of 169 patients, Shelton and Noe[25] did not recommend routine urinary tract evaluation. Khuri and colleagues,[19] in a review of 1076 patients, did not find any significant associated urinary tract anomalies. They concluded that patients with hypospadias and an associated inguinal hernia or undescended testis did not require further urinary tract evaluation; however, patients with hypospadias and other organ system anomalies found on physical examination should undergo upper urinary tract screening with abdominal ultrasonography.

## Cause

In the majority of patients the etiology of hypospadias remains unknown.[3] For example, 33 patients with severe hypospadias were evaluated with a range of diagnostic techniques including clinical assessment, ultrasonography, karyotyping, endocrine evaluation, and molecular genetic analysis of the androgen receptor (AR) and 5α-reductase genes to classify and determine the cause of hypospadias. Diagnoses were determined in only 12 patients (36%); the remaining 64% of patients were classified as having hypospadias of unknown etiology.[26]

## HORMONE RECEPTOR IMPAIRMENT

Many investigators have also attempted to link abnormalities in androgen metabolism or the AR to hypospadias. For example, Gearhart and colleagues[27] found no deficiencies in either AR levels or 5α-reductase in their study of preputial skin from boys with hypospadias. Allera and colleagues[28] analyzed nine patients with severe hypospadias and found a defect in the open-reading frame of the AR in only one patient. Sutherland and colleagues[29] also concluded that mutations in the AR gene are rarely associated with hypospadias. Molecular biology techniques have demonstrated that defects in the AR gene are definitely associated with isolated hypospadias. However, these genetic defects account for an extremely small subset of cases, implying that other factors are responsible for hypospadias.

## GENETIC IMPAIRMENT

Increasingly, researchers are examining the role of cellular signals other than testosterone and DHT in the morphogenesis of the phallus and the cause of hypospadias. Normal embryogenesis of the urogenital system depends on epithelial-mesenchymal interactions, and it has been hypothesized that aberrant signaling between the epithelium and mesenchyma could lead to hypospadias.[12] For example, prostate development requires testosterone-dependent Sonic hedgehog (Shh) expression in the epithelium of the urogenital sinus.[30] In mice null for Shh, penile development is inhibited and cloacal defects exist.[31,32] Mice null for fibroblast growth factor 10 have a proximal urethral opening and a flattened glans, consistent with the hypospadias defect.[32] It is likely that researchers will find similar genetic signaling molecules involved in epithelial-mesenchymal interactions in the phallus that play a role in its development.

Another area of investigation with respect to the cause of hypospadias is the expression and regulation of homeobox (Hox) genes. These genes are transcriptional regulators that play an essential role in directing embryonic development. Genes of the *Hox A* and *Hox D* clusters are expressed in regionalized domains along the axis of the urogenital tract. Transgenic mice with loss of function of single *Hox A* or *Hox D* genes exhibit homeotic transformations and impaired morphogenesis of the urogenital tract.[30,33–35] Human males with hand-foot-genital syndrome, an autosomal dominant disorder characterized by a mutation in *Hox A13,* exhibit hypospadias of variable severity, suggesting that *Hox A13* may be important in the normal patterning of the penis.[36–38] Furthermore, research has shown that the embryonic expression of certain Hox genes is regulated by hormonal factors.[39] Estrogen and the synthetic estrogen DES, for example, inhibit *Hox A9, Hox A10, Hox A11,* and *Hox A13* genes in mice. Thus in addition to defects in Hox genes, it is possible that improper regulation or expression of hormonal factors during embryogenesis could disrupt normal expression of Hox genes and lead to reproductive tract anomalies. More recently, *ATF3* and *MAMLD1 (Cxorf6)* are new candidate genes that are associated with hypospadias.[40] *ATF3* is an estrogen-responsive gene whose expression is increased in hypospadiac boys.[41,42] MAMLD1, which is expressed in the gonad during sex differentiation and interacts with steroidogenic factor 1 (SF1), a transcription factor expressed in the mammalian sex-determining pathway, has also been shown to be mutated in patients with isolated hypospadias.[43]

## ENZYME IMPAIRMENT

Despite the central role that testosterone plays, attempts to ascribe all hypospadias to an underlying genetic defect in this pathway have only rarely been successful. Holmes and colleagues[44] determined the incidence of defects in three major enzymes in the biosynthetic pathway of testosterone: 3α-hydroxysteroid dehydrogenase, 17α-hydroxylase, and 17,20-lyase. Forty-eight boys with fully descended testes and various degrees of hypospadias were compared with age-matched controls who were undergoing circumcision. Morning fasting serum samples of pregnenolone, progesterone, 11-deoxycorticosterone, 17-OH pregnenolone, 17-OH progesterone, 11-deoxycortisol, cortisol, dehydroepiandrosterone, androstenedione, androstenediol, testosterone, and dihydrotestosterone were obtained. To focus on the proximal steps in androgen biosynthesis, 12 individuals with hypospadias underwent standard adrenocorticotropic hormone (ACTH) stimulation. No significant differences in the androgen precursors and metabolites were found between the controls and the individuals with hypospadias. The response to ACTH was variable, with no significant difference between patients with different degrees of hypospadias and controls. These data indicate that enzymatic defects in the steroidogenic steps from cholesterol to dihydrotestosterone are not a common cause of hypospadias.

## ENVIRONMENTAL FACTORS AND ENDOCRINE DISRUPTERS

In the past, environmental factors were generally ruled out as causes of hypospadias.[45,46] More recently, multicausality models have included environmental contaminants to determine the risk of developing a given phenotype. For example, familial clustering of hypospadias among first-degree relatives has been perceived as being under the influence of a strong genetic and heritable component, but there have been many exceptions in which genetics was ruled out. It has thus been suggested that environmental influences should be considered as well, given that families share similar exposures. In particular, in cases in which the effects are profound, genetic predisposition exacerbated by environmental exposure should be considered.[47–49]

Attempts to determine risk factors for hypospadias have yielded a number of maternal and paternal risk factors. Among traditional studies of maternal risk factors for congenital anomalies, maternal age and primiparity are significantly associated with hypospadias, although some studies have contested the maternal age effect.[45] Paternal risk factors associated with hypospadias include abnormalities of the scrotum or testes and low spermatozoa motility and abnormal sperm morphology.[48,50] It has been suggested that the recent increase in hypospadias reflects the improvement in fertility treatments, contributing to more subfertile men fathering children. As Fritz and Czeizel state, this “relaxed-selection hypothesis, which states that there is a redistribution in the number of children born to fertile and infertile (subfertile) couples, may account for the increasing number of other defects and cancers of male genitalia observed today and the fall in sperm counts.”[48,51]

In addition to parental risk factors, there is strong consensus in the literature that boys with hypospadias have lower

birth weights.[52] Fredell and colleagues[52] examined hypospadias in discordant monozygotic twins and found that the twin with hypospadias weighed 78% of the twin without hypospadias. The birth weight difference was still significant in healthy monozygotic twins. Another study found that boys with hypospadias had a lower placental weight than control boys did.[46]

A 1995 meta-analysis of first-trimester exposure to progestins and oral contraceptives did not indicate an increased risk of hypospadias.[53] Exposure to DES was excluded in that study. However, a number of other studies did list gestational exposure to progestins as a causal agent. Another recent study linked a maternal vegetarian diet during pregnancy to an increase in the incidence of hypospadias.[54] This study looked at 51 boys with hypospadias from a group of 7928 boys born to mothers taking part in the Avon Longitudinal Study of Pregnancy and Childhood. The authors hypothesized that vegetarians have a greater exposure to phytoestrogens than omnivores do. The phytoestrogens may come in the form of soy, which is high in isoflavones, or may be related to endocrine disrupters in pesticides and fertilizers.[55]

Although these risk factors may not be direct causes of hypospadias, they provide additional information that may reveal a common developmental pathway and inform future research. For example, there is growing evidence that androgens play a central role in the lower birth weight of girls compared with boys.[56] Androgens are also crucial to the development of the male reproductive tract. Thus exposure to an agent that compromises the weight-gaining advantage of androgen during gestation could play a role in the development of hypospadias and low birth weight.

Increasing rates of hypospadias have paralleled reports of other untoward end points related to male reproductive health including increases in testicular cancer, an increased incidence of cryptorchidism, and decreased semen and sperm quality.[57,58] The increasing incidence of such anomalies over the past 50 years concomitant with the increased production and use of synthetic chemicals has raised concerns that environmental factors may play a role in these problems.[17,47] It is now well documented from wildlife studies and accompanying laboratory data that a number of synthetic and natural chemicals commonly found in the environment can mimic or antagonize hormones or otherwise interfere with the development and function of the endocrine and reproductive systems.[59,60] The offspring of pregnant mice exposed in utero to both estrogen and prednisone have been shown to develop hypospadias.[61] Whether endocrine disrupters are having an impact on human male reproductive health and on hypospadias in particular is difficult to determine.[62] Regardless, public health agencies worldwide are increasingly concerned about endocrine disruption and it remains an active area of research.[63–65]

## Normal and Hypospadiac Penile Anatomy

Surgical repair of hypospadias requires an expert understanding of the normal anatomy of the penis, as well as an understanding of the anatomy of the hypospadiac penis. The human penis consists of paired corpora cavernosa covered by a thick, elastic tunica albuginea, with a midline septum (Fig. 121-7).[9,66–69] The urethral spongiosum lies in a ventral position, intimately engaged between the two corporal bodies. The Buck fascia surrounds the corpora cavernosa and splits to contain the corpus spongiosum in a separate compartment. The neurovascular bundle lies deep to the Buck fascia, and where the two crural bodies join to form the corporal bodies, the neurovascular bundle completely fans out around the corpora cavernosa, all the way to the junction of the corpus spongiosum (see Figs. 121-6 and 121-7).[68,70] This concept disagrees with the classic dogma that the neurovascular bundle lies in the 11 o'clock and 1 o'clock positions. Superficial to the Buck fascia is the dartos fascia, which lies immediately beneath the skin. This fascia contains the blood supply to the prepuce. The prepuce is supplied by two branches of the inferior external pudendal arteries, the superficial penile arteries.[71] These arteries divide into the anterolateral and posterolateral branches. In hypospadias surgery, the island flap is typically based on the anterolateral superficial vessels. The onlay island flap, tubularized island flap, and de-epithelialized pedicle flap are dependent on careful preservation of these blood vessels. The outer skin survives from the intrinsic subcutaneous vessels.

Compared with the normal penis, the anatomy of the hypospadiac penis is no different in terms of neuronal innervation, corpora cavernosa and tunica albuginea architecture, and blood supply, except at the region of the abnormal urethral spongiosum and glans (Figs. 121-8 and 121-9).[66,72] The nerves in both the normal and the hypospadiac penis start as two well-defined bundles superior and slightly lateral to the urethra. As the two crural bodies converge into the bodies of the corpora cavernosa, the nerves diverge, spreading around the cavernosal bodies up to the junction with the urethral spongiosum, not limiting themselves to the 11 and 1 o'clock positions (see Figs. 121-7 and 121-8). The 12 o'clock position in a hypospadiac penis is spared of neuronal structures, just as in a normal penis. At the hilum of penis where the bodies of the corpora start to separate, the cavernous nerve sends nNOS-positive fibers to join the dorsal nerve of the penis, thereby changing the functional characteristics of the distal penile dorsal nerve (see Fig. 121-8). Similarly, the nNOS-negative, ventrally located perineal nerve originating from the pudendal nerve becomes nNOS reactive at the cavernosa-spongiosum junction. The redundant wiring in the penis may be important in the preservation of erectile function.[68]

The most striking difference between the normal penis and the hypospadiac penis is a difference in vascularity (see Fig. 121-9). The hypospadiac penis has large endothelium-lined vascular channels filled with red blood cells on the abnormal ventral shaft. In contrast, the normal penis has well-defined, small capillaries around the urethra, fanning into the glans. Anatomic studies of the urethral plate show no evidence of fibrosis or scarring.[73] The urethral plate is well vascularized, has a rich nerve supply, and has an extensive muscular and connective tissue backing (Fig. 121-10). These features may explain the success of incorporating the urethral plate or abortive spongiosum into hypospadias reconstruction.[74,75]

Hypospadias repair requires attention to three major anatomic defects: (1) abnormal urethral meatus, (2) penile curvature, and (3) foreskin defect and, in more severe cases, scrotal anomalies.

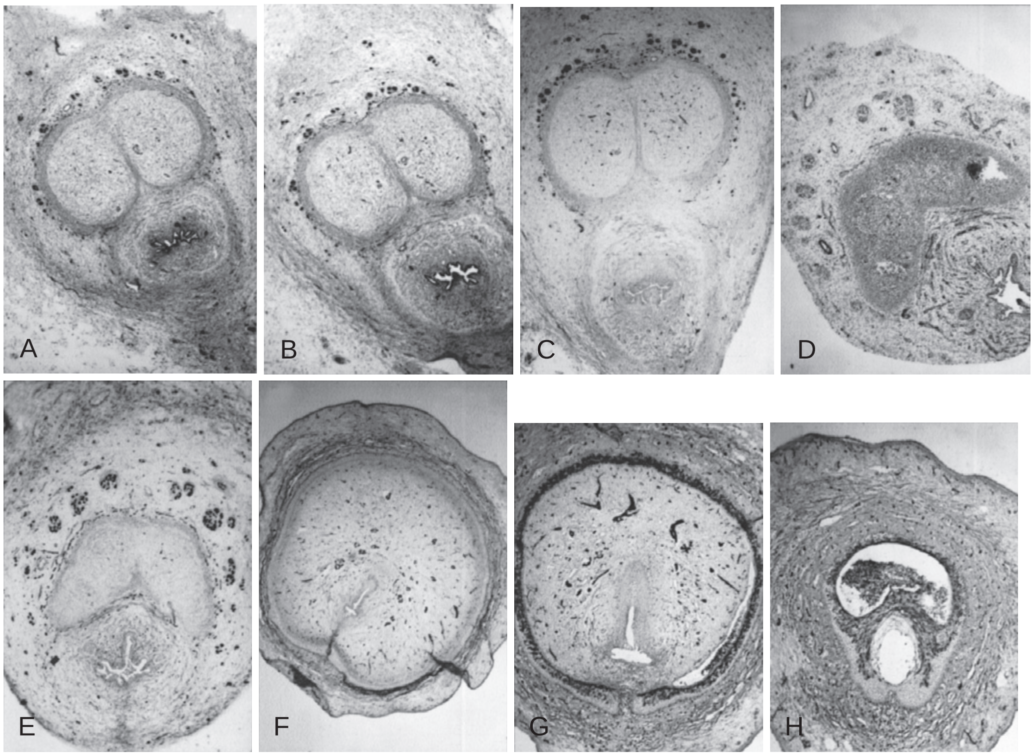

**FIGURE 121-7** Normal human fetal penis at 25 weeks' gestation. **A** to **H,** Transverse sections, distal to proximal, immunostained with neuronal marker S-100 (25×). Note localization of the S-100 nerve marker in brown, completely surrounding the cavernous bodies up to the junction with the urethral spongiosum along the penile shaft, except at the 12 o'clock position (**A** to **D**). On the proximal penis at the point where the corporal bodies split into two **(E)** and continue in a lateral fashion inferior and adjacent to the pubic rami, the nerves localize to an imaginary triangular area at the 11 and 1 o'clock positions. At this point **(E),** the nerves reach their farthest vertical distance from the corporal body (about half the diameter of the corporal body) and continue **(F, G)** in a tighter formation at the 11 and 1 o'clock positions, well away from the urethra. (From Baskin LS, Erol A, Li YW, Cunha GR: Anatomical studies of hypospadias. J Urol 1998;160:1108-1115.)

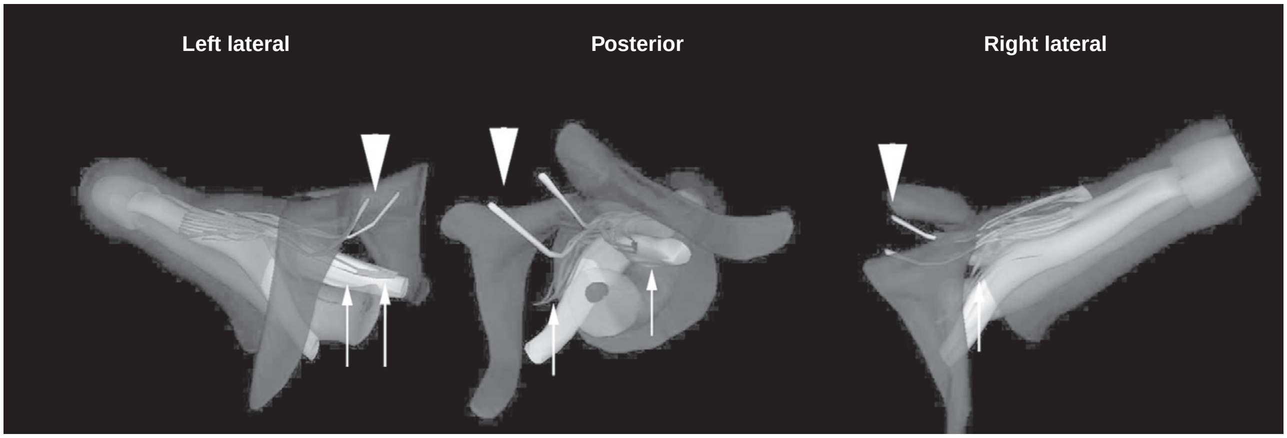

**FIGURE 121-8** Computer-generated three-dimensional reconstruction of the normal human fetal penis at 27 weeks' gestation. Note that the pathway of the cavernosal nerves (*white arrows*) and dorsal nerves (*arrowheads*) is away from the origin of the crural bodies (*white*), which is along the ischial tuberosity. The cavernosal nerves follow a more direct pathway to reach the penile hilum, where they penetrate the corporal bodies under the pubic arch. As the cavernosal nerves travel close to the penile hilum, they send interconnecting fibers to the dorsal nerves, with subsequent positive immunostaining for nNOS. nNOS-positive dorsal nerves travel on the corporal bodies (*gray*) to the glans. As the dorsal nerves of the penis change from nNOS-negative immunostaining character into nNOS positive, the proximal nNOS-negative perineal nerves turn into nNOS-immunoreactive nerves.

## MEATAL ABNORMALITIES

Hypospadias is characterized primarily by location and configuration abnormalities of the urethral meatus. The urethral meatus may be located only slightly ventrally, just below a blind dimple at the normal meatal opening on the glans, or it may be so far back in the perineum that it appears as "vaginal hypospadias."[76] Most patients present with the meatus in one of the many transitional forms. The meatus is encountered in a variety of configurations in terms of form, diameter, elasticity, and rigidity. It can be fissured in both transverse and longitudinal directions, or it can be covered with delicate skin. In the

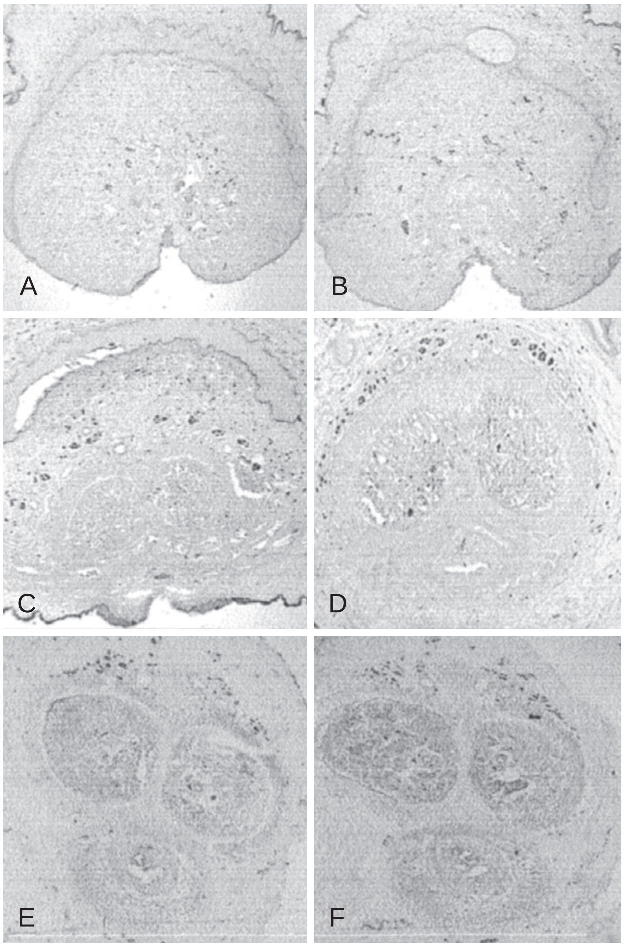

**FIGURE 121-9** Hypospadiac penis at 33 weeks' gestation. **A** to **F,** Transverse sections, distal to proximal, immunostained with neuronal marker (dark staining) S-100 (20×). Note that the anatomy of the hypospadiac penis is the same as the normal penis, except for the abnormal formation of the distal urethra and glans (**A** to **C**). (From Baskin LS, Erol A, Li YW, Cunha GR: Anatomical studies of hypospadias. J Urol 1998;160:1108-1115.)

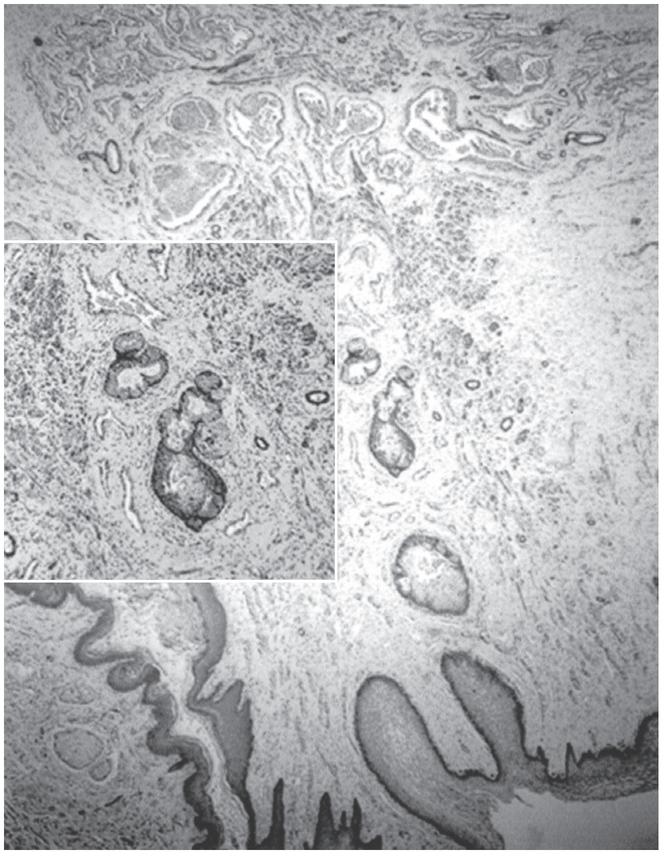

**FIGURE 121-10** Urethral plate in a newborn human penis with proximal hypospadias (smooth muscle alpha actin immunostaining, 25×). The urethral plate is well vascularized, without any evidence of fibrosis or scarring. Epithelial nest or an abortive attempt at the formation of the urethra is seen within the plate (*inset*).

case of the megameatus intact prepuce variant, the distal urethra is enlarged, tapering to a normal caliber in the penile shaft.[77] Often, there is an orifice of a periurethral duct located distal to the meatus that courses dorsal to the urethral channel for a short distance. It has a blind ending and does not communicate in any way with the urinary stream. The periurethral duct corresponds with the Guérin sinus or Morgagni lacunae.[78] Unless these ducts are inadvertently closed, leading to a blind-ending epithelial pouch, they are of no clinical consequence.

## PENILE CURVATURE

The curvature of the penis is caused by a deficiency of the normal structures on the ventral side of the penis. The causes of penile curvature are diverse: a skin deficiency, a dartos fascial deficiency, a true fibrous chordee with tethering of the ventral shaft, or deficiency of the corpora cavernosa on the concave (ventral) side of the penis.

Occasionally other penile anomalies, which represent variations of the embryologic defect causing hypospadias, are reported. They can be characterized as a defect in the course of the urethra (congenital urethral fistula) and a group of defects characterized by curvature of the penis (chordee) without hypospadias.[80,81]

## SKIN AND SCROTAL ABNORMALITIES

The skin of the penis is radically changed as a result of the disturbance in the formation of the urethra. Distal to the meatus, there is often a paucity of ventral skin, which may contribute to penile curvature. The frenulum is always absent in hypospadias. Vestiges of a frenulum are sometimes found inserting on either side of the open navicular fossa.

The skin proximal to the urethral meatus may be extremely thin, to the extent that a catheter or probe passed proximally may be readily apparent through the tissue-paper thickness of skin. The urethral plate extending from the meatus to the glanular groove may be well developed. Even with a meatus located quite proximal on the shaft, this normal urethral plate is elastic and typically nontethering. Artificial erection demonstrates no ventral curvature in these situations. A normal urethral plate may be incorporated into the surgical repair. However, if the urethral plate is underdeveloped, it will act as a tethering fibrous band that bends the penis ventrally during artificial erection. When this fibrous tissue is divided, the penis frequently straightens.

Normally, the genital tubercle should develop in a cranial position above the two genital swellings. The penis may be caught between the two scrotal halves and become engulfed with fusion of the penoscrotal area. The boundary between the penis and scrotum may be formed by two oblique raphes that extend from the proximal meatus to the dorsal side of the penis.

## TREATMENT

The object of therapy is to reconstruct a straight penis with a meatus as close as possible to the normal site (ventrum of the terminal aspect of the glans) to allow a forward-directed urine stream and normal coitus. There are five basic phases for a successful hypospadias outcome: (1) orthoplasty (straightening), (2) urethroplasty, (3) meatoplasty and glanuloplasty, (4) scrotoplasty, and (5) skin cover. These elements can be applied sequentially or in various combinations to achieve surgical success (Fig. 121-11). They are described in conjunction with a number of specific surgical techniques in this section.

## DISTAL OR ANTERIOR HYPOSPADIAS

The treatment of distal hypospadias is dependent on the cultural preference of the child's family. Many patients with distal hypospadias do not have a functional defect, lack significant penile curvature, and will be able to stand and void with a straight stream. Therefore the goal of placing the meatus in its normal position within the glans is essentially cosmetic. The outcome needs to be as close to perfect as possible. The present standard is outpatient surgery. The technique chosen depends on the anatomy of the hypospadiac penis.

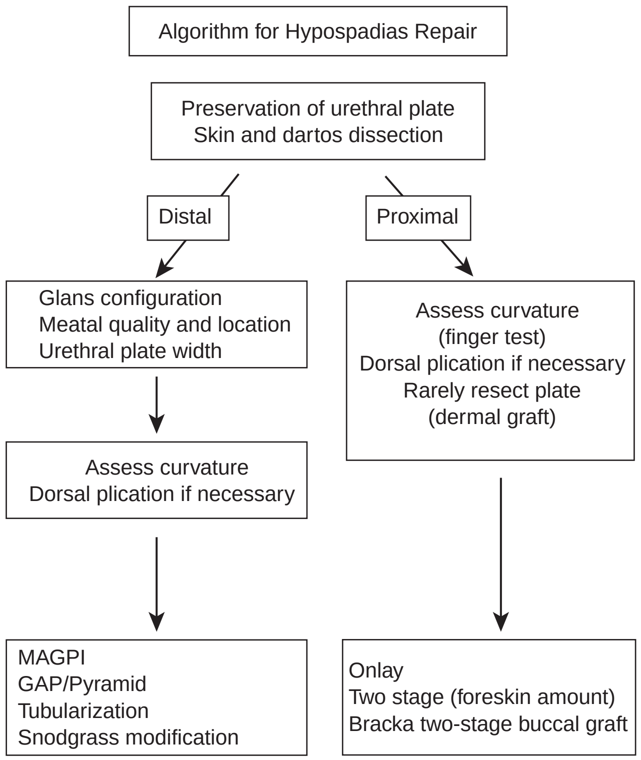

**FIGURE 121-11** Algorithm for hypospadias repair. *GAP,* Glans approximation procedure; *MAGPI,* meatal advancement glansplasty.

The most common procedures performed presently are the meatal advancement with glansplasty incorporated (MAGPI), the glans approximation procedure (GAP), primary tubularization, the Mathieu or flip-flap, and the Duplay or primary tubularization with the incision of the urethral plate (Snodgrass modification) when the plate is too small for primary closure.[75,82–86]

### MAGPI Technique

The MAGPI technique was devised by Duckett in 1981. This technique provides outstanding results in appropriately selected patients. The hypospadiac penis that is amenable to the MAGPI technique is characterized by a dorsal web of tissue within the glans that deflects the urine from either a coronal or a slightly subcoronal meatus. The urethra itself must have a normal ventral wall, without any thin or atretic urethral spongiosum. The urethra must also be mobile so that it can be advanced into the glans (Fig. 121-12).

A circumferential incision is made around the corona proximal to the meatus on the ventrum and 5 mm below the coronal margin to create a Firlit collar on the dorsum (see Fig. 121-12, *A*). The meatal advancement of the dorsal urethral wall is accomplished by a Heineke-Mikulicz vertical incision and horizontal closure (see Fig. 121-12, *B*). More commonly, a wedge of glanular tissue that includes the glanular meatal wall is removed. The horizontal closure flattens out the glanular bridge and permits the dorsal urethra to be advanced out onto the glans tissue to the apex of the glanular groove, where it is sutured with interrupted 7-0 Vicryl (see Fig. 121-12, *C*). This flattens the deflecting ridge of glans and permits the stream to be directed forward.

The glansplasty is made by reconfiguring the flattened glans into a conical shape (see Fig. 121-12, *D*). By rotating the lateral wings around to the midline proximal to the meatus, a proper conical glans shape can be recreated. The deep glanular tissue is brought together with interrupted 6-0 Vicryl, and the superficial epithelial edges are closed with 7-0 chromic suture (see Fig. 121-12, *E*). In this way, mesenchymal glans tissue heals to glans tissue between the epithelial layers of the urethra and the outer epithelium of the glans; this prevents meatal retraction. The rotation of the glans wings reconfigures a nearly normal glanular appearance. When there is ventral skin deficiency, dorsal preputial skin can be transposed in a Byar flap fashion to the ventrum (see Fig. 121-12, *E*). No stents or catheters are required for diversion in children younger than 12 months. Preservation of the foreskin is possible with the MAGPI procedure as long as penile curvature is minimal.[46,87] Polus and Lotte,[122] Gilpin,[66] and Snodgrass[88] demonstrated foreskin preservation in anterior hypospadias repair without chordee (Fig. 121-13).[88–90]

### GAP Procedure

The GAP procedure is applicable in a small subset of patients with distal hypospadias who have wide and deep glanular grooves.[86] These patients do not have a bridge of glanular tissue that typically deflects the urine stream, as seen in patients who would be more appropriately treated with the MAGPI procedure. In the GAP procedure the wide-mouthed urethra is tubularized primarily, over a stent (Fig. 121-14). Ventral glanular tilt, meatal retraction, and splaying of the urine stream can result from the inappropriate use of the MAGPI technique in these circumstances.

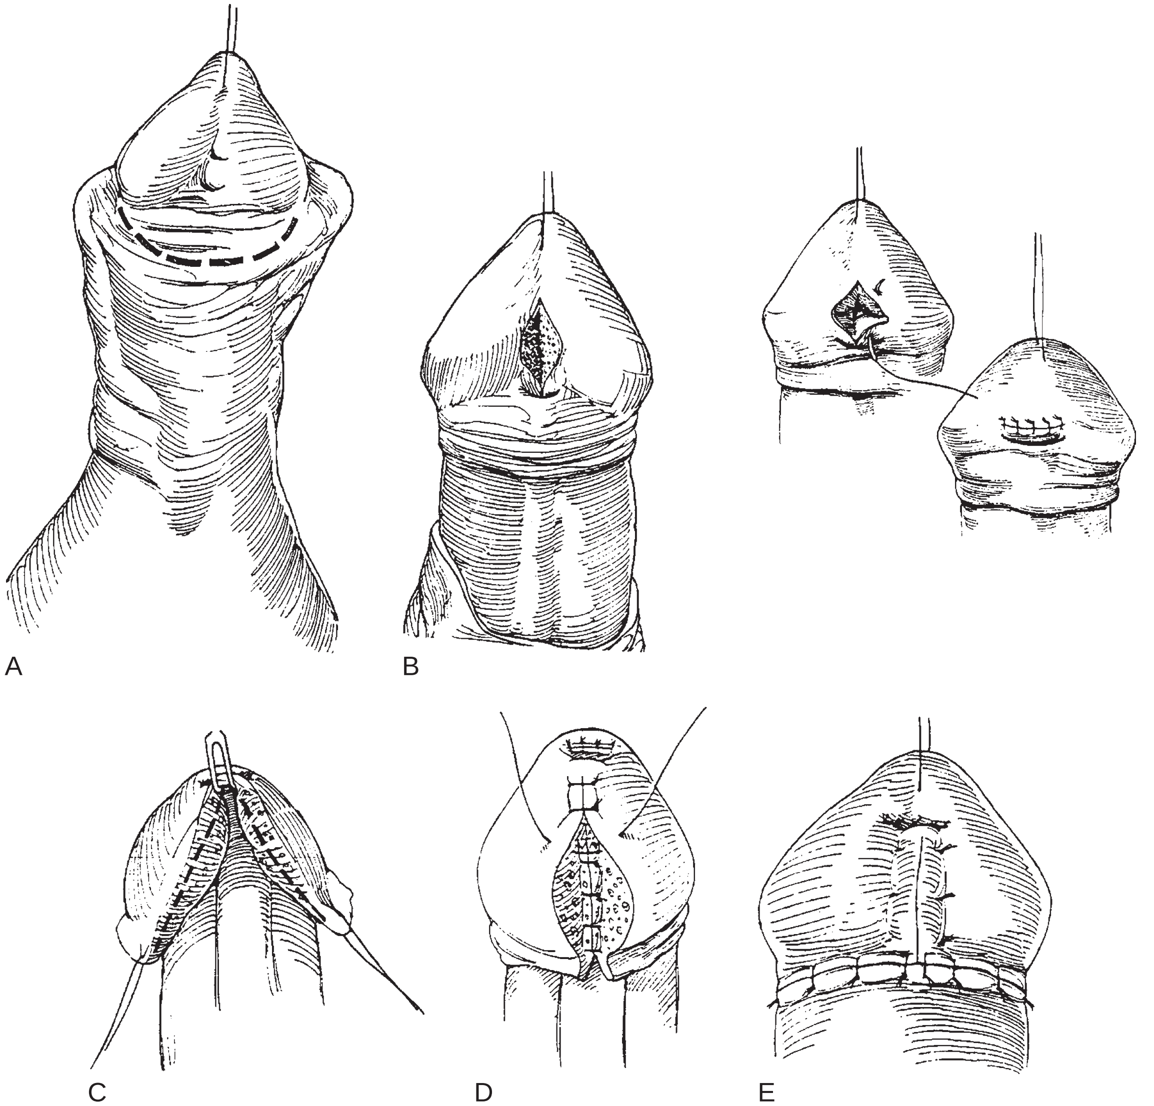

**FIGURE 121-12** MAGPI hypospadias technique. **A,** Initial circumferential subcoronal incision. **B,** Heineke-Mikulicz closure of the dorsal meatus after excision of the dorsal web skin bridge. **C,** Exposure of the glans mesenchyme, the most critical step, is accomplished by trimming the excess skin (*dashed lines*) and advancing the mobile urethra with the use of a 6-0 chromic suture or a skin hook. **D,** Two-layer closure of the glans mesenchyme over the advanced urethra, allowing for a normal-appearing glans with excellent support of the urethra. **E,** Skin closure with a sleeve approximation of the penile shaft skin. If there is ventral skin deficiency, a Byar flap rearrangement with a standard midline seam is appropriate. (From Hinman F Jr: Atlas of Pediatric Urologic Surgery. Philadelphia, WB Saunders, 1994, pp 575-578.)

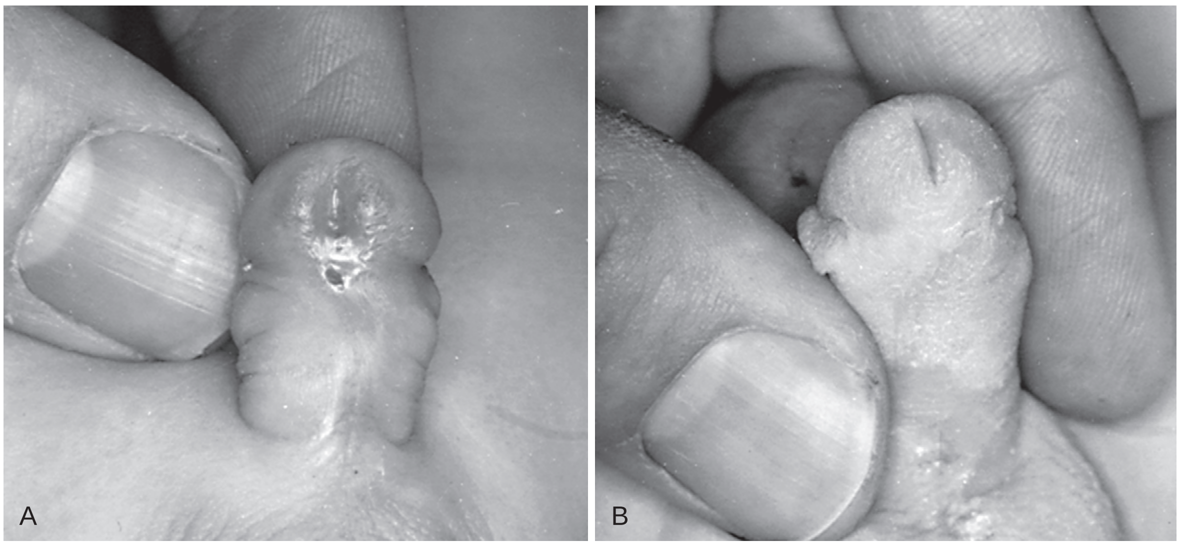

**FIGURE 121-13** **A,** Preoperative patient with anterior hypospadias amenable to the MAGPI procedure. Note the dorsal web of tissue. **B,** Postoperative result of the MAGPI procedure. (From Duckett JW, Baskin LA: Hypospadias. In Gillenwater J, Grayhack JT, Howards SS, Duckett JW (eds): Adult and Pediatric Urology, 3rd ed. St Louis, Mosby-Year Book, 1996.)

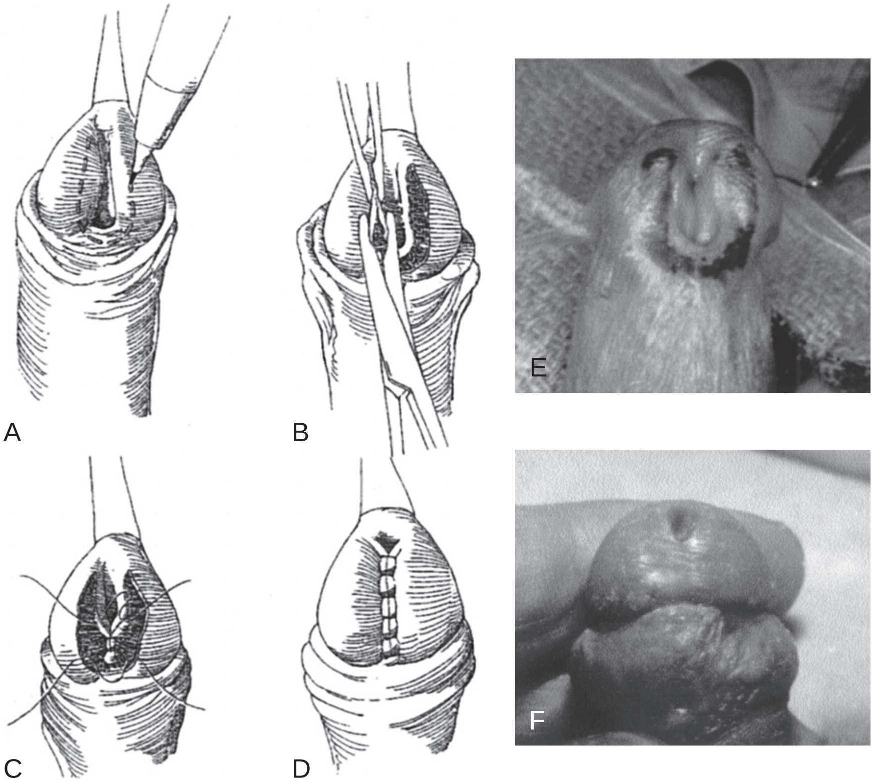

**FIGURE 121-14** GAP hypospadias technique. **A,** Initial incision. **B,** Exposure of the glans mesenchyme by de-epithelialization of tissue. This is critical for a two-layer glans closure and provides good support of the urethroplasty. **C,** Tubularization of the neourethra, followed by glans closure. **D,** Completed repair. **E,** Anterior hypospadias with a patulous fish-mouth urethra amenable to the GAP procedure. **F,** Postoperative outcome.

## Urethral Mobilization

Another method of dealing with a subcoronal meatus is urethral mobilization. Reported as far back as 1917 by Beck,[91] urethral mobilization was revived by Koff and de Sy.[92–94] This technique offers little advantage over the other distal techniques and requires a more extensive procedure to mobilize the penile urethra potential compromising the urethra's vascular supply. The meatal stenosis rate is significant.

## Pyramid Procedure

In 6% of those with distal hypospadias, the prepuce is intact and a megameatus exists under the normal foreskin, with a wide glanular defect and no penile curvature (Fig. 121-15).[77] These anomalies may be recognized only after circumcision is performed, potentially making correction more complex. Duckett and Keating designed the "pyramid" technique to repair the megameatus variant.[77] The enormous distal urethra is carefully dissected down the shaft of the glans and distal penis by way of a four-quadrant exposure (hence the pyramid designation). The urethra is tapered and buried in the glans, similar to an epispadias repair (see Fig. 121-15, *C*).

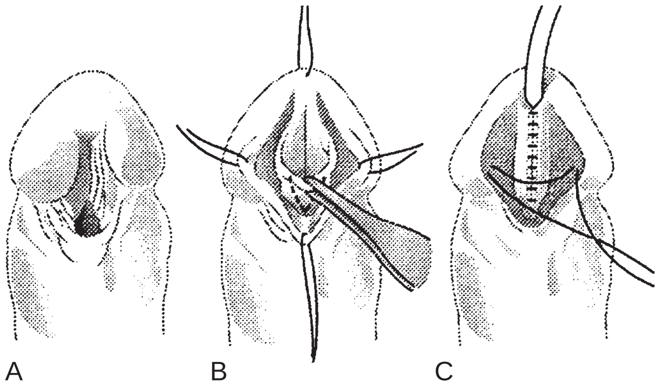

**FIGURE 121-15** Megameatus hypospadias repaired by the pyramid procedure. **A,** Patients with a megameatus have a wide glanular defect and no penile curvature. Calibration reveals that the meatus is 22 to 24 Fr in a newborn baby, compared with the normal caliber of 12 to 14 Fr. Often this anomaly is recognized only after circumcision. Correction, however, is the same as if the foreskin were intact. **B,** The technique involves careful periurethral dissection, exposing the urethra and glans tissue and then removing a wedge of the abnormally enlarged urethra. **C,** The exposed glans tissue is closed over the newly closed neourethra. Technically, this procedure involves careful dissection down the shaft and distal penis by way of a four-quadrant exposure, hence its designation as the *pyramid technique.* Tapering the urethra and burying it into the glans are similar to the technique used for epispadias.

## Mathieu or Perimeatal-Based Flap Procedure

When the meatus is too proximal on the shaft to perform a MAGPI procedure, or when there is no deep glanular groove appropriate for a GAP or in situ tubularization technique (see later), the meatus is advanced onto the glans using the technique described in 1932 by the French surgeon Mathieu.[84] This technique involves the use of a perimeatal skin flap, based on the intrinsic blood supply. To ensure viability, the length-to-width ratio of the skin flap should not exceed 2:1. The flap has also been used essentially as a free skin graft, with no attempt made to preserve any of the subcutaneous tissue. A pedicle of foreskin is brought around, as in a vascularized flap technique, and used as a recipient bed. When designing a Mathieu repair (Fig. 121-16), the ventral skin must be able to be advanced to its new location on the glans. Some modifications of the Mathieu procedure involve a second layer as a subcutaneous pedicle.

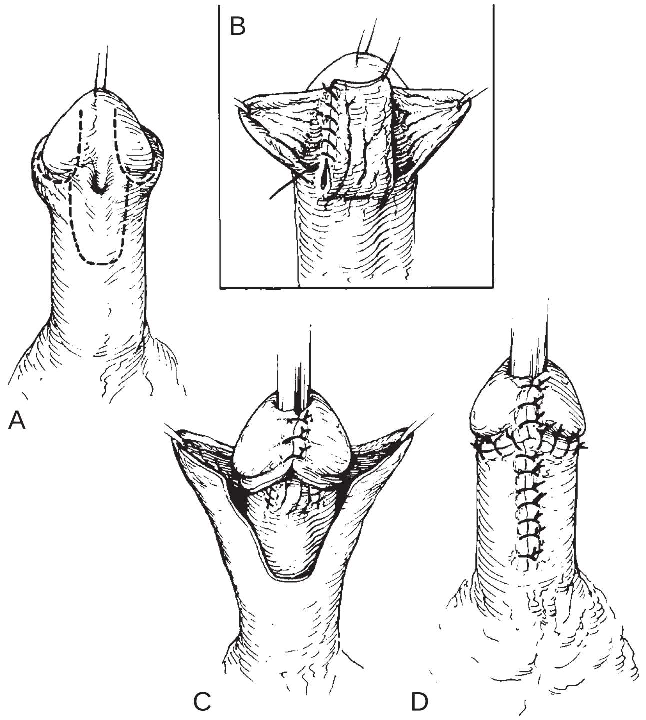

**FIGURE 121-16** Mathieu procedure. **A,** *Dotted lines* outline the skin flaps. **B,** The proximal flap is rotated, and the lateral glans flaps are developed. **C,** The glans flaps cover the neourethra, and preputial skin is moved, if necessary. **D,** Completed repair. (From Duckett JW: Hypospadias. In Walsh PC, Gittes RF, Perlmutter AD, et al [eds]: Campbell's Urology, 5th ed. Philadelphia, WB Saunders, 1986, pp 1969-1999.)

Redman[95] revived the Barcat[96] modification of the Mathieu procedure by mobilizing a glans flap in addition to the perimeatal-based flap and splitting the glans dorsally to bury the urethral extension farther toward the apex of the glans. Koff and colleagues[93] have extensive experience with this technique and have reported excellent results.

### Tubularized Plate Urethroplasty with and Without Snodgrass Modification

Historically, if the urethral groove was not wide enough for tubularization in situ, an alternative approach such as the Mathieu technique or, for more severe hypospadias, a vascularized pedicle flap was taken. More recently, the concept of incising the urethral plate, with subsequent tubularization and secondary healing, was introduced by Snodgrass (Fig. 121-17).[75] Short-term results have been excellent, and this procedure is enjoying extensive popularity.[85] One appealing aspect is the slitlike meatus, which is created with a dorsal midline incision. This technique has also been applied to more posterior forms of hypospadias.[97] Theoretically, one concern is the possibility of meatal stenosis from scarring, as occurs in patients with urethral stricture disease; in the latter, direct-vision internal urethrotomy often leads to recurrent stricture. However, reports of meatal stenosis have been rare.[98] In hypospadias, the native virgin tissue, with its excellent blood supply and large vascular sinuses, seems to respond to primary incision and secondary healing without scarring.

The tubularized incised plate urethroplasty is conducive to preservation of the foreskin (Fig. 121-18).[88] To preserve the foreskin, the incision is made only on the ventrum; therefore

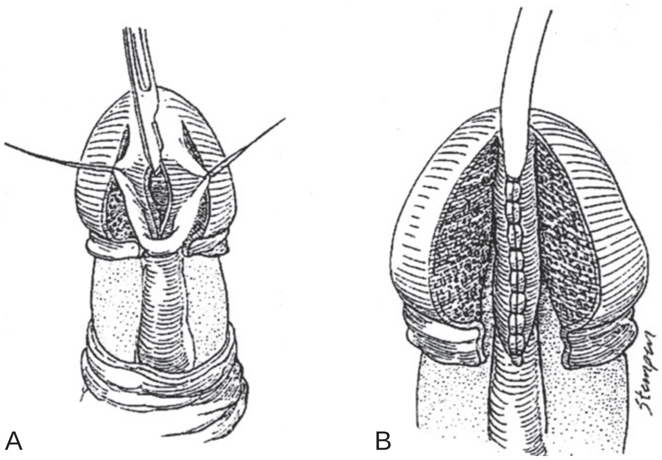

**FIGURE 121-17** Tubularized plate urethroplasty. **A,** Deep incision in the urethral plate down to corporal tissue. **B,** Tubularization of the neourethra, with subsequent glansplasty.

patients with significant penile curvature are not candidates for this procedure. A three-layer closure of the prepuce prevents foreskin fistula. The fact that the foreskin cannot be used as a de-epithelialized flap theoretically increases the possibility of urethral fistula.

## POSTERIOR HYPOSPADIAS

### Urethral Plate Preservation

Duckett popularized the concept of preserving the urethral plate, which is now standard practice for the repair of almost all hypospadias cases.[83,99] The urethral plate serves as the dorsal urethral wall, and the ventral urethra is created by a vascular onlay flap of tissue from the inner prepuce. Extensive experience has shown that the urethral plate is rarely the cause of penile curvature (Fig. 121-19). This knowledge was gained by repetitive resection of the urethral plate and subsequent artificial erection, which showed no improvement in correction of the penile curvature (see Fig. 121-19).[99] Further efforts and experience have shown that the urethral plate is typically supple and pliable and that ancillary penile strengthening procedures such as midline dorsal plication (see later), with preservation of the urethral plate, have led to fewer complications such as fistula and stenosis at the proximal anastomosis.[99,100]

The concept of preserving the urethral plate but undermining it[108,110] and exposing the corporal bodies—with the goal of releasing the chordee tissue—has been advocated.[101,102] Careful anatomic studies have shown that there is an extensive network of blood vessels supplying the urethral plate in the hypospadiac penis, and lifting the urethral plate defeats the purpose of preservation by violating this intricate blood supply.[66] Historically, posterior hypospadias was approached by complete resection of the abnormal urethra and all tissue down to normal corporal bodies. The urethra was replaced by a tubularized vascular preputial flap from either the inner or outer prepuce.[103–105] Presently, in the majority of posterior hypospadias cases including perineal hypospadias, the urethral plate can be preserved and a vascularized flap used in an onlay fashion. In the rare case in which the urethral plate needs to be resected, a two-stage technique can be used (see later).

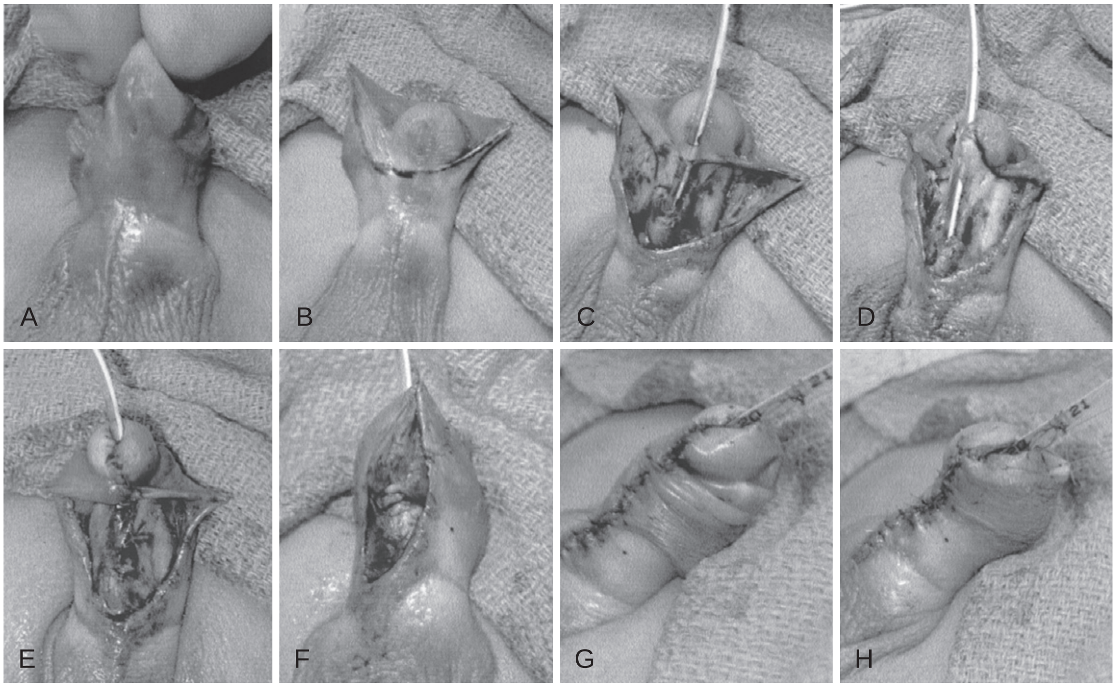

**FIGURE 121-18** Foreskin preservation technique for distal hypospadias. **A,** Distal hypospadias. **B,** The incision is marked for foreskin preservation. **C,** Dissection of ventral skin. Note the thin spongiosum with the distal urethra exposed. **D,** Glans wings have been mobilized, and the distal urethroplasty is completed by the Snodgrass technique. **E,** Two-layer glansplasty. **F,** Three-layer foreskin reconstruction: (1) inner prepuce, (2) subcutaneous tissue to prevent foreskin fistulas, and (3) outer foreskin. **G,** Completed repair with foreskin retracted. **H,** Completed repair.

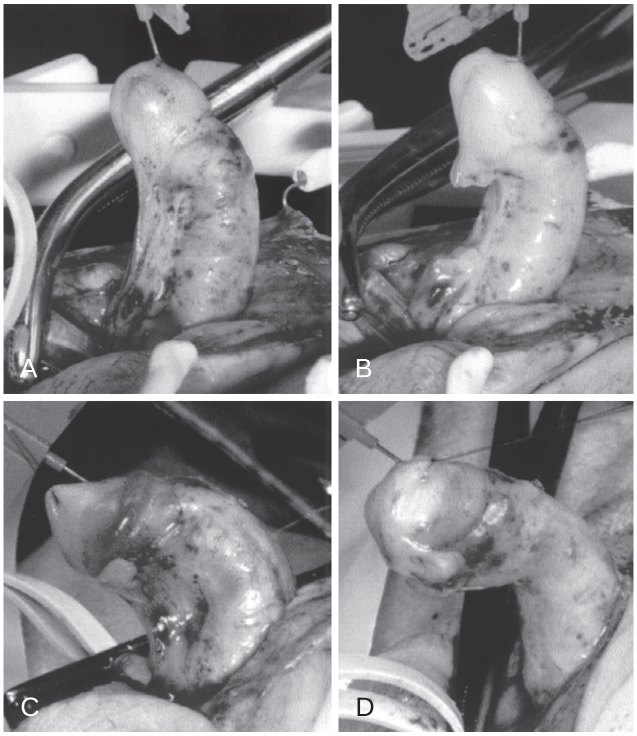

**FIGURE 121-19** **A,** Penile curvature with preservation of the urethral plate. **B,** Resection of the urethral plate with continued severe curvature. **C,** Penile curvature with preservation of the urethral plate. **D,** Resection of the urethral plate with continued severe curvature. Extensive experience has shown that the urethral plate is rarely the cause of penile curvature.

## Onlay Island Flap

The blood supply to the hypospadiac preputial tissue is reliable and easily delineated (see Fig. 121-18).[71,106] The abundance of cutaneous tissue on the dorsum of the penis is vascularized in a longitudinal fashion.[107] This tissue may be dissected from the penile skin, creating an island flap from the inner layer of the prepuce. The blood supply to the dorsal skin of the foreskin and the penile skin comes from its broad base and is not dependent on the subcutaneous tissues, except at the remote edges of the dorsal preputial skin. The tips of the distal portion of the penile skin flaps can be excised and not used in the repair.

All cases of posterior hypospadias (i.e., with or without penile curvature) are approached by initially leaving the urethral plate intact. This technique can be applied to the penile shaft, as well as scrotal and perineal hypospadias. The intact dorsal plate essentially avoids the complication of proximal stricture, and the excellent blood supply has decreased the fistula rate to approximately 15% for all cases of onlay island flap hypospadias repair (Fig. 121-20).[99] For shorter repairs, the flap may be dissected from half the prepuce, as described by Rushton and Belman,[108] leaving the remaining half of the foreskin available for a second layer of coverage. Long-term results with the onlay island flap have been durable.[101,109,110] For severe hypospadias, the prepuce can be designed in a horseshoe style to bridge extensive gaps (see Fig. 121-20, *K*).

## Transverse Tubularized Island Flap

The technique of using the transverse tubularized island flap was used extensively before the concept of preserving the urethral plate (Fig. 121-21). It is still successful in severe

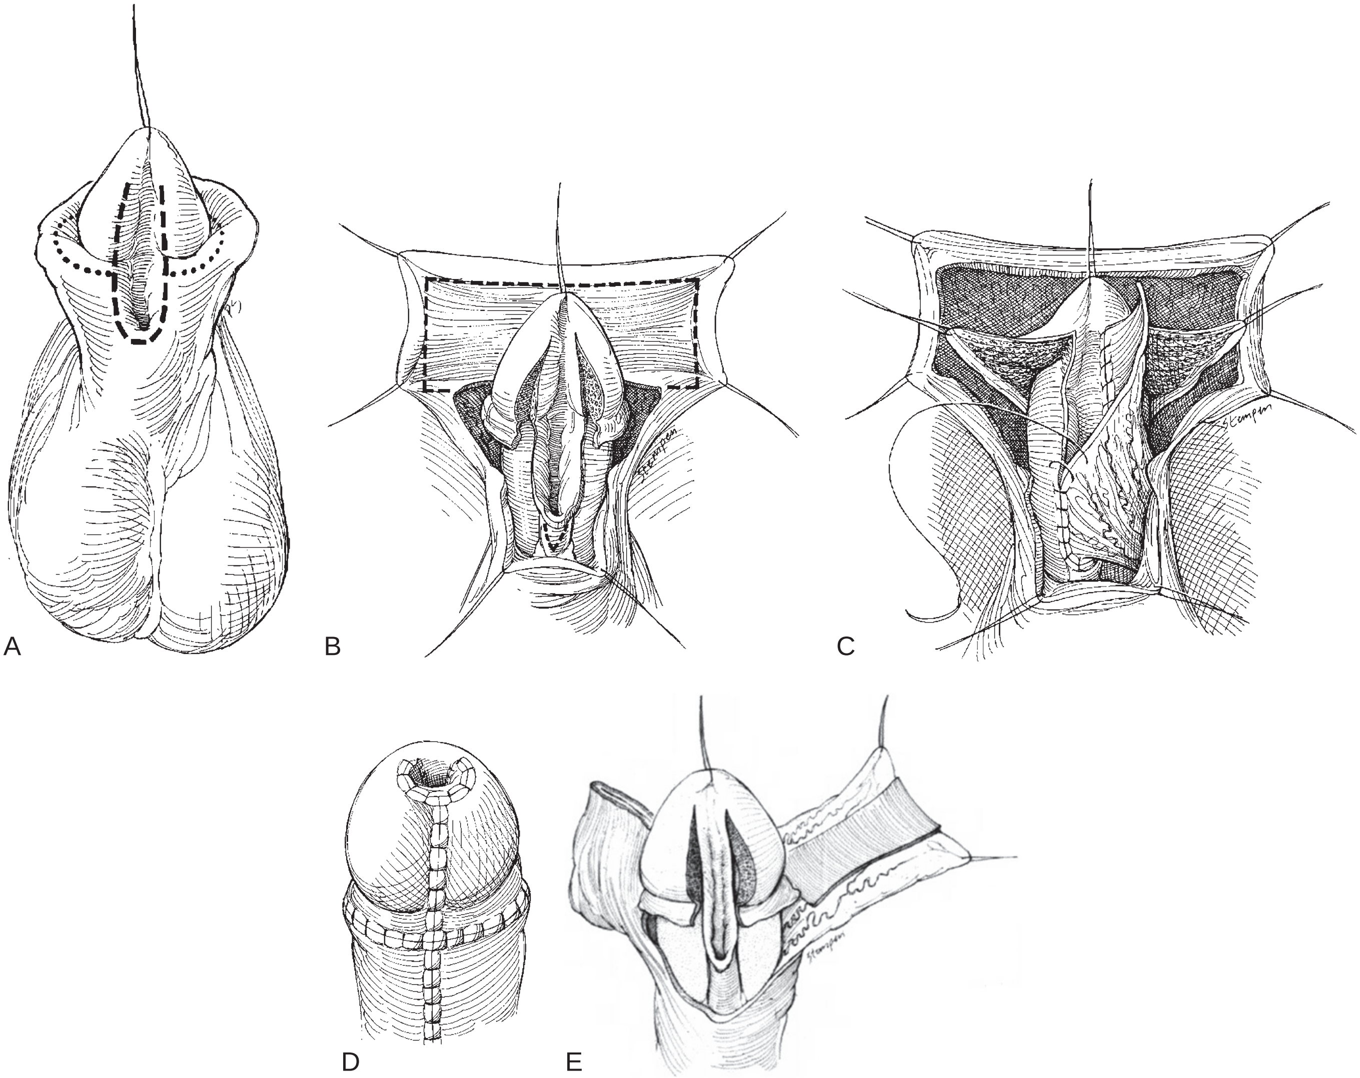

**FIGURE 121-20** Onlay island flap hypospadias repair. **A,** A U-shaped incision is made around the urethral plate, preserving a dorsal urethral strip approximately 8 mm wide. **B,** Takedown of the skin and subcutaneous tissue and outlining of the inner prepuce for the onlay island flap. Glans wings are mobilized along the plane of the corporal body and the glans mesenchyme. **C,** Preservation of the urethral plate with penile curvature in a case of penoscrotal hypospadias. **D,** Suturing of the onlay flap to the urethral plate with running 7-0 sutures. The flap is trimmed to obtain a 12-Fr bougie in a 1-year-old child to prevent the complication of urethral diverticulum, which results from leaving excess tissue. The glans wings are approximated over the new urethra after maturing the meatus. The skin is then closed by a classic Byar flap rearrangement. **E,** The split prepuce in situ technique for dissection of a short vascularized onlay island flap. This method is useful for shorter onlays, leaving the remaining half of the foreskin available for a second layer of coverage.

*Continued*

cases when the urethral plate needs to be resected, although long-term problems with diverticulum have resulted in a high reoperation rate. Technical nuances involve an oblique proximal anastomosis with interrupted sutures to avoid stenosis; fixation of the neourethra to the corporal bodies to prevent diverticulum and improve ease of catheterization; and a wide glans channel made underneath the glans cap, against the corporal bodies to avoid meatal stenosis.[104]

### Two-Stage Hypospadias Repair

An alternative approach for severe hypospadias is to transfer the dorsal prepuce to the ventrum after correcting the penile curvature (Fig. 121-22). In severe cases the urethral plate may need to be resected to correct chordee. Dermal grafting may be required, and performing a urethroplasty on top of the healing graft is not suggested. Instead, Byar flaps can be rotated from the dorsum, setting up ventral coverage for subsequent urethroplasty.[111] Occasionally the chordee can be corrected without resection of the urethral plate. In this case the dorsal skin can be sutured to each side of the preserved urethral plate (see Fig. 121-22, *D*). The second stage is performed at least 6 months after the first stage. To assist the urethroplasty within the glans, dorsal skin can be tucked within the glans wings during the first stage. Subcutaneous secondary coverage of the reconstructed urethra is performed to prevent fistula. In cases where local tissue is not readily available, a tunica vaginalis flap from the testicle can be mobilized and used to cover the urethroplasty.[112–114] Long-term results documented through puberty have been durable.[115]

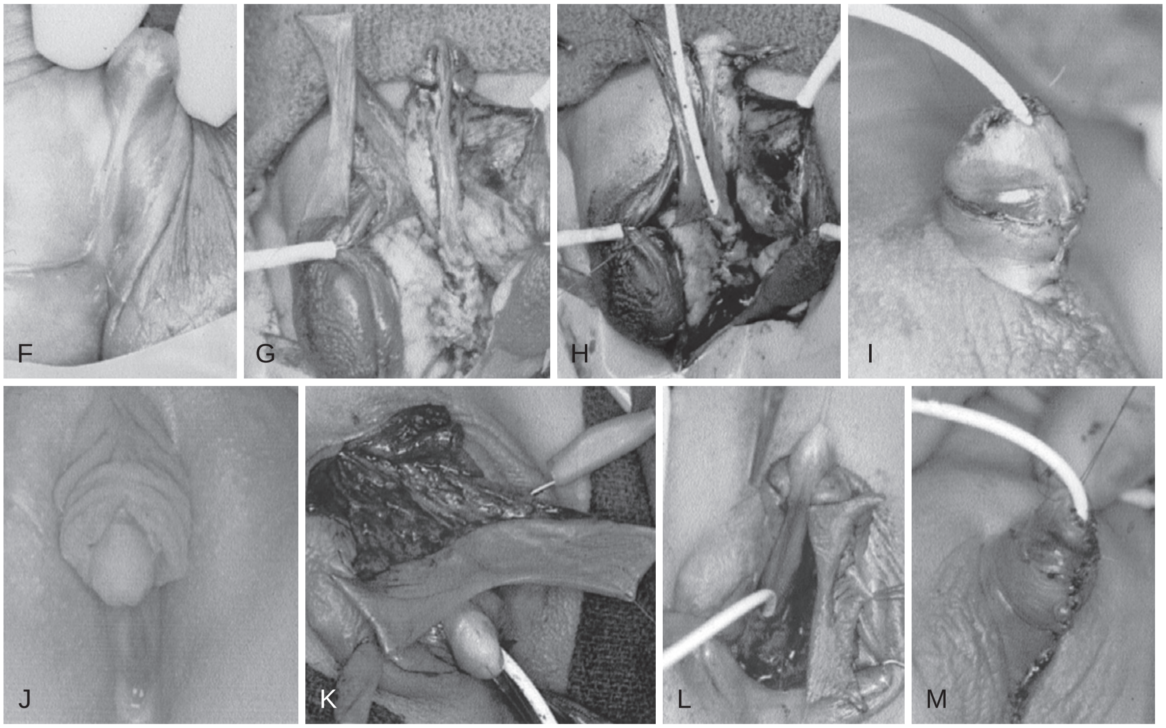

**FIGURE 121-20—CONT'D** **F,** Penoscrotal hypospadias amenable to the onlay island flap technique. **G,** Preservation of the urethral plate and flap dissection. **H,** Suturing of the onlay to the urethral plate. **I,** Completed repair. **J,** Perineal hypospadias. **K,** Horseshoe vascularized onlay island flap to bridge a long urethral deficit. **L,** Onlay flap rotated to bridge the urethral defect. **M,** Completed repair.

### Bracka Two-Stage Buccal Graft Repair

For patients with prior surgery or with severe hypospadias, Bracka described a two-stage buccal graft repair.[116–118] In the first stage the penis is straightened, and the scarred urethra is discarded (Figs. 121-23 and 121-24). Buccal mucosa is harvested from either the cheek or the lip and grafted to the prepared bed.[119] Extensive quilting of the graft is performed to prevent hematoma from lifting off the buccal mucosa. During the first stage, glans wings are mobilized in preparation for the creation of a slitlike meatus during the second stage. The second-stage urethroplasty is undertaken at least 6 months after the first stage. In the second stage, excess buccal mucosa is trimmed off the glans, setting up a two-layer glans closure (see Figs. 121-23 and 121-24). The buccal mucosa is rolled into the new urethra, and subcutaneous tissue is used for secondary coverage.

## PENILE CURVATURE

Correction of penile curvature has evolved along with the concept of preserving the urethral plate. Artificial erection, introduced by Gittes and McLaughlin in 1974, provides a mechanism to check for penile curvature and the success of correction at the time of surgery.[120] A tourniquet is placed at the base of the penis, and a corpus cavernosum is injected with saline. Both corporal bodies fill, so it is possible to determine the extent of curvature and the success after correction. The assurance of complete correction is essential before proceeding to urethroplasty and one-stage repair. There have been no reports of damage to the cavernous tissue with this technique, as long as care is taken to ensure that injectable saline is used.

In reality, all penises have penile curvature during development (Fig. 121-25). The majority of penile curvature resolves when the penile skin is dissected to the penoscrotal junction—hence the term "skin chordee."[121] Curvature may also result from differential growth of the dorsal and ventral aspects of the corpora body.[122] Finally, in rare cases the urethra itself may be short or atretic, requiring resection to correct curvature and subsequent augmentation.

Historically, chordee was corrected by a modification of Nesbit's dorsal plication, taking out wedges of tunica albuginea in an ellipse and closing this with permanent suture.[123] This technique was first described by Syng Physick, the "father of American surgery," in the early nineteenth century. Physick treated chordee by shortening the dorsal tunica albuginea.[124] When the arc of maximal curvature is identified during artificial erection, wedges of tunica albuginea are excised in a stepwise fashion. These diamond wedges are closed transversely with permanent suture until the penis is straight. Nesbit's technique has been modified into dorsal tunica albuginea plication for the correction of penile curvature in the setting of corporal disproportion, as well as hypospadias.[100] On the basis of anatomic studies of the human fetal penis, a simpler approach—placing dorsal midline plication sutures in the nerve-free zone at the 12 o'clock position—is now advocated.[66] Midline dorsal plication avoids the need for mobilization of the neurovascular bundle (Fig. 121-26).[72] Midline plication can be applied to mild to moderate degrees of curvature (Fig. 121-27).[125] If more than two rows of plication sutures or more than four permanent sutures are

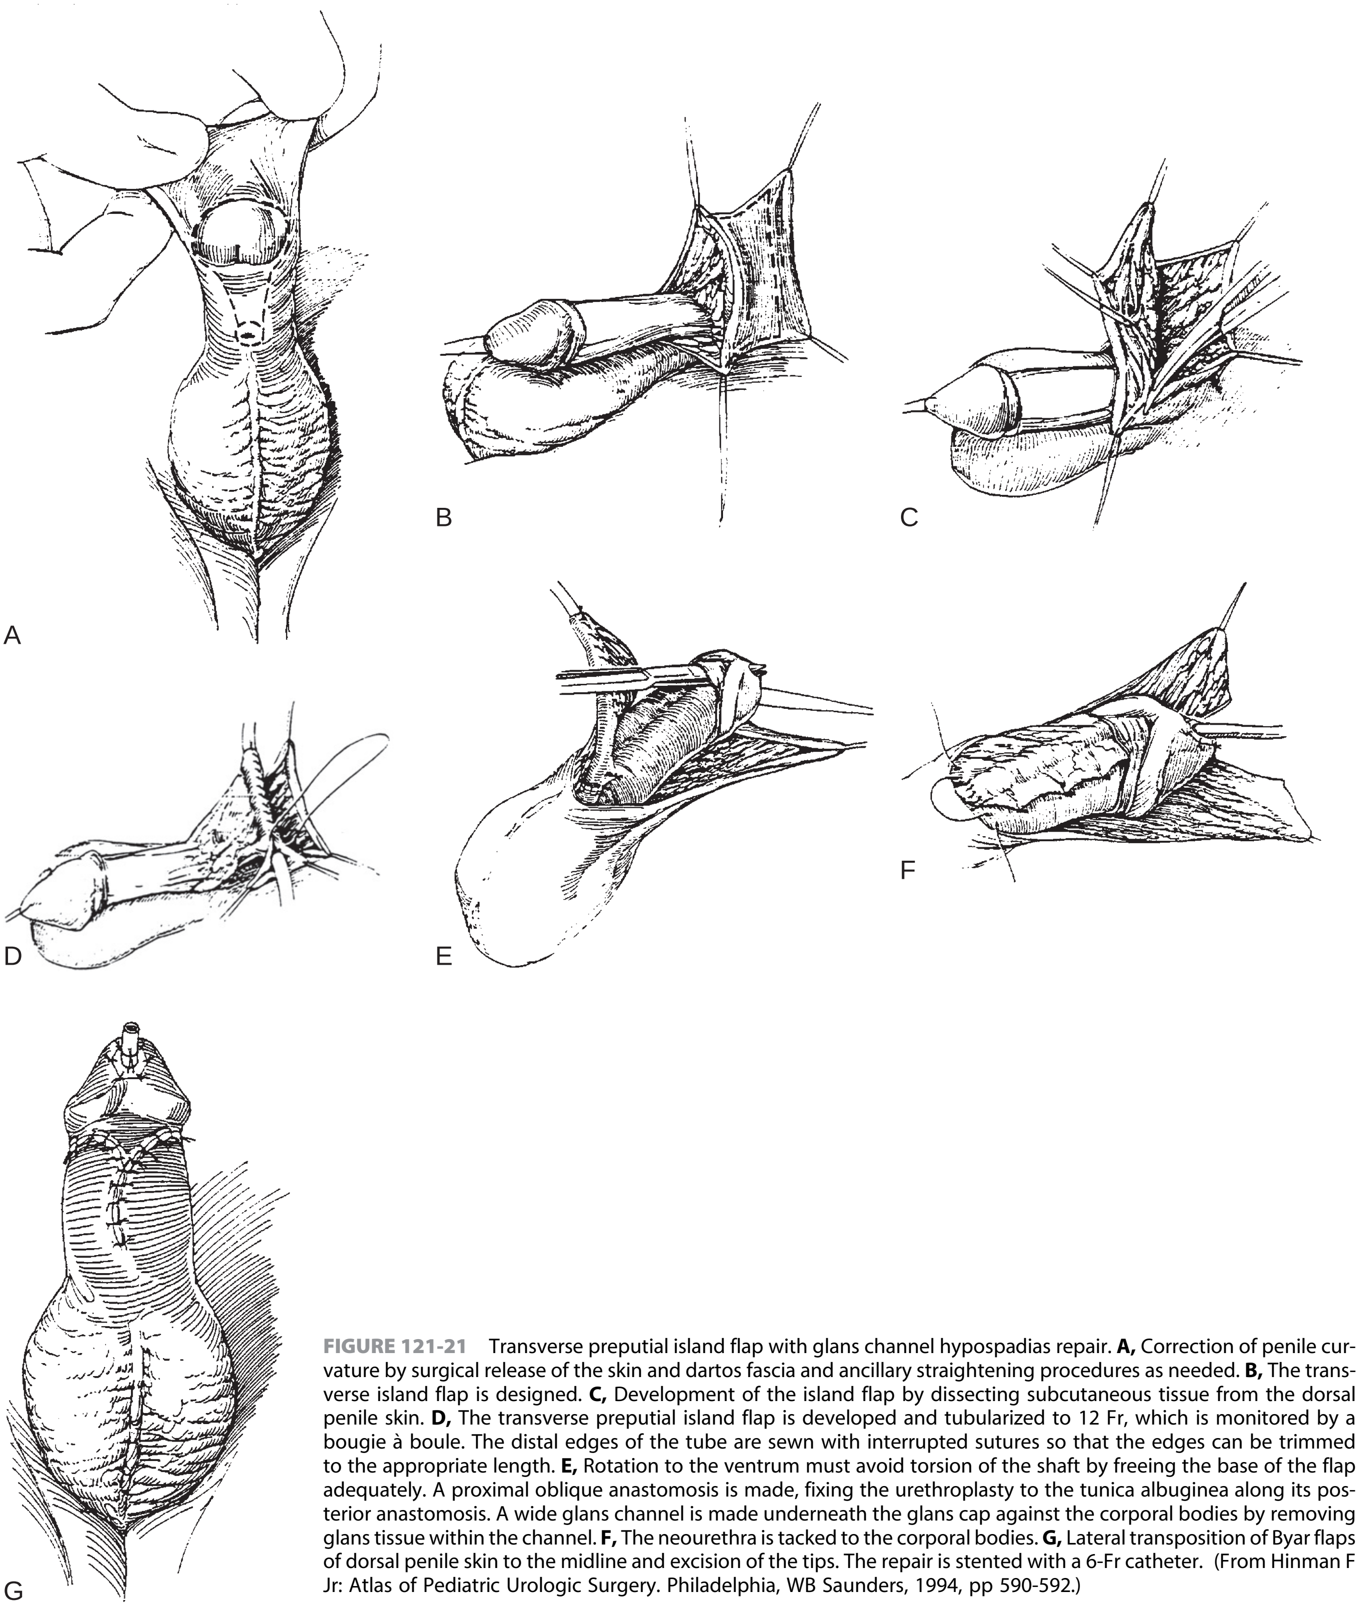

**FIGURE 121-21** Transverse preputial island flap with glans channel hypospadias repair. **A,** Correction of penile curvature by surgical release of the skin and dartos fascia and ancillary straightening procedures as needed. **B,** The transverse island flap is designed. **C,** Development of the island flap by dissecting subcutaneous tissue from the dorsal penile skin. **D,** The transverse preputial island flap is developed and tubularized to 12 Fr, which is monitored by a bougie à boule. The distal edges of the tube are sewn with interrupted sutures so that the edges can be trimmed to the appropriate length. **E,** Rotation to the ventrum must avoid torsion of the shaft by freeing the base of the flap adequately. A proximal oblique anastomosis is made, fixing the urethroplasty to the tunica albuginea along its posterior anastomosis. A wide glans channel is made underneath the glans cap against the corporal bodies by removing glans tissue within the channel. **F,** The neourethra is tacked to the corporal bodies. **G,** Lateral transposition of Byar flaps of dorsal penile skin to the midline and excision of the tips. The repair is stented with a 6-Fr catheter. (From Hinman F Jr: Atlas of Pediatric Urologic Surgery. Philadelphia, WB Saunders, 1994, pp 590-592.)

necessary, however, an alternative approach such as complete resection of the urethral plate and dermal grafting should be considered. Midline dorsal plication has also been effective for recurrent curvature.[126] During artificial erection, if the curvature cannot be corrected with the surgeon's finger, midline dorsal plication is not advised. A glans tilt may also be repaired by permanent sutures on the dorsum, but care must be taken to avoid the neurovascular structures supplying the glans.[18]

In rare cases the tunica albuginea is so deficient on the ventrum that excision of the tunica is required, with replacement

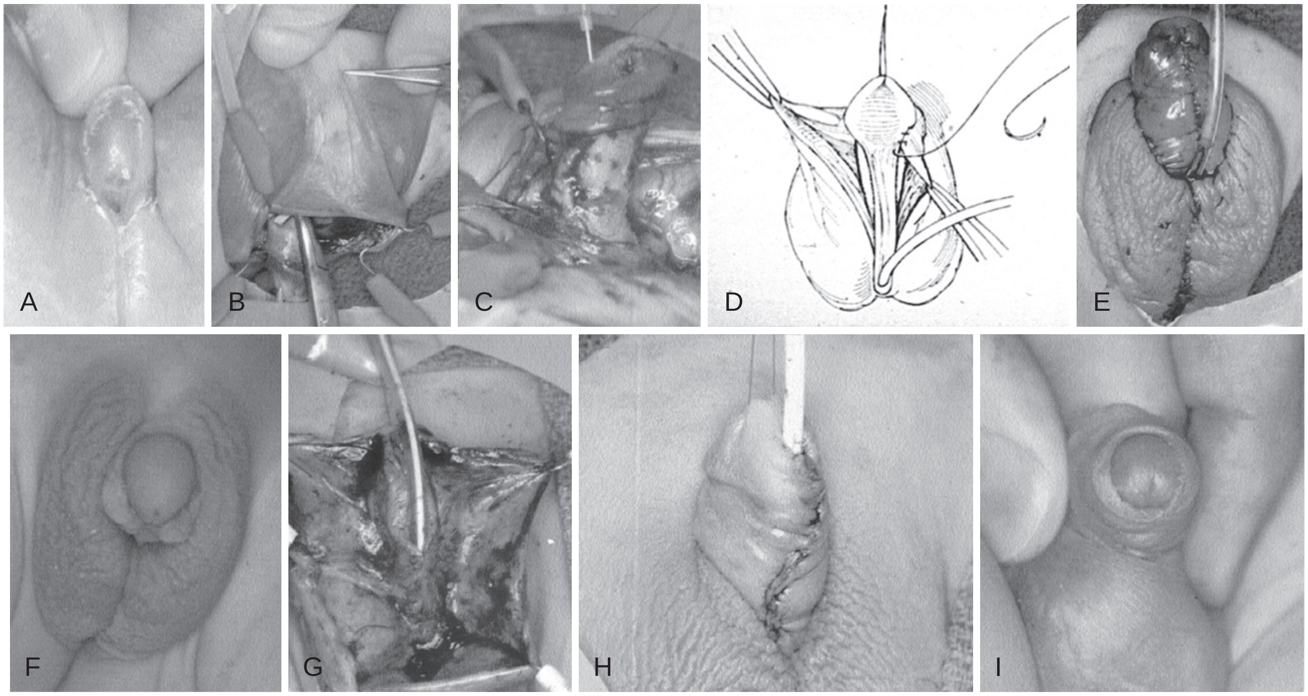

FIGURE 121-22 Two-stage hypospadias repair. **FIGURE 121-25** **A,** Congenital fistula. **B** and **C,** Chordee without hypospadias. Abnormal development of the urethral spongiosum necessitates urethroplasty and causes penile curvature.

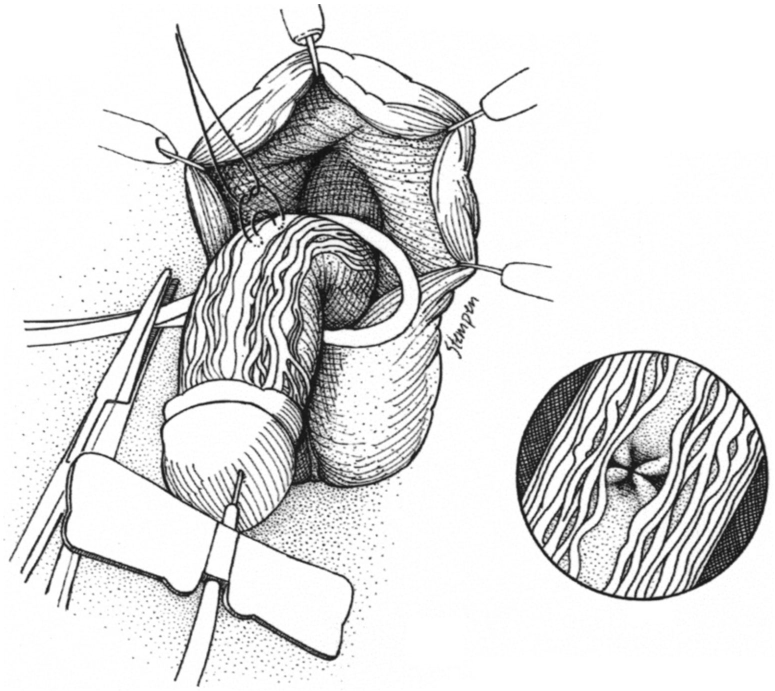

**FIGURE 121-26** Midline dorsal plication technique. In this technique, parallel plication sutures are placed in the tunica albuginea in the 12 o'clock position, which is free of both nerves and vascular structures. This technique requires a minimal amount of manipulation of the penis. It is not necessary to incise into the corporal body or extensively mobilize Buck fascia. If the curvature is severe, a maximum of two rows of parallel plications can be placed for correction.

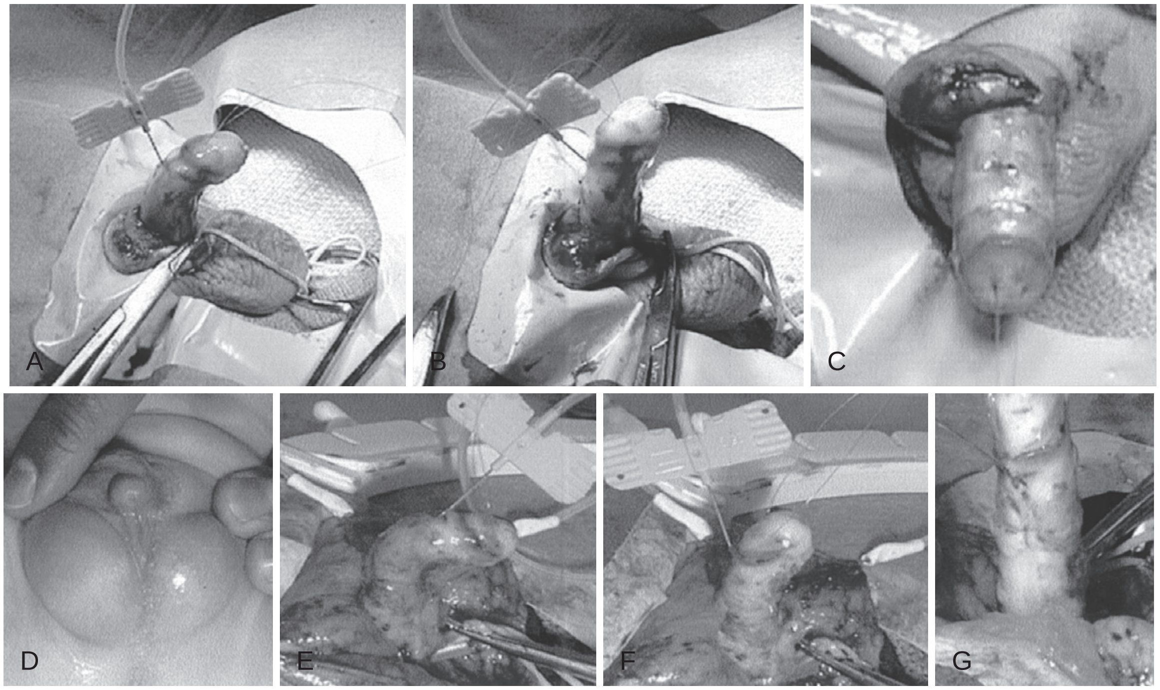

**FIGURE 121-27** Midline dorsal plication technique. **A** to **C,** Correction of mild curvature. **D** to **G,** Correction of moderate to severe curvature. Note the two permanent 5-0 Prolene plication sutures in the midline nerve-free zone.

by an elastic graft. I prefer the use of dermis, as described by Horton and Devine,[80] which has withstood the test of time (Fig. 121-28).[127]

About 5% of patients need ancillary penile straightening procedures after the release of skin curvature by aggressive dissection to the penoscrotal junction.[3,99,128] Of those requiring ancillary procedures, most (>90%) can be corrected by dorsal midline plication without the need for resection of the urethral plate. This leaves a small minority of severe cases requiring resection of the urethral plate, dermal grafting, or both.

## PATIENTS WITH MULTIPLE FAILURES

Some patients undergo multiple hypospadias repairs that fail; this unfortunate outcome can occur even in skilled hands.[129] In such patients, it is often necessary to discard the previously

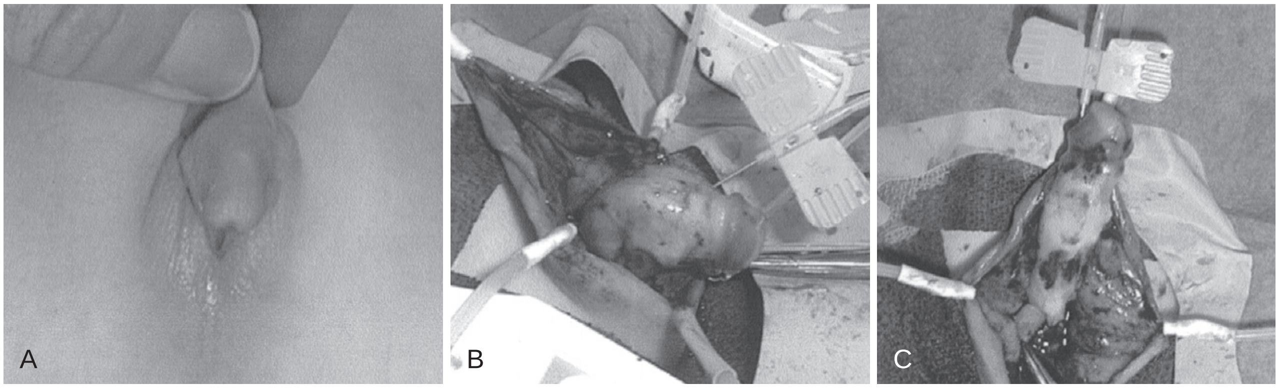

**FIGURE 121-28** Dermal graft for severe ventral penile curvature. **A,** Scrotal hypospadias. **B,** Severe right-angle curvature after aggressive skin and subcutaneous dissection. **C,** Ventral incisions for placement of dermal graft. (From Hinman F Jr: Atlas of Urologic Surgery. Philadelphia, WB Saunders, 1989, pp 91-92.)

created problem-plagued urethra and start anew. The penis may be further straightened, if necessary. In some cases it may be appropriate to place a meshed split-thickness skin graft and go back later for tubularization[130,131] or to place a free graft of buccal mucosa or skin where the scarred urethra was resected.[117] In patients with a paucity of penile skin, a full-thickness skin graft can provide adequate skin coverage.[132] I prefer harvesting the skin from the patient's buttock so that the scar from the graft site will be well hidden. A wound vac for 5 days postoperatively has ensured excellent graft take. Rarely, tissue expanders have been useful to stretch local genital skin.[133] In the past, bladder mucosa was used for the neourethra[134,135] because the long-term results with free skin grafts were not as good as previously reported.[136] Unfortunately, bladder mucosa grafts were complicated by eversion at the meatus in up to 30% of patients.[134] Meatal dilatation on a daily basis could not avoid this problem. More recently, buccal mucosa grafts have been used for urethral replacement in these difficult patients.[134,137,138] I presently advocate the two-stage approach of Bracka (see Fig. 121-23).[118,139]

In the future it may be possible to treat difficult cases of hypospadias with autologous grafts of cultured urethral epithelium.[140,141] Finding the ideal support matrix to scaffold the urothelial cells may make this technique widely applicable.

## Technical Considerations

The principles of hypospadiology have been enhanced over the years by the precise, delicate tissue handling taught by plastic surgeons and the use of optical magnification. Sharp-pointed iris scissors and delicate-toothed forceps are the principal tools. Castroviejo needle holders and 0.5-mm forceps are useful for delicate maneuvers with 7-0 sutures. Bougie à boule probes are useful as the procedure progresses for calibrating the sizes of tubes and the anastomosis, as well as the meatus. Fine lacrimal duct probes are useful for identifying fistulas and periurethral ducts.

### HEMOSTASIS

Control of bleeding from the vascular penis and glans can be achieved in a number of ways. Placing a tourniquet at the base of the penis is simplest.[142,143] Recommended tourniquet times vary from 20 minutes to 1 hour. I prefer the injection of 1:100,000 epinephrine in 1% lidocaine (Xylocaine) using a 29-gauge needle. Infiltration around the urethra and into the glans is helpful for developing glans wings. Usually, only 1 to 1.5 mL are required. There is a wide margin of safety before epinephrine sensitizes the myocardium to arrhythmias with the use of inhalational anesthetics.[144] A safe dose is 1 mL/kg of a 1:100,000 solution. I do not believe that epinephrine compromises the vascularity of the flaps. Various methods of coagulation have been recommended; I prefer a low-current electrocautery (Bovie) applied to the 0.5-mm forceps.

### ANALGESIA

In anticipation of postoperative discomfort, the anesthesia team places a long-acting caudal nerve block before the procedure.[145,146] If the repair takes longer than 2 hours, the block can be repeated at the completion of the procedure. Evidence suggests that the caudal block also reduces the amount of bleeding.[147] Alternatively, a supplemental local block with 3 mL of 0.5% bupivacaine (Marcaine) is placed just beneath the symphysis to infiltrate the dorsal penile nerve bundle.[148] Penile blocks also reduce the general anesthetic needs and prevent erections, which can be bothersome and cause extra bleeding.

### DRESSING

For distal hypospadias repair performed without urinary diversion, I currently use a Tegaderm wrap.[3] The parents remove the dressing at home in 24 to 48 hours. For hypospadias repair with urinary diversion, a "sandwich" dressing allows the application of more diffuse pressure by placing the penis onto the abdominal wall. A layer of Telfa followed by a 4- by 4-inch gauze folded three times on the ventrum of the penis is secured with a medium Tegaderm sheet of sticky plastic. The dressing is typically removed at home after 48 hours. I encourage bathing twice a day with the stent in place after 48 hours to allow the dressing to soak off. Warm bathwater allows the repair to remain clean and assists healing.

### DIVERSION

Bladder spasms caused by irritation of the trigone with a catheter can be an aggravating problem. Oral oxybutynin chloride may be of help. Another problem relates to

connections between tubing and a drainage bag. I avoid a Foley catheter, except in teenagers and adults, and prefer a "dripping stent" in infants aged 6 to 18 months. Kendall manufactures a prepackaged 6-Fr hypospadias catheter; alternatively, 5- and 8-Fr feeding tubes are effective. Urethral diversions are used for 3 to 10 days. If the diversion is used for 5 days or less, the family is advised to allow the stent to fall out when the dressing comes off. If used for more than 5 days, the temporary stents can be sutured to the glans with 5-0 polypropylene on a noncutting needle. I have had good success with this technique, which allows the overwhelming majority of hypospadias repairs to be done on an outpatient basis. Patients are followed at 6 months to 1 year after surgery, after toilet training, and after puberty. The urethra is not instrumented during follow-up visits. After toilet training the child urinary stream is observed to assess for occult fistula, diverticulum, and urethral stricture.

### AGE FOR REPAIR

Hypospadias repair is being performed at progressively younger ages. Schultz and colleagues[149] pointed out that an ideal age might be 6 to 18 months to minimize the emotional effect of this traumatic experience. The consensus statement on the timing of genital surgery from the American Academy of Pediatrics also supports early surgery before 18 months of age.[150] Gender identity does not seem to be defined until after 18 months. I now prefer to operate when patients are between 4 and 9 months old; at that age, the penis is of sufficient size to achieve success comparable with that obtained by waiting until age 2 to 5 years, which was previously popular. For many reasons (medical and social), however, surgery may be delayed. Kaplan and colleagues[151–154] studied 69 boys aged 6 to 10 years who had had hypospadias repair in infancy and found no increase in significant psychopathology during childhood, although more recent studies suggest that before age 5 is the most ideal for both functional and psychosocial outcomes.

### TESTOSTERONE STIMULATION

Enlargement of the infant penis is possible by testosterone stimulation. The recommended dose is 25 to 50 mg of testosterone propionate (2 mg/kg) intramuscularly given at 3-week intervals for up to three preoperative doses.[14,155] In Europe dihydrotestosterone transdermal gel has also proven to be effective.[156] I have not found the routine use of testosterone stimulation to be beneficial. In severe cases when the penis is small such as partial androgen insensitivity syndrome or for diagnostic purposes, testosterone is helpful. A patient with a small glans may benefit from presurgical testosterone stimulation. There is a suggestion in animal models that testosterone stimulation may be detrimental to the later maturation of prostatic tissue and penile growth.[157,158] To date, clinical practice has not documented any untoward effects in humans.[159]

## Complications

### MEATAL STENOSIS

Meatal stenosis is caused by technical errors in operative design or poor vascularization of the urethroplasty or glansplasty.[160] Postoperative dilatation is seldom therapeutic and often traumatic for the patient and family. Internal urethrotomy also has poor long-term results. Often the glansplasty will have to be taken apart and reperformed. In some cases a two-stage approach (Bracka) is necessary.[117,118]

### URETHROCUTANEOUS FISTULA

Urethrocutaneous fistulas are the most common late complication of hypospadias repair, and their incidence has been used to evaluate the effectiveness of the surgical procedure.[160,161] The expected fistula rate is between 10% and 20% for most one-stage hypospadias surgery. Often, distal obstruction is related to persistent fistulas. The principles of repairing urethrocutaneous fistulas require wide mobilization, adjacent skin flaps, and multilayered closure.[162–164] I recommend using magnification and delicate instruments for fistula repair. Dissection is carried down to the urethra, and a 7-0 suture is used to close the urethral edges in an inverting fashion. Watertight closure is ensured by irrigating the urethra with proximal compression. Irrigating the urethra will also confirm the absence of an additional fistula. In straightforward fistulas no urinary diversion is used. The patient is allowed to void through his urethra and goes home on the same day.

It is extremely important to recognize a concomitant urethral stricture or diverticulum at the time of fistula closure. These should be repaired to ensure the success of the fistula closure. Occasionally, a meatoplasty may be necessary at the time of fistula repair. A fistula near the glans is best repaired by opening the bridge between the meatus and fistula, mobilizing the inner urethral edges, and closing in two layers with good glans approximation (Fig. 121-29).

### STRICTURE

Strictures result from technical problems during the initial hypospadias repair. Proximal anastomotic strictures may result from either a luminal calibration miscalculation, resulting in a narrow neourethra, or an anastomotic overlap. A meatal stricture may result from chronic balanitis xerotica obliterans. This reaction is located at the meatus or may extend into the more proximal urethroplasty. This may be caused by a poorly vascularized meatoplasty, especially the Mathieu procedure.

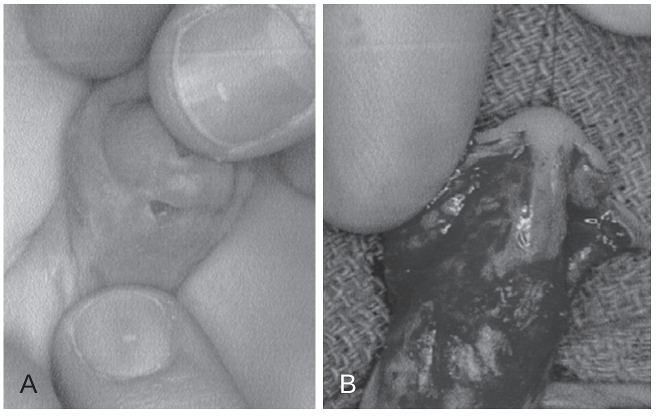

**FIGURE 121-29** Hypospadias fistula. **A,** Coronal fistula requiring redo glansplasty. **B,** Preservation of the urethral plate with eccentric vascularized onlay flap preparation.

The most likely cause of meatal stenosis is vascular compromise of the urethra at the apex of the meatus. It may be secondary to an inadequate glans channel that compresses the vascularity of the pedicle. Once a stricture has developed, it can be repaired by excision and reanastomosis, a vascularized pedicle graft, or a two-stage buccal graft using the technique of Bracka.[117,165] Of note, there has been little success treating strictures secondary to hypospadias surgery with optical internal urethrotomy.[165]

### DIVERTICULUM

A fusiform urethral diverticulum may form because the neourethra was made too wide and meatal stenosis allowed ballooning of the proximal urethra.[1] Reduction of a diverticulum may be necessary and should be done in a longitudinal fashion.[166] Most often, a circumcising incision is used and the penile skin is dropped to the penoscrotal junction, which allows for longitudinal repair of the diverticulum without overlying suture lines. Care must be taken to evaluate the neourethra for an associated fistula. A discrete diverticulum may develop from urinary extravasation into the tissues adjacent to the anastomosis.

## Results

Long-term follow-up reflects the older age at which repair was undertaken and the difficulties of hypospadias surgery in the past.[167–170] Today's results are much better both cosmetically and functionally than those in the past.[171–174,175] The use of one-stage hypospadias repair at an early age with a low complication rate encourages our current positive outlook for patients with this condition. Curvature correction with the aid of an artificial erection is extremely important for ensuring satisfactory sexual function. With the placement of the urinary meatus at the tip of the glans, the fertility potential has been improved, unless the patient has other coexisting testicular problems. Evidence shows that the neourethra grows with the child. Early hypospadias repair with minimal hospitalization helps avoid separation anxiety and castration fears. We can now counsel parents confidently that there is an excellent chance of a good cosmetic, functional, and emotional result in boys with all degrees of hypospadias.

## Summary

1. Hypospadias should be repaired within the first year of life, preferably at 4 to 6 months of age. Pain and catheters seem to be better tolerated at this age, and the baby's lack of mobility simplifies postoperative care.
2. A terminal slitlike meatus should be the goal, with or without preservation of the foreskin in distal hypospadias, depending on parental preference.
3. Preservation of the urethral plate provides the best possible chance of recreating normal urethral anatomy by incorporating the abortive spongiosum into the repair.
4. Midline dorsal plication is safe and effective for the correction of penile curvature in the majority of patients. (Placing more than two rows of sutures is a sign that another technique such as dermal grafting is indicated.)
5. In the small percentage of patients who require resection of the urethral plate, a two-stage approach is generally warranted.
6. Vascularized pedicle onlay flaps are successful in primary and redo hypospadias surgery.
7. De-epithelialized vascular flaps should be used as a second layer for all urethroplasties.
8. Patients with a paucity of skin are best managed with the Bracka two-stage buccal repair.
9. Coronal fistulas require a redo glansplasty.

# CHAPTER 122

# Abnormalities of the Urethra, Penis, and Scrotum

J. Patrick Murphy and John M. Gatti

The evaluation of abnormalities of the urethra, penis, and scrotum now begins before birth. Prenatal ultrasound (US) has become standard of care, and with it has come the early diagnosis of many congenital anomalies of the genitourinary tract. Virtually every hydronephrotic or obstructive lesion has been documented prenatally, but new controversies have been generated regarding the efficacy and appropriateness of prenatal therapy. In no area is this more apparent than in the diagnosis of posterior urethral valves (PUVs). Interventions in the way of vesicoamniotic shunting and fetoscopic urethral valve ablation have been described and used, but a benefit in outcome has yet to be confirmed.[1–3]

## Posterior Urethral Valves

PUVs are the most common obstructive anomaly of the urethra. The incidence is between 1 in 5000 and 1 in 8000 male births.[4,5] Hugh Hampton Young is credited with the first description and classification of PUVs.[6] He described three types. Type II PUVs are now generally considered to be nonobstructive and are of historical interest only. Type I represents 95% of PUVs. They are membranes that originate at the verumontanum and travel distally to insert in the anterior proximal membranous urethra with an opening present posteriorly at the verumontanum. The etiology is probably a result of the mesonephric ducts entering the cloaca more anteriorly than normal and fusing in the midline.[7] Type III PUVs represent the other 5% and consist of a ring-type membrane distal to the verumontanum with a perforation present centrally. The membrane may occasionally migrate distally, forming a windsock appearance.[8] The cause of these PUVs is an incomplete dissolution of the urogenital membrane.

Presently, most cases of PUVs are detected prenatally by US showing hydronephrosis and/or a distended thick-walled bladder. Postnatally, the US will show a thickened bladder wall and classically a dilated and elongated posterior urethra. Hydronephrosis will vary in degree and may be unilateral or bilateral. Physical examination may exhibit a distended, firm bladder, weak urinary stream, abdominal distention, and, possibly, urinary ascites. If the fetus has been subjected to oligohydramnios, there may be respiratory distress and the stigmata of Potter syndrome may be present. Older boys may present with urinary tract infection (UTI) and voiding dysfunction, particularly daytime urge incontinence. The voiding cystourethrogram (VCUG) is usually diagnostic with a dilated and often elongated posterior urethra and abrupt transition to a narrower distal urethra; a thickened bladder wall, trabeculation, bladder diverticulum, and vesicoureteral reflux (VUR) may also be seen (Fig. 122-1).

Fetal intervention for PUVs is controversial. The diagnostic accuracy of prenatal US has improved significantly over the past 10 years, but nonobstructive disorders such as prune-belly syndrome and high-grade VUR may be difficult to differentiate from PUVs. Fetal intervention may involve early delivery, vesicoamniotic shunting,[3,9] amnioinfusion,[10] percutaneous fetal cystoscopy,[11–13] or open fetal surgery.[14] All of these have significant risks to the fetus and mother including preterm labor, bleeding, and infection. Therefore the consideration of fetal intervention should be limited to centers with experienced personnel in both the diagnostic and technical skills involved. Renal dysplasia (RD) may occur early in fetal development before the time of consideration for fetal manipulation. Intervention to relieve obstruction will not reverse RD. Therefore most clinicians agree that a fetus with signs of severe RD is not a candidate for prenatal treatment. Several parameters are used for determining the severity of RD. Increased echodensity of the renal parenchyma, cystic changes of the parenchyma, and early moderate or severe oligohydramnios are all US signs of severe RD. The character of percutaneously sampled fetal urine also predicts the degree of RD.[1,2,15,16] Normal fetal urine is hypotonic and low in sodium. Fetal urine sodium greater than 100 mEq/L, osmolality greater than 210 mOsm, protein greater than 20 mg/dL, and $\beta_2$-microglobulin greater than 4 mg/L[17] are suggestive of significant RD. Improvement in these parameters on serial bladder taps is encouraging, but a fetus with these radiographic and urine parameters probably would not benefit from prenatal manipulation. Prenatal intervention has not been shown to improve the overall long-term renal function when compared with conventional postnatal therapy.[3,9] However, the patients who are treated prenatally likely represent the more severe degree of obstruction, and it could be argued that these

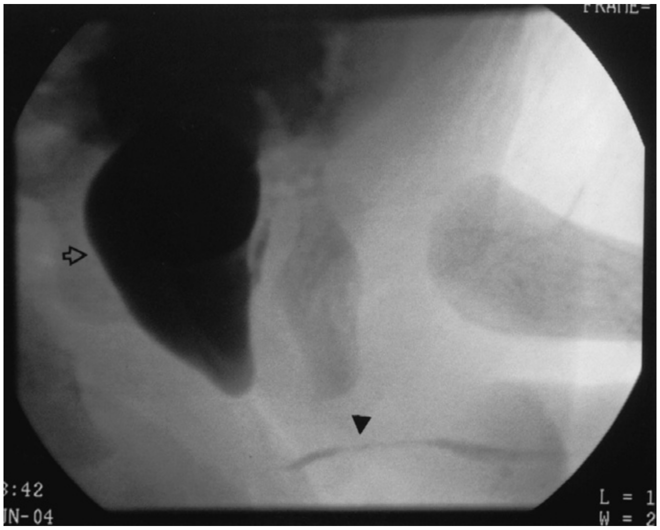

**FIGURE 122-1** Voiding cystourethrogram showing posterior urethral valves with dilated posterior urethra (*open arrow*) and abrupt transition to narrower anterior urethra (*solid arrow*). The trabeculated bladder is above the posterior urethra.

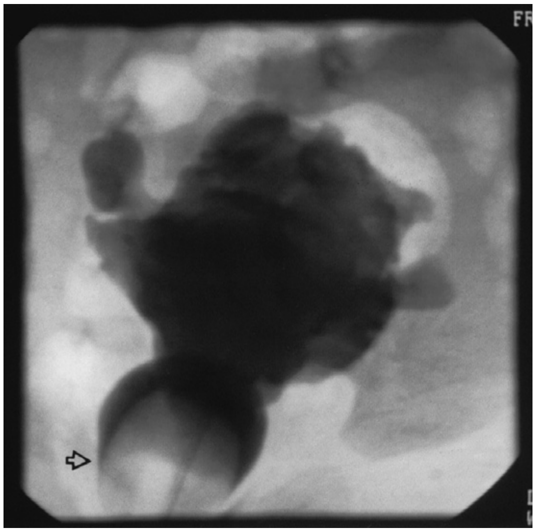

**FIGURE 122-2** Voiding cystourethrogram with posterior urethral valves and heavily trabeculated bladder and Foley balloon inflated in dilated posterior urethra (*arrow*).

patients should be predicted to have worse outcomes than those treated postnatally. Therefore prenatal treatment may have had a beneficial effect in these higher-risk patients. The ultimate role of fetal intervention for PUVs is still evolving; newer technology allowing safer and earlier treatment may improve outcomes.[2,18]

Postnatal management of PUVs initially involves obtaining bladder drainage. Usually this can be accomplished with a small, soft 5- or 8-Fr feeding tube passed per urethra. Care must be taken to ensure it does not coil in the dilated posterior urethra. Bladder US can help confirm proper placement. Generally, Foley catheters should be avoided for initial drainage because the balloon may cause bladder spasm in the thick-walled bladder and affect urine drainage, or the balloon may slip into the dilated posterior urethra (Fig. 122-2). In the rare case that the urethra cannot be cannulated, percutaneous suprapubic access can be used. Fluid and electrolyte management is critical in the first 24 to 48 hours. Postobstructive diuresis may occur, and both water and solute may be rapidly depleted, requiring aggressive fluid and electrolyte replacement. Acid-base balance is also important and is more of a problem in severe renal insufficiency. Serum creatinine is monitored closely, realizing that for the first few days of life the value reflects the maternal renal function. Historically, when the creatinine stayed elevated beyond several days, supravesical diversion was considered. However, a number of studies suggest this is not necessary and subsequent renal function was not improved when supravesical diversion was compared with treatment with standard postnatal valve ablation or vesicostomy.[19–21] Antibiotic prophylaxis is indicated, especially in those patients presenting with hydronephrosis or VUR.

When fluid electrolyte status is stable, most patients can be treated with endoscopic valve ablation. With advanced fiberoptic technology, cystoscopes of 7-Fr size are now available, allowing urethral access in all but the smallest premature infants. A Bugbee or angled wire electrode with cutting current or a small-caliber laser fiber[22] can be used to incise the valves at the 5, 7, and 12 o'clock positions in a retrograde transurethral fashion. In the older child, a small resectoscope can be used. Some have advocated a percutaneous antegrade approach to fulgurate PUVs.[23] In the rare case in which the valves cannot be fulgurated endoscopically, cutaneous vesicostomy is used. The Blocksom technique is favored, bringing the bladder dome to the skin to decrease the chance of bladder prolapse.[24,25] When the child has grown and stabilized medically, the valves may then be ablated endoscopically and the vesicostomy closed. Vesicostomy probably does not decrease long-term bladder capacity or function.[5,26,27]

The long-term prognosis for patients with PUVs has improved over the decades and is affected mostly by three factors: (1) degree of RD; (2) incidence of UTI with or without VUR; and (3) bladder function. The overall infant mortality rate has improved from about 50% to 1% to 3% in the past 3 decades.[28,29] Improved neonatal critical care, along with careful attention to the treatment of these factors, are responsible for this improvement. RD is irreversible, but attention to the other issues of UTI and bladder dysfunction can decrease or delay ongoing renal deterioration. Renal failure occurs in as high as 40% of patients treated for PUVs.[19,20] Renal transplantation has improved in this group of patients owing to improved medical care and modern immunosuppressive therapy. The graft survival is comparable with patients without significant urologic pathology.[30,31] Attention to bladder dysfunction and treating these higher pressure bladders for urge incontinence with anticholinergic therapy and frequent voiding are all important to delay renal deterioration or to protect the transplanted kidneys. In bladders that have progressed to myogenic failure and incomplete emptying, clean intermittent catheterization and/or overnight bladder drainage may be necessary. Urodynamics are helpful in directing this type of bladder therapy. In rare cases, bladder augmentation may be necessary.[20,32–34] VUR occurs in up to half of patients with PUVs.[4,5,35] The high incidence is probably related to the high-pressure bladder, but anatomic studies suggest primary VUR related to ureteral position is frequent.[36] The VUR is more often bilateral, and resolution after valve fulguration occurs in one third to one half of patients.[4,35] Unilateral VUR is sometimes associated with a dilated, dysplastic, poorly functioning

kidney. It has been suggested that this vesicoureteral reflux-renal dysplasia (VURD) syndrome may have a protective effect on the bladder and the opposite kidney, much like other "popoff" mechanisms such as a large bladder diverticulum or urinary ascites secondary to a ruptured renal fornix.[37–39]

Traditionally, it has been advocated that removal of this dilated dysplastic kidney and ureter would improve voiding efficiency and decrease potential for UTI.[38] More recent evidence suggests that retaining this dysplastic unit does not affect UTI or function, and these units may be left in place.[40] These dilated ureters also have the potential for use as a ureterocystoplasty to augment the bladder in those rare cases of high-pressure bladder refractory to standard therapy.[41]

The presence of VUR should not change the initial overall treatment of PUVs.[42] Ureteral reimplantation is generally indicated only in those patients with recurrent UTI despite appropriate chemoprophylaxis and after appropriate therapy to treat bladder dysfunction. The presence of VUR probably does not change long-term prognosis unless recurrent UTI is an issue.[35,43] Over time, with appropriate bladder therapy, the dilation of the ureters may decrease and bladder wall thickness improves, making surgery technically easier with improved results if reimplantation is ultimately necessary.

# Anterior Urethral Valves in Boys

Anterior urethral valves occur much less frequently than PUVs, but their overall presentation and impact on the urinary tract are quite similar. They can occur anywhere along the anterior urethra, with a slight predominance in the bulbar urethra.[44] The etiology is most likely to be the development of a ventral urethral diverticulum. With antegrade flow of urine during voiding, the diverticulum undermines the distal urethra with the common wall becoming an obstructive flap.[45] Others postulate that this lesion develops from a primary weakness in the spongiosum or an abortive attempt at urethral duplication.[46] The diagnosis is made radiographically, with a VCUG revealing a dilated proximal anterior urethra, a narrow distal anterior urethra, and often a subtle flap of tissue. These valves are treated with endoscopic incision and are best visualized with minimal irrigation to prevent flattening of the valve with forceful retrograde flow. Hydronephrosis and VUR are commonly associated and are generally managed in the same manner as PUVs.[47]

A similar lesion is the lacuna magna, or valve of Guérin, a dorsal urethral diverticulum located in the fossa navicularis. This is a rare entity and may require incision as described previously. The lesion can be difficult to diagnose owing to its proximity to the tip of the penis, but voiding images of the VCUG that include the glans reveal the distal lesion.[48]

# Urethral Diverticulum in Girls

Urethral diverticula are rare lesions in children. They can present as dysuria, hematuria, or symptoms of obstruction. Their diagnosis can be extremely difficult because of problems of imaging the short length of the female urethra. Cystoscopy may be required for diagnosis and treatment by excision, or, if small, incision of the distal lip endoscopically may be warranted.[49]

# Urethral Stricture

Urethral strictures are more common in boys than girls. They are classified as congenital, inflammatory, iatrogenic, or traumatic.[50] Congenital strictures are rare, but urethral hypoplasia can occur. Inflammatory strictures are uncommon in children and are more likely associated with gonococcal or chlamydial urethritis in sexually active adolescents. Inflammatory strictures related to chronic indwelling catheters are rare in the modern era. Iatrogenic strictures are encountered after urethral surgery or instrumentation.

Traumatic strictures of the anterior urethra are seen after straddle injuries in which the urethra is compressed against the pubic bone, such as falling on the crossbar of a bicycle. Posterior urethral strictures are generally seen associated with displaced fractures of the pelvis. Blood at the tip of the meatus, a high-riding bladder or prostate on abdominal and rectal examination, or a suspected pelvic fracture should all merit a retrograde urethrogram (RUG) before catheter placement to avoid converting a partial urethral disruption into a complete one. A partial injury is generally treated with endoscopic or fluoroscopic catheter placement of an indwelling catheter until the injury has healed and no extravasation of contrast agent is seen on the RUG done alongside the indwelling catheter. Controversy exists on initial management of the complete disruption. Suprapubic tube placement or vesicostomy and delayed reconstruction approximately 6 months later is generally accepted, but some advocate primary realignment of the urethra using retrograde urethroscopy and antegrade cystoscopy to place a catheter across the defect.[51]

The location and length of the stricture determine therapy. Most clinicians use antegrade cystography with RUG to define these parameters, but others report more accurate assessments using intraoperative US.[52] Short, filmy strictures can generally be incised or dilated with reasonable results.[53] Some authors have been quite successful with progressive urethral dilation in the setting of urethral hypoplasia.[54] Longer strictures or recurrent strictures of the bulbar urethra are generally treated by excision of the stricture and spatulated reapproximation in an end-to-end fashion. This may require an inferior pubectomy or corporal rerouting to cover a long distance.[55] The navicular and pendulous urethra are less forgiving because excision and reapproximation can result in ventral chordee. Longer strictures in these locations are generally treated with patch grafts or flaps using prepuce, penile shaft skin, or buccal mucosa.[56] These patients require long-term follow-up, although most strictures that recur do so during the first year.

# Urethral Atresia

Urethral atresia is incompatible with renal development unless an alternative communication with the bladder such as a patent urachus exists. Prenatal intervention with vesicoamniotic shunting may aid in getting the fetus to delivery, but there is often significant RD. There is a strong association with prune-belly syndrome.[57] The associated perinatal problems associated with obstructive infravesical uropathy must be dealt with initially. Further reconstruction is individualized to the degree of urethral development, but some will require continent diversion ultimately.

## Urethral Stenosis in Girls

It was once believed that irritative or obstructive voiding symptoms or recurring urinary tract infections in girls could be related to urethral stenosis. The diagnosis was supported by the narrowed urethra at the level of the genitourinary diaphragm and sphincter on VCUG. It is now realized that the radiographic and clinical findings represent voiding dysfunction and its associated inappropriate sphincter activity during voiding. Although some short-term benefit of incapacitating the external sphincter muscle with dilation may be seen, urethral dilation has been largely abandoned, owing to its long-term ineffectiveness and potential for creating a true urethral stricture after overly vigorous dilation.

## Urethral Mass in Girls

Multiple lesions may present as a urethral mass in young girls. Careful attention to the lesion can often make the diagnosis by inspection. Lesions of the urethral meatus include urethral prolapse, prolapsing ureterocele, urethral cyst, or sarcoma. Lesions of the vagina may be mistaken for having a urethral origin and include Gartner duct cysts, imperforate hymen, and sarcoma.

Urethral prolapse has classically been described in prepubertal African American girls, but Caucasian girls can also be affected.[58,59] The chief complaint is blood spotting in the underwear and painful urination. On physical examination, the markedly edematous urethra protrudes circumferentially at the level of the meatus and is often seen as a friable rosette that is bright red or cyanotic with a central dimple (the urethral meatus). A trial of sitz baths, estrogen cream, or a mild corticosteroid cream is reasonable, but if this is ineffective, the redundant tissue is excised and the urethral mucosa is anastomosed to the adjacent introital epithelium in the operating room.[60] Complications are rare but can include bleeding, recurrence, or urethral stricture.

A prolapsing ureterocele can also be quite edematous, but it can usually be discerned because it is not connected to the surrounding urethral meatus. The presentation may include blood spotting in the underwear, painful urination, or urinary retention. The diagnosis is confirmed by findings of hydroureteronephrosis associated with the ectopic moiety on US. If the ureterocele cannot be manually reduced, it can be reduced and unroofed cystoscopically with definitive excision/reconstruction performed in staged fashion.

Rhabdomyosarcoma is the most common primary malignant tumor involving the uterus, vagina, or bladder in infants and children and can present in similar fashion. The botryoid type lesion is usually exophytic and commonly emanates from the vagina or urethrovaginal septum. It generally presents before 2 years of age. The urethral margins are at least partially discrete, which differentiates it from urethral prolapse. It is classically a grapelike clustered mass that extrudes through the introitus and presents as bleeding. Radiographic imaging is warranted to fully evaluate the mass and rule out metastases to the lungs, liver, or bone marrow. After tissue diagnosis, multimodal therapy including chemotherapy, radiation, and surgical excision is usually used.[61,62]

Imperforate hymen may present as hydrocolpos or hydrometrocolpos as a bulging introital mass often with palpable distended abdominal uterus or vagina. The urethra is discretely visualized anterior to the mass. Treatment is incision and drainage.

Various cysts including epithelial inclusion cysts, Skene's duct cysts, müllerian duct cysts, and wolffian or Gartner duct cysts (GDC) can occur in this area, which can be incised and drained or excised if they recur. GDCs, which line the vaginal wall adjacent to the bladder, are worth elaboration because of their embryologic origins from the wolffian or mesonephric duct. As a result, ectopic ureters may end in a GDC, and rupture into the vagina results in chronic drip incontinence. Although GDCs are unusual in infants, they are the most common benign cause of vaginal swelling in children. They are generally asymptomatic, but when large they can protrude from the vagina and can be associated with urinary retention or dyspareunia in sexually active adolescents.[63] These are usually treated with marsupialization, but those associated with ectopic ureters require more proximal reconstruction involving ureteral reimplant or nephrectomy.

Urethral polyps are rare but present as intermittent bleeding or obstruction and are treated with excision.[64] Anterior vaginal wall or retention cysts are commonly seen in newborn females and lie between the posterior urethral wall and the anterior vaginal wall. These most commonly resolve spontaneously with a few days after birth.

## Labial Adhesions

Labial adhesions, or fusion of the labia minora, are believed to occur as a result of chronic inflammation related to vulvovaginitis or chronic dampness resulting from urinary incontinence. The labia may fuse near completely, causing obstructive-type symptoms or incontinence with trapping of urine. More commonly they present as postvoid drip incontinence as small volumes of urine pool above this shelf of tissue while seated to void, and they drip into the underwear when the child stands. This chronic dampness can also cause irritative symptoms of itching or dysuria, and an aseptic urine specimen is difficult to obtain owing to the impediment of preparing this adhesed area for culture acquisition.

Treatment of labial adhesions is not warranted in the absence of urinary tract infection, dysuria, obstruction, or drip incontinence because these adhesions commonly resolve with the physiologic estrogen surge at puberty.[65] If the adhesions warrant treatment, a trial of topical estrogen cream (0.01%) applied twice daily for 2 to 4 weeks may be attempted but can be unsuccessful in up to half of patients.[66] Estrogens also carry the risk of vulvar pigmentation, development of breast buds, or breast tenderness in prepubertal patients with prolonged use. The effects reverse with the withdrawal of treatment. An effective alternative is the use of betamethasone cream (0.05%) topically twice daily for 1 month.[67]

If the adhesions are persistent or thick and well developed, surgical lysis can generally be performed in the office setting using eutectic mixture of local anesthetics (EMLA) cream. A cotton-tipped applicator or hemostat can then be used to bluntly push the adhesions apart in an anterior to posterior direction. It is imperative that the excoriated labia minora

be dressed with a lubricating or antibiotic ointment to prevent the recurrence of adhesions until healed and an ointment be applied regularly for a period of time after lysis to ensure re-epithelialization of the lysed edges.

## Cowper Gland Anomalies

Cowper glands are paired urethral glands that sit in the urogenital diaphragm and drain into the bulbar urethra. When the ducts draining these glands become obstructed, cysts termed *syringoceles* can form.[68] They may be seen on a urethrogram as a filling defect in the bulbar urethra or found on cystoscopy for another reason in which they appear as a blue-domed cyst on the floor of the bulbar urethra. Most cysts are asymptomatic; some may present with terminal hematuria, blood spotting from the urethra, urinary tract infection, or obstructive symptoms. These are generally treated with endoscopic unroofing, incising the leading lip to prevent obstruction. Open resection perineally is reserved for large cysts.[69]

## Urethral Polyps

Urethral polyps are fibromuscular epithelial structures with transitional epithelium covering the surface.[70] They may occur either in the posterior or anterior urethra.[71,72] In either position, they may cause hematuria, urgency, or obstructive symptoms. Bladder ultrasound may show the polyps in the posterior urethra (Fig. 122-3), but VCUG and cystoscopy are diagnostic and excision through the cystoscope is usually curative.[73] Polyps can present as congenital obstructing lesions with all of the characteristics of bladder outlet obstruction.

## Prostatic Utricle

Prostatic utricles are müllerian duct remnants, which are common in patients with ambiguous genitalia or proximal hypospadias. Enlarged utricles can cause urinary tract infection, dysuria, urgency, hematuria, or epididymitis.[74] Diagnosis is usually made by VCUG or RUG. However, US may detect the larger remnants.[75] Surgical treatment is reserved for those that are associated with recurrent symptoms. The surgical approach may be transabdominal, transvesical, perineal, posterior sagittal (transrectal or perirectal), or laparoscopic depending on the experience of the surgeon.[74,76–80]

## Urethral Duplication

Urethral duplication is rare but more common in males. Although embryologic explanations for the defect have been proposed, the multiple variants of the anomaly suggest that there is probably not a common etiology for all forms. Duplication of the urethra can occur along with bladder and genital duplication. In males the duplications usually occur in the same sagittal plane on a single phallus.[81] Less often, the urethras may be side by side on the glans with either a widened or duplicate phallus (Fig. 122-4). With the sagittal-type duplications, the ventral urethra is almost always the more normal one and passes through the prostate and sphincteric mechanism. It may end anywhere from the tip of the glans to the perianal area.

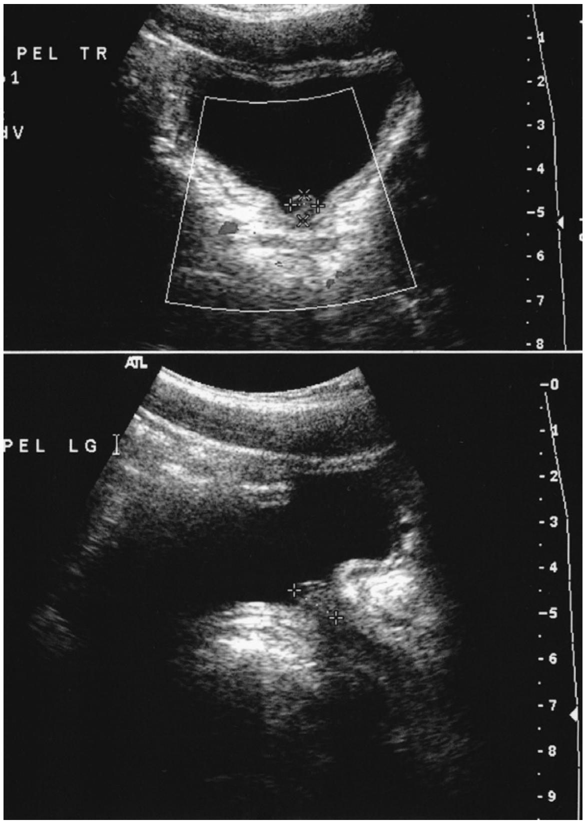

**FIGURE 122-3** Posterior urethral polyp seen on ultrasound of bladder. Top view shows transverse image of bladder with polyp arising from urethra (*cursors*). Bottom view shows longitudinal view of bladder with polyp seen at entry to posterior urethra (*cursors*).

**FIGURE 122-4** Duplicate urethra with a meatus on each side of glans and counterclockwise penile torsion.

The dorsal urethra may open anywhere on the shaft from an epispadiac location on the glans to the penopubic area. Dorsal chordee may be present, and a widened symphysis pubis may be present, suggesting possible association with the exstrophy complex.[82–85] This dorsal urethra may communicate with the bladder or ventral urethra (Fig. 122-5) but can end blindly beneath the symphysis pubis. If it does communicate, incontinence can be an issue because it often does not traverse the sphincter. Treatment in the symptomatic patient involves excision of the dorsal accessory urethra and correction of the chordee. Urethroplasty may be necessary to bring the ventral urethra to the glans. In the rare case of a dominant dorsal urethra and an accessory ventral one, the excision of the ventral tract cures the incontinence. The treatment of the even more rare side-by-side type requires an individualized approach depending on the varied anatomy. Full urinary tract evaluation radiographically is required in all forms of urethral duplication.

Female duplication may have complete bladder and genital duplication and may be associated with colonic atresia and/or cloacal anomalies.[86] A dorsal accessory urethra may occur in the pubic area and has been reported to communicate with a urachal remnant.[87] Treatment again is individualized to the particular anatomy involved, with attempts to preserve bladder tissue and maintain continence.

**FIGURE 122-5** Urethral duplication with dorsal urethral duplication (*arrow*) exiting in suprapubic area.

## Megalourethra

Megalourethra is a rare syndrome of urethral dilation. There are two types: scaphoid and fusiform. The scaphoid form is associated with abnormal development of the corpus spongiosum, and anterior bulging of the urethra is seen with voiding. In the more severe fusiform type (Fig. 122-6), the corpora cavernosa are also involved, which may have an impact on long-term potency, and the dilation during voiding is circumferential.[88] The lesion is generally discovered at birth but has also been diagnosed on prenatal US.[89]

The etiology is unclear, but it is thought to be a defect of mesodermal development, especially given its association with prune-belly syndrome.[90] A renal-bladder US is indicated to rule out other congenital anomalies. The dilation is nonobstructive, and urethroplasty with excision of the redundant tissue and tapering of the urethra is generally undertaken for cosmetic reasons.

## Congenital Urethral Fistula

Congenital urethral fistula is rare and usually occurs in the subcoronal area of the penis. Associated hypospadias and chordee occur, suggesting this may be a form of the hypospadias anomaly. The fistula generally has a well-formed urethra distally, but it may be thinned with poor glans formation. Repair involves the techniques used in hypospadias surgery and may involve simple multilayer closure of the fistula or more complex reconstruction of the distal urethra and glans.[91,92]

**FIGURE 122-6** Megalourethra, fusiform type.

# Phimosis

Phimosis is defined as the inability to retract the foreskin. At birth, physiologic phimosis is present as adhesions between the prepuce and glans preclude retracting the foreskin. As the child grows, the two layers begin to separate as sloughed epithelial debris, or smegma, accumulates between them, defining this plane. This smegma is commonly referred to as "foreskin pearls" and can be mistaken for infection or purulence by the uneducated parent. With spontaneous erections and natural manipulation, more than 90% of foreskin becomes retractable by age 3 to 4 years.[93]

Forceful retraction is not required for this to occur and may initiate the vicious cycle of tearing and scarring, which can lead to pathologic phimosis. In children older than 4 years who are unable to retract the foreskin and are symptomatic with episodes of posthitis or balanoposthitis or ballooning of the foreskin with voiding, a trial of betamethasone cream (0.05%) two times per day for 1 to 2 months allows the foreskin to retract in up to 90% of boys.[94] For those refractory to corticosteroid treatment, a temporizing dorsal slit, preputioplasty (surgical enlargement of the phimotic ring), or circumcision is indicated.

# Circumcision

Circumcision remains one of the most controversial topics in urology. The American Academy of Pediatrics issued a policy guideline in 1975 stating that there is no absolute medical indication for routine circumcision of the newborn.[95] In 1999 the Academy offered the opinion that there are some medical benefits of the procedure but not enough to warrant routine circumcision.[96]

Circumcision advocates argue that circumcised boys have lower urinary tract infection rates, lower incidence of zipper injury or paraphimosis, and lower rates of sexually transmitted disease and penile cancer as adults.[96–100] Circumcision opponents argue the procedure is nonphysiologic and may be unnecessary or even harmful. Some more extremist groups argue that circumcised males have decreased penile sensation, less satisfaction with intercourse, and possibly even higher divorce rates.[101] Unfortunately, this issue tends to be emotionally charged and a large body of "supportive research" is highly subjective. In a cost utility analysis of circumcision, Ganiats and colleagues determined that financial and medical advantages and disadvantages of routine neonatal circumcision cancel out one another and that personal cultural or religious views rather than cost or health outcomes should be the basis of decision making.[102]

Despite the controversy, circumcision is still one of the most common elective procedures in the United States and is usually done for cosmetic and cultural reasons.

The risk of circumcision is generally low in larger series (<1%) and includes bleeding, infection, skin separation, adhesions, too much or too little skin removed, and meatal stenosis.[103,104] The two major techniques used in neonates are the Plastibell and the Gomco clamp. Similar complication rates are noted with both, the Plastibell having more problems with infection and the Gomco clamp more problems with separation.[105] The Mogan clamp carries the additional risk of glans injury, and this technique should be limited to those adequately trained in its use.

## TECHNIQUE

Newborn circumcisions can be carried out at the bedside or in the office safely to 2 or 3 months of age. The authors advocate the use of local anesthetic, either topically or subcutaneously before the procedure. With the foreskin in an unstretched position, the palpable coronal margin is marked on the overlying shaft skin to indicate the appropriate position of the clamp device. A hemostat is used to develop the plane between the glans and adherent prepuce. In the dorsal midline, the tissue is clamped with a straight hemostat and then incised with scissors to allow placement of the device. All adhesions should be taken down and smegma débrided. The appropriate size of clamp device should be chosen. The conical portion of the clamp should cover the majority of the glans. Once this portion is in position, the excess foreskin is reduced back over the clamp device and the clamp is engaged (Gomco) or the suture is tied (Plastibell) at the previously marked site. Care should be taken to draw the foreskin over the clamp at its leading edge to avoid the foreskin intussuscepting over the clamp and giving a mismatch of inner prepuce and proximal shaft skin engaged in the clamp. The amount of inner prepuce and shaft skin excised should be equal to avoid the risk of recurrent phimosis creating a hidden or buried penis due to an inappropriately large amount of residual inner prepuce. Hemostasis is usually excellent with these techniques. Electrocautery should never be applied to the metal clamp because the penis can be completely devascularized (Fig. 122-7).

In older children, the procedure is performed under a general anesthetic when the risk of anesthetic is minimized (after 60 weeks' gestation). Because the clamp devices become less reliable in older children and have a less-tailored fit, a freehand surgical technique is used at our institution. The proximal and distal incisions are carefully marked before cutting sharply, with the proximal mark overlying the coronal margin when any prominent prepubic fat pad is reduced. The excess shaft skin is excised at the level of the dartos pedicle with electrocautery. Hemostasis is attained by electrocautery as indicated, and larger vessels can be ligated. The edges are reapproximated with fine chromic suture in an interrupted subcuticular technique to avoid the formation of epithelialized suture sinuses. A minimal dressing of antibiotic ointment and gauze is placed with the expectation of it falling off spontaneously or being removed the following day. The authors also advocate early bathing on postoperative day 1 and have the family apply the ointment to the area at least three times daily for the next few weeks. A caudal block or dorsal penile nerve and ring block is usually given at the end of the procedure to help with postoperative pain management.

# Meatal Stenosis

Meatal stenosis occurs in approximately 10% of circumcised boys.[106] It is virtually nonexistent in uncircumcised boys, with the exception of those with balanitis xerotica obliterans. It is thought to be related to subclinical chronic inflammation of the meatus in the circumcised phallus related to exposure to

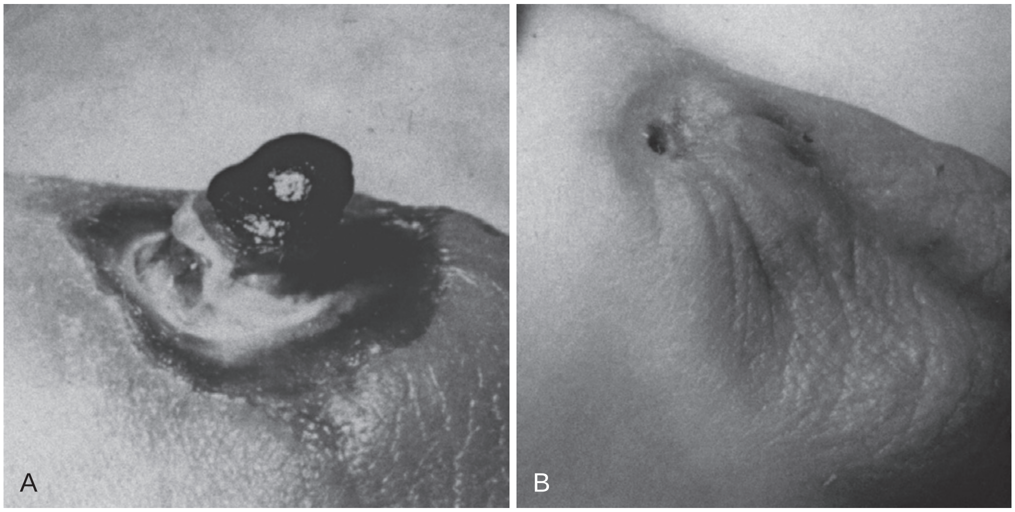

**FIGURE 122-7** Neonatal circumcision injury after applying electrocautery to metal clamp. **A,** Immediate postoperative appearance. **B,** End result 3 months after surgery.

urine (ammoniacal dermatitis) or to relative ischemia caused by compromising the vasculature to the meatus when the frenular artery is taken during circumcision. The classic history is that of a fine-caliber urinary stream with dorsal deflection, often greater than 90 degrees. The meatus is pinpoint and tight with 6- or 8-Fr calibration. It may or may not be associated with pain or blood spotting in the underwear. The disorder is commonly overdiagnosed, and those with painful urination who lack these physical findings often have voiding dysfunction and its associated inappropriate sphincter activity during voiding.

The treatment of meatal stenosis is a meatotomy in which the ventral parameatal tissue is engaged in a clamp or hemostat (the authors prefer a nontoothed bowel clamp), then incised roughly half the distance to the coronal margin. The edges are dressed with antibiotic ointment, and the family is encouraged to continue this application three times daily for at least a week to avoid recurrence, which is uncommon. This procedure can be performed safely in the office with local anesthetic or in the operating room setting.[107]

## Penile Agenesis

Congenital aphallia is extremely rare, with an incidence of 1 in 10 million to 30 million.[108,109] It is a result of partial or complete developmental failure of the genital tubercle. The karyotype is almost always 46,XY, and the urethra usually opens into the anal verge or rectum.[108,109] Common associated anomalies can include cryptorchidism, renal anomalies, VUR, anal anomalies, and cardiac anomalies.[108–110] The more proximal the urethral communication, the higher the incidence of associated anomalies and of neonatal mortality.[109] Female gender reassignment with orchiectomy, along with urinary tract and genital reconstruction, has traditionally been recommended for this anomaly.[108,111] However, recent evidence that persistence of male gender identity may occur despite female gender reassignment makes it imperative that careful consideration by a team dedicated to disorders of sexual differentiation including urology, endocrinology, and psychiatry be done before full informed consent is obtained from the family.[112] Discussion of maintaining male gender assignment with later construction of a neophallus along with the cosmetic and functional limitations of this approach should be included in the informed consent.[112]

## Diphallia

Penile duplication has a frequency of 1 in 5 million births.[113,114] The extent of the duplication varies, and the etiology is suggested to be a failure of mesodermal banding or mesoderm encountering two urethral anlages.[115] Presentation may range from a small accessory penis to complete duplication of urethra, glans, and corporal bodies (Fig. 122-8). There is often size discrepancy, and orientation is most commonly side by side. Associated abnormalities include

**FIGURE 122-8** Diphallia, side-by-side configuration.

hypospadias, scrotal anomalies, duplicate bladder, renal anomalies, exstrophy defects, and anal and cardiac anomalies. Complete imaging of the urinary tract should be performed, and US or magnetic resonance imaging may be helpful in assessment of penile anatomic development.[116] Surgical treatment must be individualized to the extent of the defect and may range from simple resection of the accessory penis to complex reconstruction.[113]

## Penile Torsion

Torsion of the penis is a rotational defect of the phallus, which is usually counterclockwise in direction and may be associated with hypospadias, chordee, and hooded dorsal foreskin. The median raphe generally courses obliquely around the shaft to the left. Rotation of less than 90 degrees often is not symptomatic and will not require correction. Surgical treatment involves degloving the penis and releasing any fibrous, dysgenic bands all the way to the base of the penis, allowing the phallus to reorient to the appropriate position.[117] In rare cases, fixation of the base of the corporal bodies to the symphysis pubis or creation of a dartos flap to rotate the corpora may be necessary to maintain proper orientation.[118]

## Penoscrotal Transposition and Scrotal Ectopia

The scrotum forms by migration of the labioscrotal folds inferomedial to the genital tubercle. Failure of migration possibly related to a gubernacular defect results in scrotal anomalies such as penoscrotal transposition, bifid scrotum, or scrotal ectopia.[119] Association with hypospadias and chordee is common. The more significant the scrotal defect, the more likely other anomalies are to occur including caudal regression, VATER syndrome, cryptorchidism, and other urinary tract abnormalities.[119–121]

Repair of significant forms of penoscrotal transposition require various advancement flap techniques. When associated with severe hypospadias, which requires preputial island flap type repairs, correction of penoscrotal transposition is usually done at a second stage to avoid the possibility of devascularizing the preputial flap.[122,123] Others propose combined repair of the hypospadias and scrotal transposition in one stage, but complications tend to be higher.[124–126] In cases of scrotal ectopia associated with cryptorchidism, scrotoplasty and orchiopexy can usually be accomplished at the same time.

CHAPTER 123

# Disorders of Sexual Development

Rafael V. Pieretti and Patricia K. Donahoe

## Nomenclature

"Disorders of Sex Development" (DSD) and "Disorders of sexual differentiation" (DSD)[1] are more inclusive terms than "ambiguous genitalia" or "intersex." They include a broad clinical spectrum of hormonal, metabolic, and chromosomal abnormalities resulting in abnormal genital development.[2,3]

## Developmental Biology of Mammalian Sexual Differentiation

Phenotypic males and females develop as a result of a precise cascade of sequential morphologic, genetic, and molecular events, many of which have recently been elucidated. The intermediate mesoderm situated between the ectoderm and the endoderm is the site that gives rise to the urogenital ridge in the early embryo (Fig. 123-1).[2] The urogenital ridge, which develops from a thickening of the ventromedial aspect of the intermediate mesoderm, contains the undifferentiated gonad and the mesonephros, wherein both the reproductive wolffian and müllerian ducts reside. Formation of the ridge depends on the expression of a number of important genes including the Wilms' tumor gene *(WT1)* and steroidogenesis factor *(SF-1)* genes; in their absence, the gonad and adjacent structures fail to form. For example, mutations in *WT1* in mice result in absence of the gonad and kidney[4] and abnormalities of the urogenital system, heart, and thorax. Mutations in Wilms' tumor 1 (WT1) cause Denys-Drash syndrome, Frasier syndrome, and Wilms' tumor associated with aniridia, genitourinary (GU) malformations, and mental retardation (WAGR) in human patients.[5] Mutations in *SF-1* in mice result in absence of gonads and adrenal glands[6] (see Fig. 123-1) and produce similar phenotypes in humans.[7] Other genes such as *LIM1, LHX9, EMX2,*[8,9] and *GATA-4* that are essential for development during this early process are shown in Figure 123-1.

Simultaneously, genes important for wolffian and müllerian duct development are expressed. The wolffian duct requires the action of *PAX2* and possibly *PAX8,* which are paired genes important in *Drosophila* development. Müllerian duct formation requires the activity of a series of secreted factors whose expression is directed by the WNT family of proteins.[10] During formation of the urogenital ridge, primordial germ cells, the progenitors of the oocytes and spermatocytes, must migrate from outside the embryo in the epiblast.[11] During this time they undergo proliferation and imprint erasure imposed by DNA methylation and complex histone modification to reset epigenetic memory in germ cells as elucidated during mouse development,[12–14] where, under the influence of Blimp-1,[15] expression of BMP 2, 4, and 8b and Fragilis expands this alkaline phosphatase and Stella-expressing population[16,17] at 3 weeks' gestation in the human.[11] These germ cells migrate through the ectodermal layer of the embryo, the primitive streak, the base of the allantois, the wall of the hindgut, and then to the urogenital ridge, where they take up residence in the as yet undifferentiated gonad. Fragilis induces *Stella,* which in turn induces the pluripotency genes *OCT/4, SOX 2,* and *Nanog*. The migratory phenotype, controlled by integrins[18] and cKit signaling,[19] is characterized by extensive mitosis (170-fold in mice).[20] After entering the mesonephros, female germ cells enter meiosis in an anterior to posterior wave under the influence of retinoic acid–mediated *STRA8* (Fig. 123-2). Because the testes degrade retinoic acid with the enzyme CYP26b1, *STRA8* is unavailable to initiate meiosis, so male germ cells remain arrested in Go.[21,22] Further ovarian development of the urogenital ridge requires the presence of germ cells. Oocyte development also requires residence in the urogenital ridge,[23] as ectopic germ cells either fail to develop or form tumors outside the confines of the urogenital ridge.[8,24]

Differentiation of the gonads commences as an indifferent blastema of mesenchymal cells covered by coelomic epithelium. The testes are directed by the expression of small transcription factors such as *SRY,* a master switch gene present on the short arm of the Y chromosome, and an *SRY*-related autosomal gene called *SOX 9* from chromosome 17q. The fact that testicular differentiation requires a signal from the Y chromosome became evident in 1959, when the 45,X Turner phenotype was first recognized.[25] Subsequent cytogenetic studies progressively localized the male differentiation region to the short arm of the Y chromosome.[26] Much later, Page and colleagues[27] defined a critical region for testis determination near the pseudoautosomal region of the short arm of the Y chromosome by comparing chromosomal deletions and

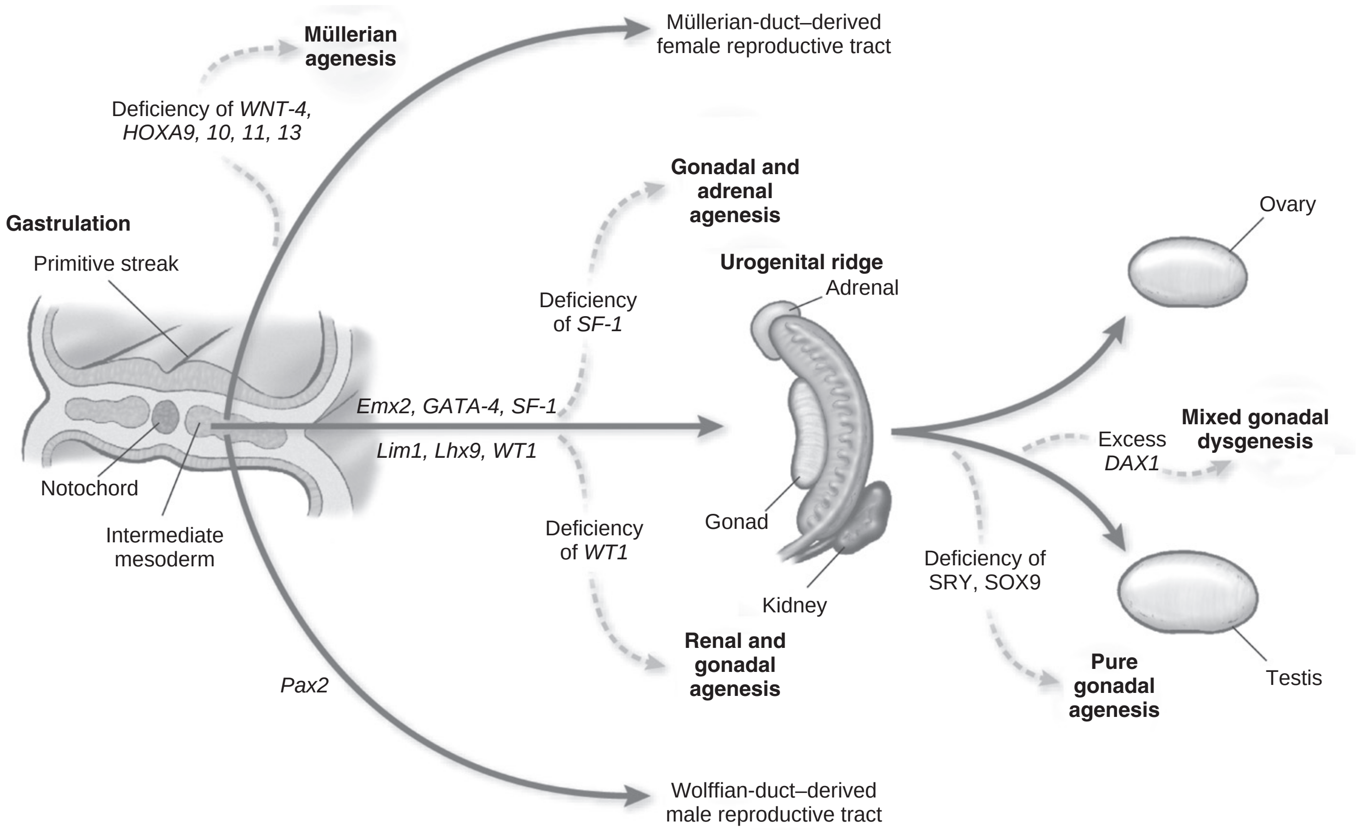

**FIGURE 123-1** Mutations in a number of genes can lead to a variety of syndromes of dysgenesis involving the müllerian or wolffian ducts, gonads, kidneys, and adrenal glands as a result of a deficiency or excess of the proteins shown. *DAX1,* Tgene duplicated in congenital adrenal hypoplasia on the X chromosome; *Emx2,* the empty spiracles homeobox gene; *GATA-4,* the gene encoding a protein that binds to a GATA DNA sequence; *HOXA,* homeobox protein; *Lhx9,* a LIM homeobox family member; *Lim1,* a homeobox gene important for limb development; *Pax2,* a paired box homeotic gene; *SF-1,* the gene for steroidogenic factor 1; *SRY,* the sex-determining region of the Y chromosome; *SOX9,* SRY homeobox 9; *WNT-4,* a protein that induces development of the müllerian mesenchyma; and *WT1,* Wilms' tumor suppressor gene 1. (From MacLaughlin DT, Donahoe PK: Sex determination and differentiation. N Engl J Med 2004;350:367-378.)

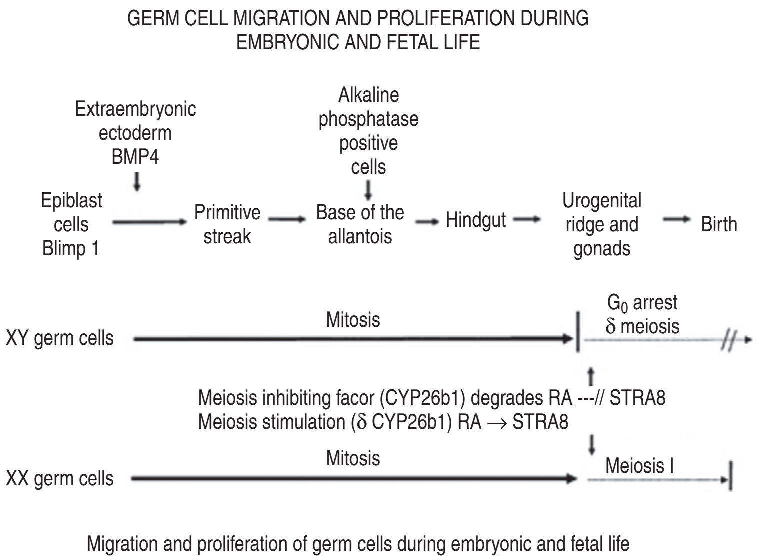

**FIGURE 123-2** Migration and proliferation of germ cells during embryonic and fetal life.[2,133]

translocations in a series of XY phenotypic females. Later, Sinclair and colleagues[28] defined a single-copy gene called the *sex-determining region of the Y chromosome (SRY)* that encodes a DNA binding protein, which is expressed in the gonadal ridge immediately before testis differentiation.[29] When the *SRY* gene, which expresses a protein homologous to the high mobility group (HMG) class of nuclear proteins, was transfected into XX female mouse embryos, a substantial proportion of these transgenic animals developed testes and assumed anatomic and functional male phenotypes.[30,29]

In addition to the Y chromosome, autosomal and X factors contribute to sex differentiation. For example, mutations on the long arm of chromosome 17q, found in cases of camptomelic dysplasia associated with sex reversal,[31–33] caused a defect in the *SRY*-related gene product, SOX 9, which contributes to sex differentiation. In addition, analysis of 46,XY sex-reversed females with intact *SRY* led to the discovery of the dosage-sensitive sex (DSS) reversal locus on the short arm of the X chromosome, duplication of which is required for female differentiation.[34] This region, which contains the gene *DAX-1,* was then assumed to have a negative influence on testis differentiation because a double dose of the X chromosome is associated with dysgenesis of the testis. However, knockout of *DAX-1* resulted in normal female gonadal development,[35] which undermines the hypothesis that *DAX-1* is responsible for ovarian differentiation. The only abnormality seen as a result of null mutation in *DAX-1* occurs, counterintuitively, in the male, which displays abnormalities in spermatogenesis and spermatogenic cord formation.[36] Defects in the distal end of the short arm of chromosome 9p[37] and the distal end of the long arm of chromosome 10q[38] are also associated with sex reversal.

The genes responsible for ovarian development are relatively obscure; in fact, the conventional wisdom has been that the ovaries developed passively as a result of the absence of testicular determining genes. Of the few genes studied in the mouse, it is clear that *WNT-4* is associated with ovarian development, as homozygous females have masculinized gonads and absence of the müllerian ducts.[39] Furthermore, *WNT-4* activation was recently shown to be regulated by *Respondin-1,* which regulates canonical-β-catenin, cytoplasmic stabilization of which in the XY gonad causes male-to-female sex reversal[9,40]; *FOXL2,* a forkhead transcription factor, was identified as another gene that represses the male development, allowing for normal ovarian development.[41–43] It is important to note, moreover, that prenatal ovarian development appears to be independent of steroid hormone action.[44] Taken together, it now seems reasonable to assume that ovarian differentiation is not merely a default pathway resulting from improper testis differentiation.

Thus the embryo must have the appropriate chromosomal endowment (i.e., 46,XX for females and 46,XY for males). Germ cells must then accurately migrate to the hindgut and subsequently take up residence in the retroperitoneum, where they condense in the urogenital ridge to become either a testis or an ovary. Germ cell migration into the urogenital ridge coincides with and probably induces the morphologic formation of a sex-specific gonad, which in turn produces steroid hormones and proteins. Receptors in local and more distant sites subsequently respond to the secreted extracellular hormones and proteins to activate intracellular signaling pathways and somatic gene responses, which lead to morphologic and biochemical changes resulting in the appropriate male or female phenotype.[45]

Male and female primordial reproductive ducts coexist for a short period in all mammalian embryos. Müllerian ducts, the anlage of the uterus, Fallopian tubes, and upper third of the vagina, develop autonomously in the female in the absence of the testis. Wolffian ducts, the anlage of the epididymis, vas deferens, and seminal vesicles, require testosterone to develop. The müllerian duct first forms by invagination of the coelomic epithelium, which tubularizes under the influence of *WNT-4* and then elongates, as the epithelial cells migrate in close approximation to the wolffian duct.[46] The wolffian duct provides no cells, but its presence is essential for full elongation of the müllerian duct to the urogenital sinus.[47] Wnt9b[47] and a functional PI3K/AKT pathway are essential for this final tubularization of the müllerian duct.[48]

The fetal testis, after morphogenesis into seminiferous tubules with Sertoli cells surrounding germ cells and interstitial differentiation to Leydig cells, produces two products required for further male differentiation, müllerian inhibiting substance (MIS), which inhibits differentiation of the müllerian duct, and testosterone, which stimulates wolffian structures.[49] The external genital primordia develop autonomously into clitoris, labia minora, and labia majora. Complete differentiation of the external genitalia to phallus and scrotum requires reduction of testosterone to dihydrotestosterone by 5α-reductase.[50] The interaction of dihydrotestosterone and an intracytoplasmic androgen receptor results in lengthening of the phallus into a penis, the urogenital folds fuse to form the penile urethra, and the labioscrotal swellings fuse in the midline to form the scrotum. The influence of testosterone is discussed in more detail later in the chapter. Autonomous female development can occur in the absence of ovaries.

The existence of a müllerian inhibitor was proposed by Jost,[49] who showed that testicular implants in female rabbit embryos stimulated the wolffian duct but also caused regression of müllerian ducts. This regression is characterized morphologically by programmed cell death. Because of the importance of these events, MIS was purified[51,52] and then used to clone the MIS gene.[53,54] The bioactive C-terminal domain of MIS is homologous to a group of evolutionary conserved proteins, referred to as the *transforming growth factor*-β (TGF-β) family, which is composed of TGF-β, MIS, activin, inhibin, bone morphogenesis factor, *Drosophila* decapentaplagia, *Xenopus* Vg1, and a number of growth and differentiation factors (GDFs).[54] The MIS ligand binds to a heterologous receptor composed of at least two serine-threonine kinase transmembrane units, the type II receptor,[55] which phosphorylates or activates the type I receptor,[56] which signals downstream via SMAD1/5/8 to begin the series of molecular events that results in regression of the müllerian ducts. This substance has been developed as an antiproliferative agent for tumors of müllerian duct origin and ovarian,[57,58] endometrial,[59] cervical,[60] breast,[61–63] and prostate[61] cancers. Abnormalities of the *MIS* gene itself can result in the retained müllerian duct syndrome, in which otherwise normal males, usually with undescended testes, have persistent müllerian structures that have not undergone normal regression.[64,65]

# Pathophysiology of Disorders of Sexual Differentiation

Three major categories of developmental aberrations are responsible for the most common forms of DSD in newborns (Table 123-1). In the first category, genetic females are masculinized by an overabundance of androgenic steroid production, causing a genital abnormality that requires highly specialized medical or surgical management (or both). In the second category, DSD occur because of deficient

androgen production or action in genetic males. The third category of abnormalities results from mutations leading to absent, incomplete, or asymmetric gonadal differentiation.[45] It is essential to understand the pathophysiology underlying these disorders in order to make a timely and accurate diagnosis and to plan optimal treatment strategies.

## 46,XX DSD (OVERANDROGENIZATION OF 46,XX GENETIC FEMALES)

The most common cause of overandrogenization or virilization is a defect in the P450 (heme pigment 450 oxidases, which metabolize multiple substrates) adrenal enzymes responsible for the conversion of progesterones to glucocorticoids and mineralocorticoids, resulting in the syndrome of congenital adrenal hyperplasia (CAH) or adrenogenital syndrome, which is now known as 46,XX DSD (overandrogenization).[66] This syndrome affects both males and females but causes ambiguous genitalia only in females. Adrenal differentiation occurs in the human fetus at 11 weeks' gestational age, after differentiation of the gonads and reproductive tract. Therefore the excess androgen most severely affects the developing external genitalia, the genital tubercle, and the urogenital folds, which develop after 11 weeks. When exposed to excess androgens, the genital tubercle, instead of forming a clitoris, is stimulated to develop as a penile structure. The urogenital folds, rather than developing as labia, acquire a bifid infused or fused scrotal appearance. Important to the differential diagnosis, ovaries remain in their normal intra-abdominal position above the inguinal canal.

Mutations in the *P450c21,* or 21-hydroxylase gene, now known as *CYP21* (Table 123-2), cause 90% of cases of CAH. The mutated gene, which resides on chromosome 6p in the HLA locus, results from recombination between the functional CYP21B and the nonfunctional pseudogene *CYP21A.* Incorporation of deletions from this pseudogene act to disable the functional gene.[67–70] The remainder of CAH cases are distributed among deficiencies of P450c11, 3β-hydroxysteroid dehydrogenase, CYP17, or steroid acute regulatory protein (StAR), depending on the ethnic origin of the patient.[45,71,72] Rarely, 46,XX DSD can result from exposure to exogenous androgens such as those given in the past to prevent loss of pregnancy. In case of classical CAH, deficient glucocorticoids and mineralocorticoids result in negative feedback on the pituitary, which then leads to excessive production of adrenocorticotropic hormone. This, in turn, results in hyperplasia of the fasciculata and granulosa layers of the adrenal gland and preferential production of androgenic steroids from the reticulata layer. 17-hydroxyprogesterone accumulates proximal to the P450c21 block, resulting in overproduction of pregnenolone and progesterone and their 17-hydroxylated derivatives, leading to the overproduction of testosterone and ultimately its reduced derivative, dihydrotestosterone (see Fig. 123-2). Elevations in 17-hydroxyprogesterone can be detected from a spot serum sample.[73] Polymerase chain reaction (PCR), sequencing of known genes, or fluorescent in situ hybridization (FISH) can now be used to make this diagnosis in utero.[45]

The molecular defect in these 46,XX genetic females with adrenogenital syndrome resides in the adrenal glands. The condition presents in a wide clinical spectrum. The ovaries, uterus, and Fallopian tubes are normal. The vagina, however, is foreshortened as a result of having failed to migrate to the perineum. It joins the urethra either at the position of the prostate, if masculinization is severe, or at a more distal position, if masculinization is less severe. The external genitalia are

characterized by variable clitoral enlargement, ranging from trivial to severe; some patients form an almost normal phallus. The labia can be masculinized to form either labioscrotal folds or, in the most severe cases, complete scrotal fusion. Because the ovaries are normal, the gonads never descend into these labioscrotal folds or fused scrotum.[74] Therefore an infant with bilateral nonpalpable testes should have a spot test for 17-hydroxyprogesterone and a karyotype determination to identify the presence or absence of the Y chromosome. All the enzymatic defects result in deficient cortisol biosynthesis. Failure of feedback results in increased corticotropin production, which continues to stimulate the adrenal gland and leads to hyperplasia, elevated production of products proximal to the enzymatic defect, and preferential overproduction of androgenic steroids. Concomitant production of melanocyte-stimulating hormone can also darken the genitalia and breast areolae.

## 46,XY DISORDERS OF SEX DEVELOPMENT, UNDERVIRILIZATION OF THE MALE (46,XY)

Insufficient masculinization of a 46,XY genetic male can occur due to insufficient testosterone production, an androgen receptor deficiency, or an inability to convert testosterone to dihydrotestosterone resulting in 46,XY DSD (formerly known as *male pseudohermaphroditism*).[75] Deficiency of androgen production (Fig. 123-3) occurs because of genetic enzymatic defects including steroid acute regulatory protein (StAR), resulting in lipoid adrenal hyperplasia (formerly thought to represent defects in cholesterol desmolase, P450scc, or CYP11A1). CYP11A1 (20,22 desmolase), CYP17 (17-hydroxylase or lyase), 3β-hydroxysteroid dehydrogenase (3β-HSD), and 17β-hydroxysteroid dehydrogenase (17β-HSD), formerly known as 17-ketosteroid reductase, together and sequentially are responsible for the cascade of metabolism from cholesterol to testosterone.[71] In these patients, stimulation by chorionic gonadotropin produces little or no testosterone; in contrast, MIS levels are normal or high for age. The testes may be undescended, small, or both. Under the influence of normal MIS, there should be no müllerian structures. Because of testosterone deficiency, the penis may be small and hypospadiac.[70]

Androgen insensitivity can occur because of receptor deficiency. Most abnormalities are caused by point mutations in the androgen receptor gene,[76,77] which can now be detected by PCR and DNA sequencing. Only rarely have large deletions been found. The phenotype can be mild or severe; the complete androgen insensitivity syndrome (CAIS) manifestation was often referred to as *testicular feminization,* in which the patient has an almost complete female phenotype. Serum levels of testosterone may be high; MIS may be normal or,

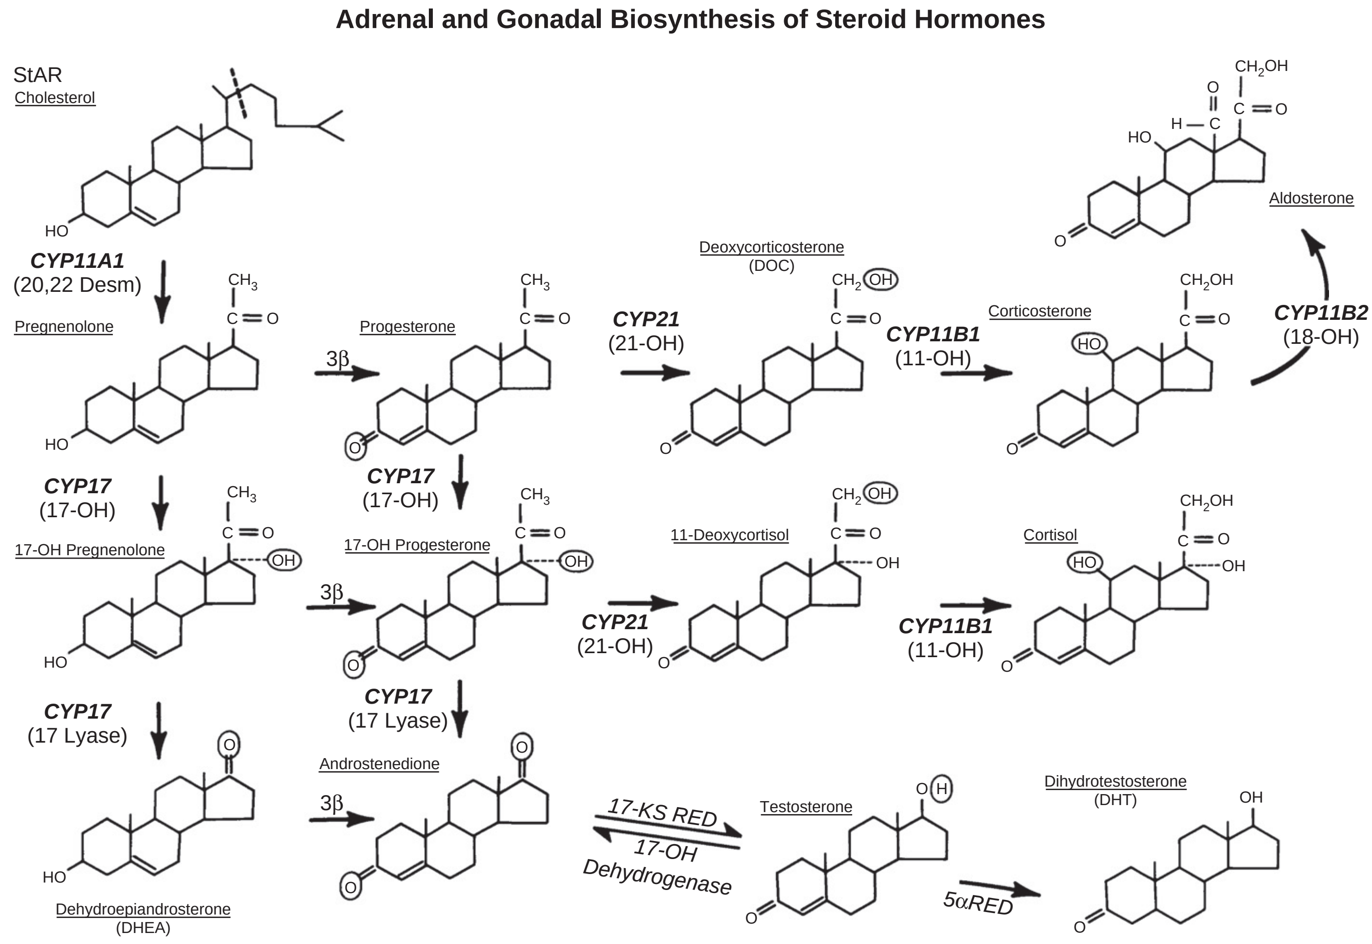

**FIGURE 123-3** Pathways of steroid hormone biosynthesis from cholesterol. New enzyme nomenclature is in bold lettering; old nomenclature is in parentheses. Enzymatic defects of CYP21, CYP11, or 3β-hydroxysteroid dehydrogenase can lead to congenital adrenal hyperplasia. Deficiencies in testosterone production leading to a form of male pseudohermaphroditism can result from defects in $CYP11A_1$, CYP17, 3β-hydroxysteroid dehydrogenase, and 17-ketosteroid reductase.

in some cases, considerably elevated; and müllerian structures are normally regressed. The gonads are symmetric and may be intra-abdominal or descended. However, not all patients with the 46,XY karyotype and the characteristics of 46,XY DSD have a detectable molecular defect in the coding region of the androgen receptor. It is possible that the noncoding promoter, the 3′ untranslated region, or other transcription factors or their cofactors are the cause of 46,XY DSD in the large subset of patients in which the molecular defect has not yet been defined.

3β-HSD acts by reducing the 3β-hydroxyl group to a 3-ketone, and by isomerizing the C5-6 double bond to the C4-5 position in the conversion of pregnenolone to progesterone, or 17-hydroxypregnenolone to 17-hydroxyprogesterone. All these steps are essential for the production of glucocorticoids and mineralocorticoids. The activity is also important in the testis for the conversion of dehydroepiandrosterone (DHEA) to androstenedione. Various isoforms of this enzyme have also been found in the placenta, but their functions have not been as carefully detailed. Another non-P450 enzyme in the pathway is 17β-HSD, which converts androstenedione to testosterone.

Mutations in the 5α-reductase type 2 genes cause another form of 46,XY DSD. Because of this deficiency, testosterone is not converted to dihydrotestosterone in peripheral, particularly genital, target tissues.[50,78] This non-P450 enzyme depends on the reduced form of NADPH (nicotinamide-adenine dinucleotide phosphate). Action in the genital area results in elongation and ventral closing of the penile raphe, which encloses the urethra and displaces the urethral orifice from the perineum to the tip of the penis.[75] The labioscrotal folds are also fused in a posterior direction to create scrotal sacs. This autosomal recessive form of severe hypospadias is associated with undescended testis, prepenile scrotum, and enlarged prostatic utricle. The enzyme has binding sites for both testosterone and the NADPH cofactor, where point mutations have been associated with the defective phenotype. Two known isoforms exist; however, type 2, located on chromosome 19, is the one expressed predominantly in the external genitalia. The paradoxical virilization that occurs at puberty and results in a change of sexual identity is caused by increased activity of the 5α-reductase type 1 isoform in a multitude of other tissues in these genetic males.

### ABNORMALITIES OF GONADAL DEVELOPMENT AND DIFFERENTIATION

Abnormalities of the sex chromosomes usually manifest as failed, incomplete, or asymmetric gonadal differentiation. Patients with these disorders have either bilateral streak gonads, as in 46,XY pure gonadal dysgenesis, or asymmetric gonadal development, as in mixed gonadal dysgenesis (MGD) or ovotesticular DSD (formerly termed *true hermaphroditism*). Patients with pure gonadal dysgenesis and a 46,XY karyotype may have a defective Y chromosome, with either deletion in the 1A1 pseudoautosomal region[27] or a point mutation in the *SRY* gene.[79] Mutations associated with camptomelic dysplasia, a severe disorder occurring in patients with a translocation in the distal arm of chromosome 9p near the *SRY*-related *SOX 9* gene,[31,33] or mutations in *WT1* associated with Frasier syndrome[37] also result in pure gonadal dysgenesis. These streak gonads fail to develop bilaterally, producing little or no end products of testosterone or MIS; gonadotropin levels are compensatorily high. Müllerian ducts are preserved, and the phenotype is female.

MGD (also known as *asymmetric gonadal dysgenesis*) with a 45,X/46,XY karyotype is by far the most common of the chromosomal abnormalities.[45,80] The gonads are asymmetric, most often with a small dysgenetic testis on one side and a streak gonad on the other.[81] Most patients with this defect have retained müllerian ducts. The small testis can produce enough testosterone to cause masculinization and hypertrophy of the clitoris. The vagina fails to migrate to the perineum and enters the urethra as a urogenital sinus defect more distal to the bladder neck than seen in severe cases of CAH. It is important to note that 40% of patients with MGD can have a 46,XY karyotype, and some have bilateral testes or streak ovaries. The absence of the second X chromosome is in some way related to the early ovarian dysgenesis. The mosaicism of MGD results from the presence of at least two gonadal (chimeric) germ cell lines, and the degree of testicular differentiation is determined by the percentage of cells expressing the XY genotype, which may also influence the degree of asymmetry. Loss of the Y chromosome can occur because of nondisjunction, the failure of paired chromosomes to migrate to opposite poles during cell division.[2,25,82,83] Because prenatal genetic testing has become more common, the 45,X/46,XY karyotype is now being detected in a small percentage of amniotic cells in phenotypically normal males.

True ovotesticular DSD (true hermaphrodites) are rare, except among the Bantu in Southern Africa; the cause of this anomaly remains elusive.[84,85] More than 90% of these patients have a 46,XX karyotype. Asymmetry characterizes many of these patients, who have simultaneous ovarian and testicular differentiation without the dysgenesis characteristic of MGD. The testicular and ovarian tissue can be separated on both sides or combined in one or both gonads as an ovotestis. When ovarian tissue and testicular tissue coexist in the same gonad, the testis is always central and the ovarian tissue is polar.[86] Although the molecular cause of this disorder has not been elucidated, translocation of a fragment containing the *SRY* gene to a cryptic site on the X chromosome has been observed.[87] Otherwise, *SRY* has not been detected in these patients. Although early testicular differentiation occurs, spermatogenesis is not evident,[84] which may reflect the absence of other necessary Y-directed functions. The müllerian structures are regressed on the side of the testicular tissue but retained on the side of the ovarian tissue and in the midline as well, with the vagina entering the distal urethra as a urogenital sinus defect. The asymmetry associated with this disorder remains an enigma.

## Diagnosis

A baby born with DSD must have an expeditious and thoughtful evaluation to determine whether gender assignment can be made. It is important to minimize the emotional trauma to the family and later to the child. Referral to a well-organized team of endocrinologists, geneticists, psychologists, and pediatric surgeons/urologists experienced with the complexity of these disorders is absolutely necessary. Although many syndromes can affect later sexual development, only four result in DSD at birth: 46,XX DSD (formerly known as *female pseudohermaphroditism*), ovotesticular DSD (true hermaphroditism);

46,XY DSD (previously termed *male pseudohermaphroditism, undervirilization of an XY male,* and *undermasculinization of an XY male*); and MGD 45,X/46,XY. A child with pure gonadal dysgenesis, although having a 46,XY karyotype, is phenotypically female. It is critical that the sex of rearing not be biased by the skills of the surgeons, who must be equally capable at reconstructing the infant as male or female. Two screening criteria can be used to diagnose the infant as having one of the four disorders: symmetry and the presence of a Y chromosome (Table 123-3). The diagnostic evaluation of patients with ambiguous genitalia is outlined in Table 123-1.

The first criterion is the physical finding of gonadal symmetry or asymmetry, and the second is a rapid analysis of the sex chromosomes. Probes for *SRY* can now be used to detect the distal end of Yp, the short arm of the Y chromosome, by PCR or FISH. Direct sequencing of the *SRY* gene is now available. Symmetry of the gonads is determined by the position of one gonad relative to the other, either above or below the external inguinal ring. Both gonads lie either above or below the external inguinal ring when a diffuse biochemical cause underlies the abnormality. For example, in 46,XX DSD or 46,XY DSD, a biochemical defect influences both gonads equally. Asymmetry occurs in chromosomal abnormalities such as MGD or ovotesticular DSD (true hermaphroditism), in which a predominant testis descends and a predominant ovary remains above the external ring. In cases of 46,XX DSD (female pseudohermaphroditism with adrenogenital syndrome) and in most cases of ovotesticular DSD (true hermaphroditism), the karyotype is 46,XX. Patients with 46,XY DSD (male pseudohermaphroditism) or MGD have a Y chromosome in their karyotype.

After this initial evaluation, rapid analysis for 17-hydroxyprogesterone to detect CYP21 disorders should be done emergently in patients with 46,XX with symmetric undescended gonads. This screening test is done in some states' laboratories on all newborns. A detailed history and physical examination can be coupled with PCR, FISH, or direct sequencing to detect mutations or deletions known to cause defects in the four major categories (Table 123-4) and to define these disorders more fully and guide sex assignment. Subsequently, ultrasonography, magnetic resonance imaging, contrast radiography, and later panendoscopy, coupled with accurate laboratory analysis for disorders of enzymes affecting testosterone synthesis, should provide a definitive diagnosis and permit appropriate gender assignment with a high degree of accuracy.

The size and location of the penis with respect to the scrotum should be carefully noted. Although the size of the phallus varies considerably, some guidelines are helpful.[70,88] The average length of the penis is $3.5 \pm 0.4$ cm at term, $3.0 \pm 0.4$ cm at 35 weeks' gestation, and $2.5 \pm 0.4$ cm at 30 weeks' gestation. At term, a diameter of 1 cm is average. A penis smaller than $1.5 \pm 0.7$ cm in full-term infants may raise the option of female gender assignment, except in cases of 17-ketosteroid reductase or 5α-reductase deficiencies, in which large body habitus or sex reversal at puberty, respectively, may favor or dictate male sex assignment. An early rectal examination

**TABLE 123-3**
**Rapid Diagnostic Algorithm**

| Y Chromosome Absent or Abnormal | | Y Chromosome Present | |
|---|---|---|---|
| *Symmetry* | *Asymmetry* | *Symmetry* | *Asymmetry* |
| 46,XX DSD [congenital adrenal hyperplasia] | Ovotesticular DSD | 46,XY DSD | 46,XX/46,XY MGD [Mixed gonadal dysgenesis] |

These two diagnostic criteria—presence or absence of Y chromosome and gonadal symmetry or asymmetry—allow the rapid, accurate assignment of a patient into one of the four diagnostic categories with approximately 90% accuracy.

**TABLE 123-4**
**Mutations in Genes Involved in Sex Determination and Development and Associated with Disorders of Sex Development**

| *Gene (Locus)* | *Protein and Proposed Function* | *Mutant Phenotype* |
|---|---|---|
| WT1 (11p13) | Transcription factor | Frasier syndrome; Denys-Drash syndrome with Wilms' tumor |
| SF-1 (9q33) | Transcription factor, nuclear receptor | Gonadal and adrenal dysgenesis |
| SOX 9 (17q24) | High mobility group (HMG) protein transcription factor | Camptomelic dysplasia and male gonadal dysgenesis or XY sex reversal |
| DAX-1 (Xp21.3) | Transcriptional regulator, nuclear receptor | Gonadal dysgenesis and congenital adrenal hypoplasia |
| SRY (Yp11) | HMG protein transcription factor | Gonadal dysgenesis, XX sex reversal |
| MIS (AMH) type II receptor (12q12-13) | Serine threonine kinase receptor | Persistent müllerian duct syndrome |
| MIS (AMH) (19p13) | Secreted protein, fetal müllerian duct regressor, Leydig cell inhibitor | Persistent müllerian duct syndrome |
| AR (Xq11-12) | Androgen receptor, ligand transcription factor | 46,XY DSD, CAS or PAIS |
| HSD17B3 (9q22) | 17-hydroxysteroid dehydrogenase–17-ketosteroid reductase 3 | 46,XY DSD |
| SRD5A2 (5p15) | 5α-steroid reductase type 2 | 46,XY DSD (may virilize at puberty) |
| CYP17 (10q24q25.) | 17-hydroxylase, 20,22-lyase | 46,XY DSD |
| CYP21 (6q21.3) | 21-hydroxylase | 46,XX DSD (Congenital adrenal hyperplasia) |
| HSD3B2 (1p13.1) | 3β-hydroxysteroid dehydrogenase type 2 | 46,XX DSD (Congenital adrenal hyperplasia) |
| CYP11B1 (8q24) | 11β-hydroxylase | 46,XX DSD (Congenital adrenal hyperplasia) |
| StAR (8p11.2) | Steroidogenic acute regulatory protein | Congenital lipoid adrenal hyperplasia |

From MacLaughlin DT, Donahoe PK: Sex determination and differentiation. N Engl J Med 2004;350:367-378.

may allow the detection of the uterus while it is still under the influence of placental human chorionic gonadotropin, after which the uterus softens. The presence and severity of hypospadias should be noted; the confluence point of the vagina with the urogenital sinus (UGS) (urethra) in relation to the bladder neck and perineum and the length of the vagina should also be noted. Palpation of the gonads can help differentiate the firm testis from the softer ovotestis, and the wrapping of the epididymis around the testis can help differentiate it from an ovary in the inguinal position.[45] Often the hypospadiac phallus is displaced posteriorly behind a prepenile scrotum.

## 46,XX DSD (OVERANDROGENIZATION OF GENETIC FEMALES, 46XX)

Female pseudohermaphroditism is a diagnostic problem if the patient is the proband for the family. If a sibling already has the disease, the level of awareness for this autosomal disorder will be high. Amniocentesis with cytogenetic analysis for the genetic defect allows early prenatal diagnosis. However, in unsuspected cases, when the child is born at term, the clitoris is hypertrophied, the gonads are symmetric and intra-abdominal, and the vagina fails to descend to the perineum and enters the UGS (urethra) distal to the bladder neck; however, a significant subset of patients may have a verumontanum, with the urethrovaginal confluence quite close to the bladder neck.[89] These patients can also have an enlarged, placentally stimulated, palpable prostate at the level of the verumontanum. The labioscrotal folds are rugated, enlarged, and, in some cases, completely scrotalized. In addition to normal ovaries, the uterus and Fallopian tubes are normal. The vagina, however, is foreshortened, as a result of having failed to migrate to the perineum. It is essential to measure the distance from the bladder neck to the UGS confluence at the time of panendoscopy to aid future plans for definitive reconstruction. The external genitalia are characterized by variable clitoral enlargement, ranging from trivial to severe. Some patients have a male-appearing phallus. The labia may be masculinized to form labioscrotal folds or, in severe cases, complete scrotal fusion may occur. Because the ovaries are normal, the gonads never descend into the labioscrotal folds or fused scrotum.[45,74] The karyotype is always 46,XX in females, MIS is undetectable, and a spot serum analysis reveals elevated 17-hydroxyprogesterone. Androgen levels are also elevated. Concomitant production of melanocyte-stimulating hormone can darken the genitalia and breast areolae. PCR with appropriate probes demonstrates point mutations in the *P450c21* gene.[69] Electrolytes are often normal at birth, but when maternal steroids wane after 5 to 7 days, potassium levels may become markedly elevated and serum sodium levels may fall. As a result, electrocardiography reveals inverted Twaves, which, if unattended, can lead to cardiac arrest. Hence this disorder must be considered a medical emergency in the new forum.

In rare cases with 3β-HSD deficiency, 17-hydroxypregnenolone, pregnenolone, and DHEA levels are elevated and serum 11-deoxycortisol or deoxycorticosterone levels are elevated in patients with P450c11 deficiency. Gender assignment in these patients is almost always female, except when the diagnosis is delayed and the patient has already been raised as a male.[90,91]

## 46,XY DSD (MALE PSEUDOHERMAPHRODITISM)

### Testosterone Deficiency

By definition, 46,XY DSD have deficient androgenization of the external genitalia with a 46,XY karyotype. If the disorder is caused by an enzymatic defect in the testosterone-androgen pathway, patients have low basal serum testosterone and stimulation by chorionic gonadotropin produces little or no increase in testosterone. Because the genes coding for the enzymes in the pathway have been cloned, PCR or direct sequencing can be performed to detect deficiencies in *StAR, 3β-HSD, CYP17,* or 17-ketosteroid reductase genes. The testes may be small and are often bilaterally and symmetrically undescended. The penis is small, and hypospadias is usually severe. Under the influence of normal MIS, there are no detectable müllerian structures. In some cases, the phenotype is completely female.[70,92] Gender assignment depends on the size of the phallus. It may be better to raise those with a small phallus as females, whereas it is invariably preferable to raise those with a reasonably sized phallus as males because they will respond to exogenous testosterone. Special consideration should be given to those rare children with 17-ketosteroid reductase deficiency, which may be better raised as males (P. K. Donahoe and R. Pieretti, oral communication).

### Androgen Receptor Deficiency

Cases in which the androgen receptor is severely dysfunctional, as occurs in CAIS (complete androgen insensitivity syndrome), previously known as *testicular feminization,* have been attributed to complete androgen receptor insufficiency.[93] The phenotype is completely female, so these children should be raised in concordance with that phenotype. No müllerian structures are present because high levels of biologically active MIS are produced. The testes are usually in the inguinal region, and their firmness and investing epididymis can be palpated to distinguish them from ovaries. The karyotype is 46,XY. Although the androgen receptor is deficient, levels of testosterone and MIS are high. PCR or sequencing of the androgen receptor gene can often pinpoint the molecular defect and provide the definitive diagnosis.

PAIS (partial androgen insensitivity syndrome) results in only partially masculinized 46,XY patients, with a wide variation from minimal to severe anomalies. As with testosterone-deficiency syndrome, the penis is small and hypospadiac. The testes may be small and are often undescended but symmetric, and müllerian structures are not present. The testosterone levels are normal, and MIS levels are elevated. Most abnormalities are caused by point mutations in the androgen receptor gene,[76,77] which can be detected by PCR and DNA sequencing. Only rarely have large deletions been found. Gender assignment, again, depends on the size of the phallus.

### 5α-Reductase Deficiency

46,XY DSD can also result from a deficiency of 5α-reductase, which is responsible for the conversion of testosterone to dihydrotestosterone. The normal action of 5α-reductase on the genital area results in elongation and ventral closing of the penile raphe, displacing the urethral orifice from the perineum to the center of the glans penis.[75] This process is abnormal in these patients, resulting in severe penoscrotal

hypospadias. Normal and symmetric testes can be either undescended or fully descended. The labioscrotal folds are also closed posteriorly to create partial or bifid scrotal sacs. The prostatic utricle is often quite enlarged. Again, the karyotype is 46,XY. Serum levels of testosterone are high, but levels of dihydrotestosterone are low. The MIS levels are normal. PCR and full DNA sequencing can be used to genotype and detect mutations in the 5α-reductase type 2 gene. Given the dramatic phenotypic conversion at puberty, it may be more appropriate to raise these children as males. It should be noted, however, that in this group, gender assignment involves the greatest dilemma in societies committed to two sexes, but not in societies that more readily accept assignment to a third sex.[50,94,95]

## CHROMOSOMAL ABNORMALITIES

### 46,XY Pure Gonadal Dysgenesis

Patients with pure gonadal dysgenesis are born as phenotypic females. Amniocentesis with a 46,XY karyotype that does not produce the expected phenotype on fetal ultrasonography now allows earlier diagnosis than was previously possible. Dorsal pedal edema and some Turner characteristics may be the only obvious somatic manifestations of the defect. Müllerian structures are present, but gonads are not palpable due to failure of gonadal differentiation. Testosterone and MIS are undetectable, indicating dysgenesis of the gonad. Candidate gene mutations include *SRY, SOX 9, WT1,* and *SF-1.*[2]

### Mixed Gonadal Dysgenesis

Patients with MGD are characterized by asymmetry, with a streak gonad on one side and a dysgenetic testis on the other. They also have retained müllerian structures.[80,81,96] The clitoris is usually hypertrophied. The most common karyotype is 45,X/46,XY, but 40% of patients have the 46,XY karyotype. Because the testes are dysgenetic, testosterone and MIS levels may be low. There is a propensity for neoplastic transformation to gonadoblastoma or seminoma (or both),[83,97,98] even as early as the neonatal period. These tumors can cause torsion and apparent loss of a gonad that, in rare cases, leads to a unilateral dysgenetic testis or streak ovary. Because gonadoblastomas may occur at any stage, gonadectomy and female reconstruction and rearing are the options usually chosen. The X-linked DAX-1, which may suppress testicular differentiation, may have a role in MGD, which is the least understood of the intersex abnormalities at the molecular level.[99] When we identify the genes responsible for the separation of paired chromosomes during meiosis, the defects responsible for this enigmatic abnormality may be discovered. We should mention a subgroup of 45,XO/46,XY who are diagnosed prenatally with normal external genitalia and raised as males—indicating a spectrum of the disorder.

### Ovotesticular DSD (True Hermaphroditism)

The molecular cause of this disorder remains enigmatic.[84,85] Patients with this disease also have asymmetry, with a testis on one side and an ovotestis on the other; however, various other gonadal combinations can occur. If an ovotestis is present, testis is always central and the ovarian tissue is polar.[86] Neoplastic transformation is not characteristic of these unique gonads. The müllerian structures are regressed on the side of the testicular tissue but retained on the side of the ovarian tissue and as a midline uterus as well, with the vagina entering the urethra as a urogenital sinus defect. The clitoris is hypertrophied. The karyotype is 46,XX in 90% of cases; the levels of testosterone and MIS are low or sometimes normal. Although early testicular differentiation occurs, spermatogenesis is not evident,[84] which may reflect the absence of other necessary Y-directed functions. Abnormalities in SRY have not been detected in these patients;[100] both the molecular cause and the reason for the asymmetry remain an enigma. The sex of rearing is dictated by the phenotype, which is directed by the predominant gonad.

# Medical Management

## 46,XX DSD (CAH)

Masculinized females with pseudohermaphroditism can be at profound risk for life-threatening complications including cardiac arrest in the prenatal period. Because maternal cortisone crosses the placenta and is released slowly from fat stores, the clinical manifestations of adrenogenital crisis may not become apparent until 5 to 7 days after birth. Heightened clinical awareness and prompt, appropriate metabolic treatment can prevent serious complications. Glucocorticoid replacement as oral hydrocortisone 8 to 10 mg/m$^2$ per day in two or three doses or cortisone acetate 25 mg/m$^2$ injected every 3 days[101] will prevent serious metabolic abnormalities associated with acute adrenal insufficiency.

Fludrocortisone (9α-fluorocortisol) 0.05 to 0.2 mg/day is started in severely virilized infants and in those less virilized with a family history of salt wasting as part of 46,XX DSD (CAH). Recent evidence that even patients with milder virilizing hermaphroditism have subclinical aldosterone deficiency has led to more liberal use of fluorocortisone, although some clinicians follow electrolyte levels and plasma renin activity before starting such treatment.

An infant in adrenal crisis should be rehydrated with isotonic saline. After the first hour, half-strength saline in 5% to 10% dextrose should be administered. This regimen corrects plasma sodium and chloride imbalances rapidly, but hyperkalemia and acidosis are corrected more slowly. Dramatic elevation of plasma 17-hydroxyprogesterone can be used to monitor the effectiveness of treatment. Infants (average 0.25 m$^2$) in adrenal crisis are treated with 25 mg hydrocortisone sodium succinate (2 mg/kg), whereas older children receive 50 to 100 mg. This preparation has both glucocorticoid and mineralocorticoid activity; the mineralocorticoid activity is equivalent to 0.1 mg of fludrocortisone. A similar regimen is used for infants exposed to the stress of surgery. Parents are taught to recognize situations that contribute to adrenal insufficiency such as high fever, exposure to hot environments, or surgery. Breast milk and prepared formulas are low in sodium, so table salt should be given as a supplement. Growth charts must be monitored carefully to avoid inadequate or inconsistent treatment or oversuppression and chronic adrenal insufficiency.

Prenatal diagnosis and treatment are now available.[102,103] Dexamethasone treatment, if used to suppress masculinization in utero, is initiated by the fifth or sixth week of gestation before the start of sexual differentiation. Dexamethasone crosses the placenta to suppress the fetal adrenal gland and

decrease fetal androgen production, thereby minimizing in utero virilization. The sex of the fetus is determined by chromosome analysis at amniocentesis or chorionic villus sampling, and PCR and DNA sequencing can be used to analyze the *CYP21* gene. Treatment is discontinued in males and unaffected females. Affected females can be treated to term. Currently, embryo selection or genetic manipulation can be done at the early blastocyst stage. Blastocysts with a normal *CYP21* gene can be preselected for subsequent implantation if a previous pregnancy produced a child with the CYP21 mutation.

### 46,XY DSD (MALE PSEUDOHERMAPHRODITISM)

46,XY DSD patients with poor penile development who have testosterone biosynthetic defects or androgen resistance may be considered for female gender assignment. However, for those with 5α-reductase or 17β-hydroxysteroid reductase deficiency, it may not be appropriate to assign a gender at birth. Patients assigned to the female gender should receive early surgical correction of the external genitalia and gonadectomy but do not receive hormone therapy until puberty, at which time they will require estrogen and progesterone treatment. Vaginal replacement should be planned for late puberty.

If it is elected to assign these infants to the male gender, 25 mg of testosterone enanthate or cypionate is given once every 3 or 4 weeks for about 3 doses to confirm that the penis responds to androgens or to improve the size of the penis before surgery. Repair should be done before 1 year of age if the size of the phallus permits. This approach takes advantage of an early period of presumed enhanced sensitivity to androgens. After one to three courses of monthly testosterone for 3 months, an interval of at least 1 month without testosterone must be allowed before undertaking hypospadias repair to reduce postoperative hyperactivity that can accompany testosterone therapy. If the child requires a staged procedure, testosterone therapy, if needed, can precede the second stage. Testosterone replacement is resumed at adolescence. Patients with 5 α-reductase deficiency should receive dihydrotestosterone replacement, if available. Otherwise, replacement can be achieved by giving higher doses of testosterone to overcome the enzyme block.

### CHROMOSOMAL ABNORMALITIES

In patients with MGD or ovotesticular disease assigned to the female gender, no steroidal replacement is required in childhood. However, if the child has been assigned to the male gender, presurgical testosterone stimulation of the penis may be required before hypospadias repair. Treatment does not recommence until adolescence. If the patient is assigned to the female gender, replacement of estrogen and progesterone is started at adolescence. Patients with 46,XY pure gonadal dysgenesis require neither surgical nor medical therapy as newborns, and estrogen and progesterone replacement begins at adolescence. Renal function must be followed carefully in patients with the various WT1 isoform defects. Adrenal replacement therapy may be complex in patients with SF-1 mutations characteristic of the adrenal hypoplasia congenita syndrome. Vaginal replacement should be planned for late puberty.

## Surgical Treatment of Urogenital Sinus Anomalies and Disorders of Sexual Differentiation

Patients with DSD and UGS abnormalities who have anatomic problems such as clitoral enlargement and labial fusion are a source of great concern and challenges for parents, patients, and the medical team involved in their treatment. Although we have witnessed significant advancements resulting from studies on clitoral innervation and new nerve-sparing clitoroplasty techniques,[15,104] we lack convincing long-term results regarding sexual function and acceptance of genital appearance in females with CAH because most of the published studies correspond to patients reconstructed, which have been revised.[107]

## Preoperative Evaluation

### IMAGING EVALUATION

A retrograde genitogram is performed by occluding the opening of the urogenital sinus with the balloon of an 8-Fr Foley catheter placed outside the meatus and secured in place with tape. Lateral and oblique images are then obtained. The study should be performed by the surgeon and an experienced radiologist. Next, the catheter should be advanced into the bladder for a vesicoureterogram (VCUG). The study allows a preliminary diagnosis of the level of confluence of the urogenital sinus in relation to the bladder neck, thus facilitating the planning of the surgical procedure (Figs. 123-4, *A* and *B*, and 123-5).

Ultrasonography gives valuable information about the urinary tract, and in most cases the uterus, vagina, and gonads can be visualized (Fig. 123-6, *A* and *B*). In those cases in which the anatomy is not well demonstrated, magnetic resonance imaging (MRI) of the pelvis could clearly outline the anatomy of the pelvic organs (Fig. 123-7).

## Laparoscopy

Laparoscopy provides excellent visualization of the pelvic structures and may play an important role in those cases that need a gonadal biopsy or gonadectomy. It can also be helpful for identification or removal of müllerian structures.[108,109] Also, laparoscopy can be used to perform other procedures such as a laparoscopic-assisted sigmoid vaginoplasty, or the excision of an enlarged müllerian duct remnant.

## Preoperative Preparation

It is important to prepare the bowel adequately before repair. This should be done at home because most children are preferentially admitted on the morning of surgery. For low repairs, magnesium citrate should be given on each of the 2 days before repair. For high repairs, Golytely, a polyethylene glycol isotonic solution, is administered by mouth beginning 3 days before surgery for 2 consecutive days, followed by magnesium citrate 1 day before surgery. In some cases, ondansetron may be indicated to prevent nausea, or Golytely can be

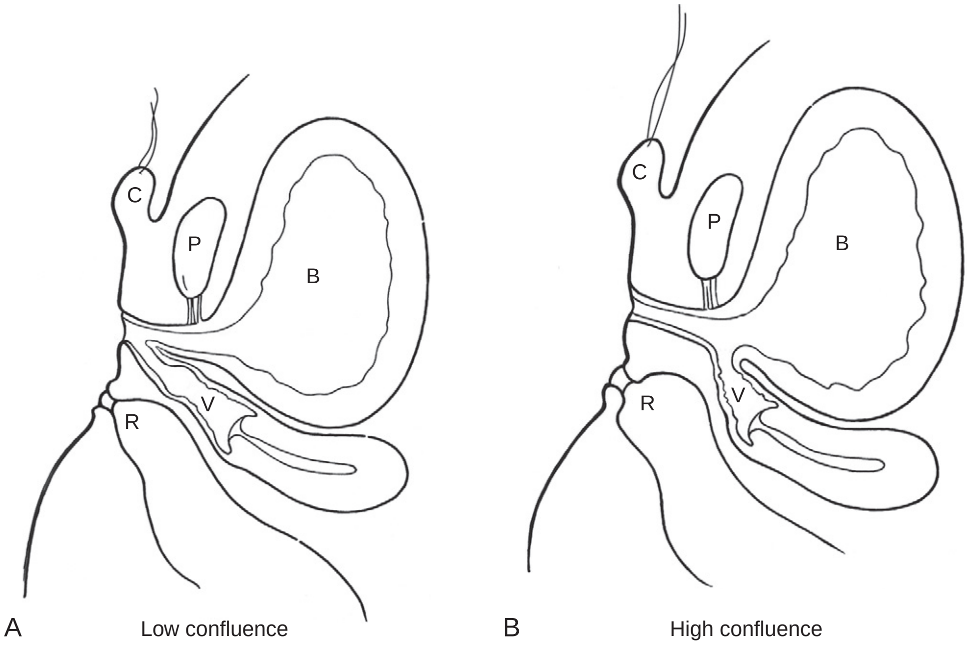

**FIGURE 123-4** **A,** Low-confluence urogenital sinus. **B,** High-confluence urogenital sinus. *B,* Bladder; *C,* Clitoris; *P,* pubis; *R,* rectum; *V,* vagina.

administered through a small nasogastric tube. It is important to discontinue Golytely at least 24 hours before surgery to avoid leakage during the procedure. Magnesium citrate, which shrinks the bowel, is given on the last day to prevent leakage. Oral administration of neomycin plus erythromycin can be used to reduce bacterial concentration.

As outlined earlier, stress doses of steroids, based on the weight of the child, are given at the time of anesthetic

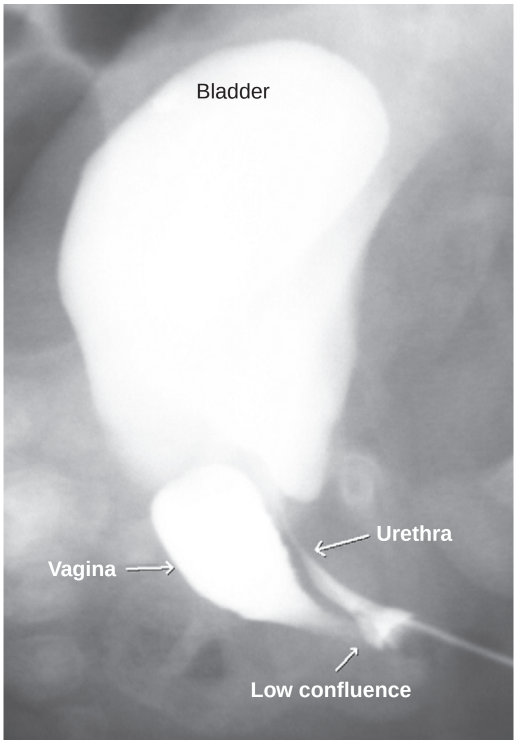

**FIGURE 123-5** Retrograde genitogram showing a low-confluence urogenital sinus in a patient with 46,XX DSD (CAH).

induction. Steroids are continued during surgery and for 2 to 3 days after surgery at double the usual oral dose, followed by a tapering of the dosage. Children on dexamethasone are asked to omit their medications, but children on prednisone take the usual morning dose on the day of surgery. Medications after surgery are planned with pediatric endocrinology consultation, and dosing is dependent on the length and extent of surgery and the expected length of hospitalization.

## Surgical Reconstruction

### PANENDOSCOPY

Each reconstructive procedure is preceded by a panendoscopy using a pediatric cystoscope with 0- and 30-degree optics. High-flow irrigation of the urogenital sinus assists finding a small vaginal orifice in the back wall of the UGS; in some cases, there may be only a pinpoint orifice, and in some patients probing with a 3-Fr ureteral catheter can be used to find a small vaginal orifice (Fig. 123-8). For surgical planning one must precisely define the location of the confluence point between the vagina and urethra in relation with the bladder neck. To do so, we use the verumontanum/external sphincter as a landmark. In addition, more accurate measurements can be obtained with a 3- or 4-Fr ureteral catheter with 1-cm markings passed alongside the cystoscope, with its tip placed at the bladder neck and using the catheter markings as a ruler. Those anomalies with the confluence point at or above the verumontanum/external sphincter are considered high, and those below are considered low (Fig. 123-4, *A* and *B*). Patients with 46,XX DSD, MGD, and ovotesticular DSD have a cervix at the most proximal part of the vagina. Patients with 46,XY DSD have either a small prostatic utricle or a deeper, more generous cavity that has no proximal cervix. This prostatic utricle is characteristically found in the center of a flattened verumontanum but has no surrounding prostatic tissue. In midlevel and high-confluence cases, a Fogarty catheter with a stopcock valve is passed into the vagina. The balloon is inflated, a small Foley catheter is placed in the bladder, and both are tied together.

## Reconstruction for Female Gender Assignment

All 46,XX DSD newborns should be assigned to the female gender, regardless of the extent of masculinization, and undergo surgical reconstruction consistent with the female gender assignment. Similar repairs can be used for selected patients who are not severely masculinized because of 46,XY DSD, MGD, or ovotesticular DSD. The mainstays of a feminizing genitoplasty are clitoroplasty, labioplasty, and vaginoplasty. Surgical procedures should preserve clitoral sensation and provide a female appropriate cosmesis, with a well-lubricated vagina that will allow pleasant and painless intercourse. It should be mentioned that recent trends have raised concerns regarding the benefits of clitoroplasty. Therefore it should be undertaken only after extensive discussions with the family because another option would be deferral until the patient is capable of deciding by herself.

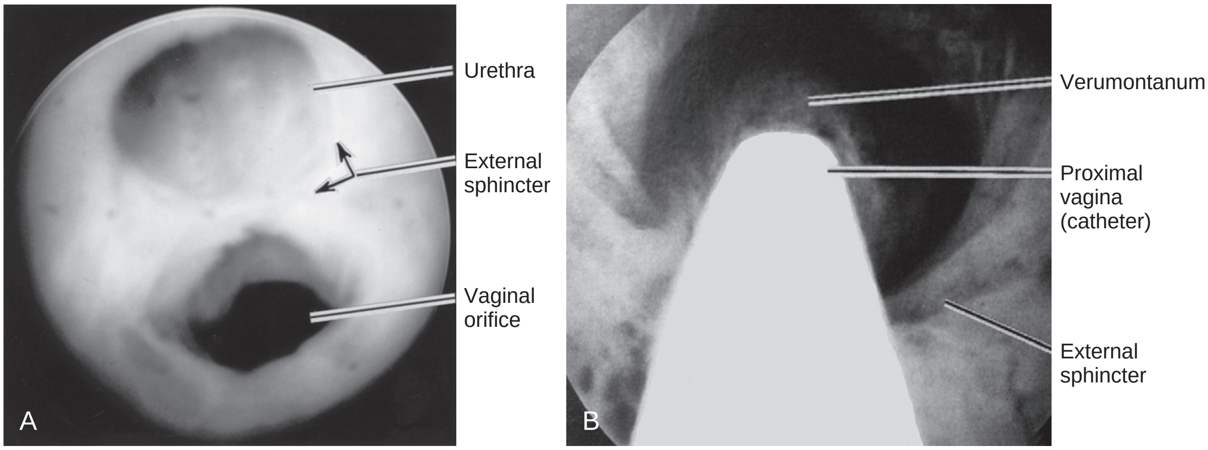

**FIGURE 123-8** Cystoscopic examination indicates whether the vagina joins the urethra in a high or low confluence. **A,** The vaginal orifice is clearly high. **B,** Catheter entering the vaginal opening at the verumontanum in a patient with severe masculinization from female pseudohermaphroditism.

## Planning and Timing the Surgical Reconstruction

The timing and magnitude of surgical reconstruction is the subject of significant controversy. Some groups advocate delaying sex assignment to an age in which each patient can make his or her own decisions[110]; however, as mentioned earlier, most of these studies analyze the outcomes of older surgical procedures.[111,112] We believe that newer techniques result in an improved cosmetic appearance, achieve a reduced complication rate, and are more likely to preserve sensation; however, long-term studies are required to evaluate the outcomes of these procedures, which include ventral clitoroplasty and the total and partial urogenital sinus mobilization (TUM and PUM).

We discuss with the parents all available treatment alternatives and recommend that the different steps of the surgical reconstruction should be incorporated into a single surgical procedure and be performed at an early age in order to take advantage of all available tissues, with the objective of achieving the best possible functional and cosmetic results. This approach is in keeping with the recommendations of an international group charged with drafting a consensus statement on the management of children with disorders of sexual differentiation.[1] Patients with a low-confluence urogenital sinus can be operated once their metabolic management is well controlled; in most cases we undertake an elective reconstruction at 3 to 6 months of age. Patients with a midlevel or high confluence can be electively repaired at 9 to 12 months of age.

## Clitoroplasty, Vaginoplasty, Labioplasty, Incorporated into a Single Procedure

Planning of the surgical reconstruction should incorporate the three components of a feminizing genitoplasty, in which the prepuce is used to create labia minora, the clitoris is reduced with preservation of sensation, and the labioscrotal swellings are used to fashion female-appearing labia majora and to enhance the vaginoplasty.

To optimize surgical exposure and elevate the perineum, we place our patients in a hyperextended lithotomy position with the buttocks lying over and slightly beyond several folded towels. As previously described, all procedures must begin with a panendoscopy.

## Clitoroplasty

Surgical procedures to correct the enlarged clitoris have undergone significant advances. Surgeons now recognize that preservation of clitoral sensation is essential for future orgasms. Clitoral resection and recession are only of historical interest and are no longer recommended. In cases with severe masculinization, the clitoris is too large, resembling a penis; in such cases, we discuss the anatomic characteristics with the parents and recommend a clitoroplasty. The goal of current techniques is to preserve sensation (neurovascular integrity) for future orgasms, provide an acceptable cosmesis, and avoid painful erections. Kogan described a subtunical excision of the erectile tissue, which has been used extensively and led to newer nerve-sparing techniques.[113] Baskin and colleagues (1999) found that distribution of the sensory nerves of the clitoris is similar to the sensory nerves of the penis. These nerves are found on the top or dorsal aspect of the clitoris and course under the pubis; circumferential branches from the dorsal neurovascular bundle encircle the clitoral shaft toward the ventrum, thus making a ventral approach to the corpora most likely to avoid nerve injury (Fig. 123-9).[104–106] In Baskin's technique corporal tissue proximal to the bifurcation is left intact. Hypothetically this preserved erectile tissue may play an important role in sexual function. In most cases we try to avoid reduction of the glans clitoris, aiming to preserve sensation, but in patients with a large clitoris a wedge of glans tissue may be cautiously excised from its ventral aspect (Fig. 123-10, *A* and *B*).

It is our practice to incorporate the three components into a unified surgical strategy. A 5-0 Prolene holding suture is placed in the glans. Two vertical incisions are outlined with a marking pen on each side of the urethral plate, and the meatus is circumscribed as one does for hypospadias surgery, taking care of leaving a redundant segment of dorsal inner foreskin to allow the fashioning of a hooded prepuce to preserve an important source of sensation (Fig. 123-11).[114] Prior injection of incisions with 1% lidocaine/1:200,000 epinephrine prevents excess blood loss. The vaginoplasty is incorporated into the surgical reconstruction, outlining a wide-base, inverted "U"-shaped perineal incision based on the anus; the apex of this is placed at the estimated final location of the vagina, using the ischial tuberosities as a landmark (see Fig. 123-14). The clitoris is degloved down to the peno-scrotal junction; the ventral strip of the urethral plate should be initially kept intact. Following degloving of the dorsal skin, the distal portion of the UGS (urethral plate) is divided horizontally below the glans clitoris. The urethral plate (UGS) is mobilized off the ventral aspect of

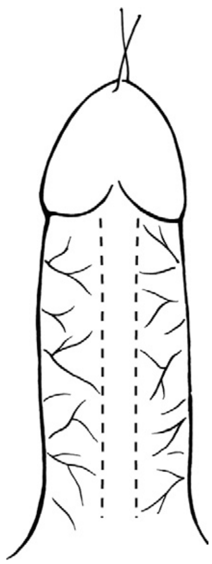

**FIGURE 123-9** Circumferential nerves branches coming from the dorsal neurovascular encircling the clitoral shaft toward the ventrum. Vertical incisions outlined on each side of the urethral plate for the excision of the erectile tissue.

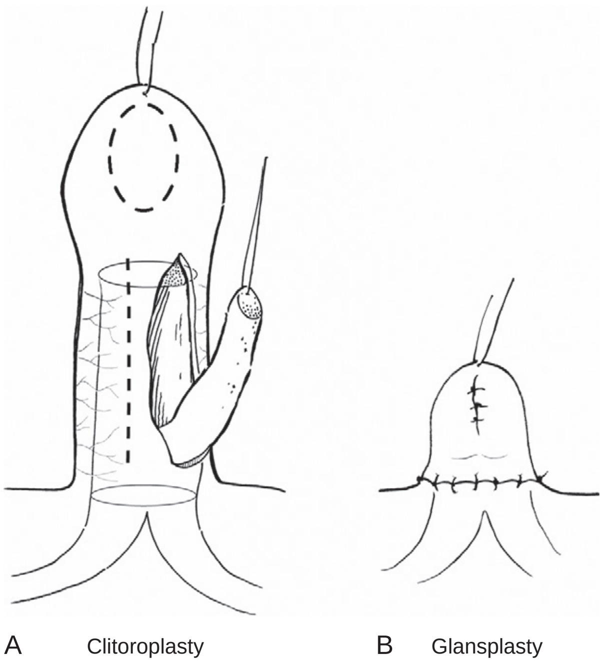

**FIGURE 123-10** **A,** Excision of erectile tissue. An elliptical incision is outlined on the ventral aspect of the glans for glansplasty. **B,** Completed clitoroplasty and glansplasty (body of the glans sutured to the corporal body stumps with absorbable sutures).

the clitoral shaft downward to below the bifurcation of the corporal bodies. Next, clitoral reduction is carried out; in our experience placement of a tourniquet is unnecessary because we have observed that bleeding from the erectile tissues is not significant, particularly in infants, although it can be considerable in the older child. Longitudinal ventral incisions are made; the erectile tissue is dissected within the bodies (see Fig. 123-10, *A* and *B*). The body of the glans is sutured to the corporal body stumps with absorbable sutures (Fig. 123-10, *B*). This step should, hypothetically, allow for painless engorgement of the proximally preserved corpora remnants with sexual activity. The redundant dorsal tunica albuginea and neurovascular bundle are placed in a subcutaneous pocket above the pubic bone, folded without impairing the neurovascular supply, and its lateral edges are sutured to the adjacent periosteum of the pubis. The reduced clitoral shaft is covered with surrounding fat tissue, thus fashioning a normal-looking mons pubis. In cases with a large glans clitoris, a wedge of glans tissue can be excised from the ventral aspect of the glans with careful reapproximation of the glans tissue with interrupted 6-0 polydioxanone sutures (PDS) (see Fig. 123-10, *A* and *B*). The dorsal mucosal collar should cover the glans partially, giving it a hooded appearance (see Fig. 123-11). The remainder of the dorsal prepuce is divided in the midline (Byars technique) and reattached to the mucosal collar as with hypospadias repair. The preputial skin wings are rotated inferiorly and incorporated lateral to the urethral plate to create labia minora (Fig. 123-12).

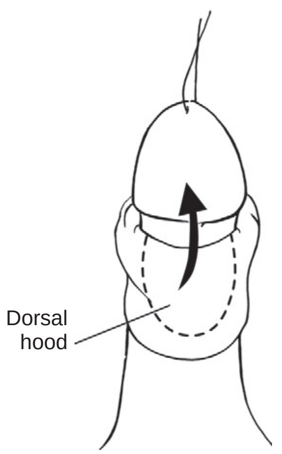

**FIGURE 123-11** Outlined incision to fashion a hooded clitoris from the dorsal foreskin.

## Labioplasty

Most girls with CAH have labioscrotal swellings that are more anterior than normal labia majora. Significant skin rugation may be present as well. To move this labioscrotal skin posteriorly, Y- shaped incisions are outlined with an extension posterior to the swellings. The scrotal flaps are cautiously defatted and moved posteriorly, beside the introitus, as bilateral Y-V advancements. The medial aspects of these skin flaps are then sutured to the lateral edges of the preputial skin flaps mobilized during clitoroplasty (now labia minora). The end result is an anatomically correct positioning of the labia minora and majora posteriorly, beside the introitus, rather than anterior-laterally (Fig. 123-13).

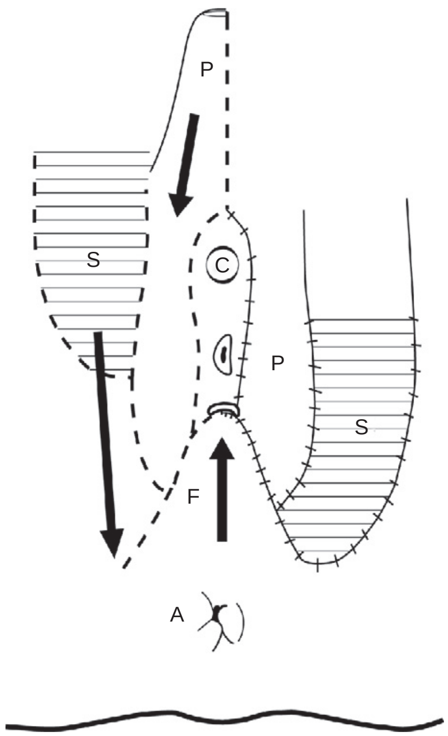

**FIGURE 123-12** Split prepuce used to create labia minora; labia majora Y-V-plasty; and flap vaginoplasty. *C,* Clitoris; *F,* flap; *P,* split prepuce; *S,* labioscrotal fold.

# Vaginoplasty

The type of vaginoplasty required depends on the anatomic location of the merging point of the vagina into the urethra as a UGS. There are six types of vaginoplasty: cut-back, flap, pull-through, TUM and PUM, and vaginal replacement.

## LOW-CONFLUENCE FLAP VAGINOPLASTY

Flap vaginoplasty is only indicated for cases with a very-low-confluence UGS because otherwise it does not bring the merging point of the vagina with the urethra any closer to the perineum. The technique is based on the description by Fortunoff and colleagues of an inverted perineal skin U-flap that could be advanced into the opened vagina.[115] The posterior flap based on the anus is outlined with a marking pen, and anteriorly it should reach the edge of the sinus. A thick, long, flap is mobilized and then the posterior wall of the vagina is dissected with care not to enter the rectum. Next, the posterior wall of the sinus is opened longitudinally into a normal-caliber vagina to avoid a vaginal stricture. The apex of the flap is inserted into the apex of the vagina wall and secured in place beginning with three interrupted, full-thickness sutures of 4-0 Vicryl, which should be tied simultaneously to prevent tearing the fragile vaginal wall; the rest of the sutures are placed in a sequential manner. In low-confluence vaginoplasty, there is no need to insert a finger in the rectum, but a roll of petroleum jelly (Vaseline) gauze can be inserted in the rectum to avoid rectal injury (Fig. 123-14, *A* to *C*). In a low vaginoplasty there is no need to do a complete mobilization of the UGS. Once it is dissected off the corpora, the dorsal wall is opened longitudinally down to the vaginal opening to create a more normal-looking introitus. Later during labioplasty, the medial edge of the prepuce (labia minora) will be sutured to the outer edge of the opened, nonmobilized urethral plate/UGS.

## VAGINOPLASTY USING UROGENITAL MOBILIZATION

Total urogenital sinus mobilization (TUM) was described in 1997 by Alberto Peña as a technique to repair the UGS component of cloacal malformations.[116] Currently, this procedure, or a modification thereof, is being used by most surgeons for UGS repair.[117] Circumferential, partial mobilization of the UGS allows the midlevel vaginal confluence to be brought down to the perineum without tension, avoiding the need for separation of the vagina from the urethra as in the classical pull-through vaginoplasty. The Fogarty balloon, placed in the vagina during the panendoscopy, allows the identification of the confluence. Urogenital sinus mobilization has the advantage of better visualization of the merging point, and it

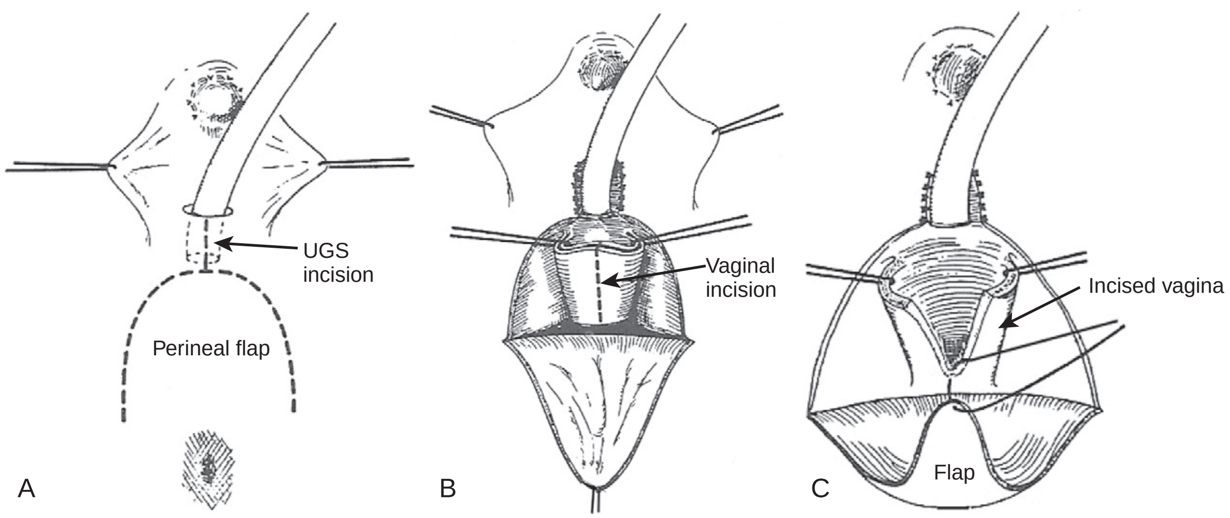

FIGURE 123-14 Flap vaginoplasty. **A,** Wide-based inverted perineal U-flap based on the anus. **B,** Dissected vagina with outlined back wall incision. **C,** Inverted U-flap sutured to back wall of the vagina.

obviates the need for vaginal separation, thus reducing the difficulty of the procedure. Also, in those cases where vaginal separation is required, it becomes less extensive. In this technique, because the confluence is brought closer to the perineum, the mobilization of skin flaps is minimized. The posterior dissection is similar to that done for a pull-through or flap procedure, with careful, midline mobilization of the UGS off the rectum. The anterior dissection in cases requiring a total urogenital sinus mobilization is done, staying close to the urogenital sinus under the pubis, and dividing the ligament from the pubis to the urogenital sinus, resulting in significant mobilization of the sinus, and in most cases the confluence can be brought more easily to the perineum (Fig. 123-15, *A*).

In response to concerns for possible complications of urinary incontinence, resulting from the circumferential dissection of the UGS beyond the pubourethral ligament, Rink and colleagues (2006) proposed the use of a PUM. In this technique the anterior dissection stops at the pubourethral ligament, aiming to avoid compromising the innervation to the bladder outlet (Fig. 123-15, *B*).[118] This procedure is adequate in most cases except for patients with a high confluence in whom additional mobilization beyond the pubourethral ligament may be necessary. Alternatively, if the perineum cannot be reached without tension the vagina must be sharply dissected from the back wall of the bladder before the anastomosis to the inverted perineal U-flap can be attempted. In these cases the use of a prone position can assist the dissection of the vagina off the bladder.

In both total and partial urogenital sinus mobilization, as previously described for low-confluence vaginoplasty, the distal segment of the vagina can be quite narrow; hence its posterior wall must be incised up to a normal-caliber vagina to avoid a vaginal stricture. The apex of the inverted perineal U-flap is inserted into the apex of the vagina wall and secured with interrupted full-thickness sutures of 4-0 Vicryl as previously described for a low vaginoplasty (see Fig. 123-14, *A* to *C*).

## SPLITTING THE UROGENITAL SINUS

As proposed by Rink, the urogenital sinus can be split to enhance the feminizing genitoplasty.[118] The common urogenital sinus can be used in the following manners: (1) In very-low-confluence cases we do not mobilize the urogenital sinus and incise it longitudinally on its ventral aspect up to the confluence point; the lateral aspects of the opened sinus are sutured to medial aspects of the prepuce wings, thus resulting in a more normal anatomic configuration; (2) ventrally to fashion a mucosa-lined vestibule, (3) dorsally to create a flap to enhance the anterior half of the vaginoplasty, and (4) laterally to create a flap that will be rotated to extend the vagina, thus completing the vaginoplasty (Fig. 123-16).

## PULL-THROUGH VAGINOPLASTY FOR MID- AND HIGH-LEVEL VAGINAL CONFLUENCE

Before the advent of the urogenital sinus mobilization procedures, the majority of girls were reconstructed using a pull-through vaginoplasty as described by Hendren and Crawford.[89] All patients undergo a total lower body preparation from nipples to toes, the legs are wrapped, and the lower body is

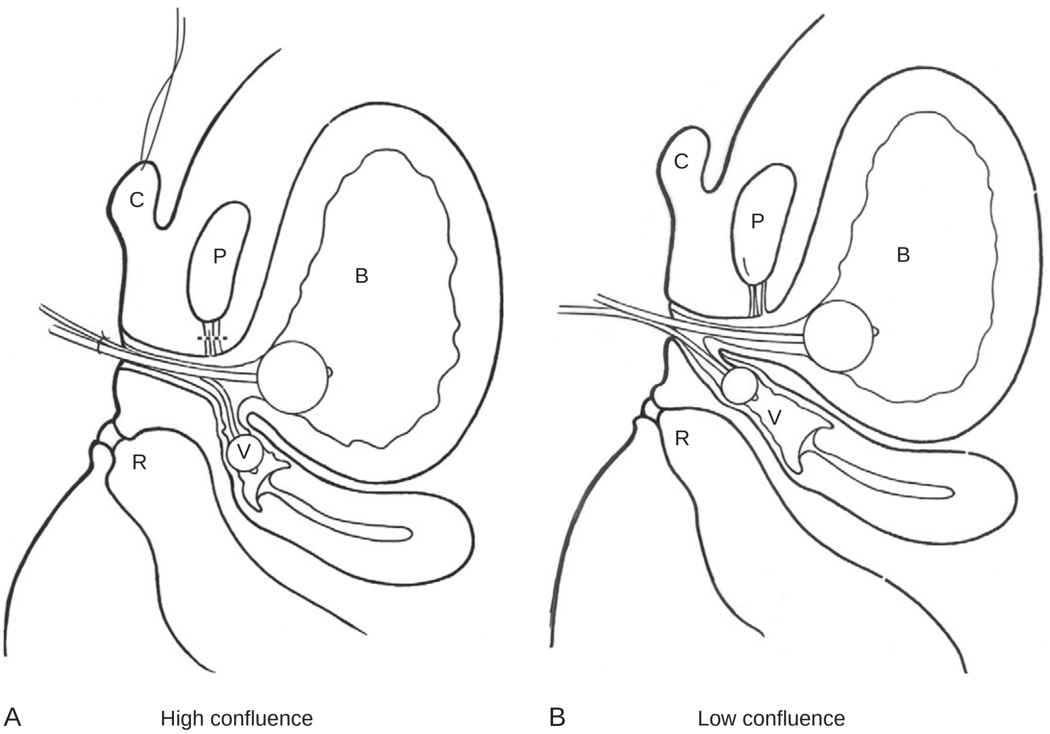

**FIGURE 123-15** **A,** Total urogenital sinus mobilization: mobilization of the urogenital sinus past the pubourethral ligament. *B,* Bladder; *C,* clitoris; *U,* uterus. **B,** Partial urogenital sinus mobilization: circumferential mobilization of the urogenital sinus stops at the pubourethral ligament. *B,* Bladder; *C,* clitoris, *U,* uterus.

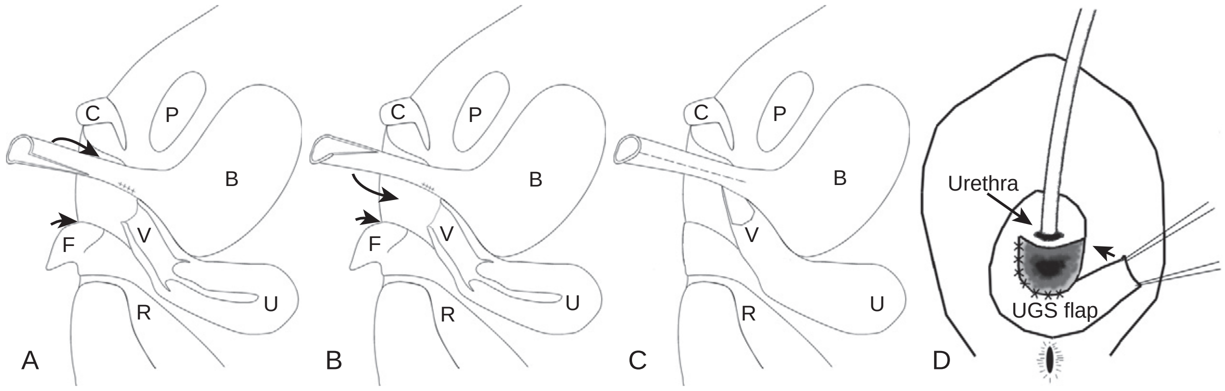

**FIGURE 123-16** Use of the redundant sinus. **A,** Split the sinus ventrally to fashion a mucosa-lined vestibule. **B,** Split the sinus dorsally to create a flap to enhance the anterior half of the vagina. **C** and **D,** Split the sinus laterally and rotate the flap to extend the vagina, thus completing the vaginoplasty.

passed through the aperture in drapes, which allows the patient to be rotated either supine or prone during the procedure. The initial aspects of the dissection are similar to the description previously mentioned for lower confluences. The operation begins with a panendoscopy, during which the confluence is localized, and a Fogarty catheter, connected to a stopcock valve, is maneuvered into the vagina, where the balloon is inflated and the valve closed. A Foley catheter is passed into the bladder; both catheters are secured together with a silk suture. An inverted perineal U-flap is made, the urogenital sinus is exposed, and the balloon of the Fogarty catheter is palpated. Intermittent insertion of a finger inside the rectum, to flatten out its anterior wall, reassures the surgeon that the rectum has not been injured. The vagina is mobilized circumferentially and meticulously separated off the bladder anteriorly.[119] The UGS is closed with interrupted stitches of 6-0 PDS. A labial flap or an anterior island flap, which for this procedure must be fashioned in the midline, can now easily reach the anterior vagina. In patients with a very high confluence we have found that rotating to the prone position improves visualization and exposure, allowing the vagina to be safely mobilized off the urogenital sinus and bladder.[120] The placement of a small malleable retractor into the vagina combined with slight upward traction assists the surgical dissection. The opening in the UGS is then closed with interrupted stitches of 6-0 PDS. The vagina is then mobilized circumferentially and brought to the perineum, where it is sutured to the perineal skin flap as described for vaginoplasty (Fig. 123-17).

## Postoperative Care of the Female Patient

At the end of each procedure a small Foley catheter is left indwelling for 3 to 4 days. The use of epidural anesthesia has improved pain management. Immobilization with a mermaid dressing in which the lower extremities are wrapped with stockinet prevents tension on the suture lines. A soft plastic foam or cotton is placed between the knees and ankles, and the anus is left exposed. The legs are loosely wrapped with an elastic bandage without covering the anus. The mermaid dressing is kept in place for 4 to 5 days. A broad-spectrum antibiotic is used during the first 2 postoperative days. Hormonal replacement appropriate to the patient's diagnosis is given.

## Reconstruction for Male Gender Assignment

The treatment strategy is similar for all patients assigned to the male gender. Most of these patients have a small penis with a penoscrotal, scrotal, or perineal hypospadias; a severe ventral curvature; and a partial or complete prepenile scrotum (Fig. 123-18). As expected, the dorsal foreskin is redundant and the glans is often split, lacking its normal conical configuration. Preoperative treatment with testosterone is helpful in those cases with a small penis.

Our preferred approach now is to perform a one-stage hypospadias repair in patients with an adequate urethral plate, using the extended applications of the tubularized incised plate urethroplasty described by Snodgrass.[121] In this technique the urethral plate is preserved; aggressive, meticulous degloving of the foreskin is undertaken beyond the hypospadiac meatus into the scrotum, thus achieving in many cases significant correction of the ventral curvature. Next, an artificial erection is induced and, if needed, additional ventral curvature correction is accomplished with a dorsal plication, placing one or two 5-0 Prolene stitches at the 12 o'clock position dorsally, at the point of maximum angulation. In some cases dissecting and elevating the urethral plate from the corpora cavernosa down to normal urethra can be done with excellent results. This maneuver can avoid the need to divide the urethral plate (Fig. 123-19). We perform the anastomosis in two layers, the first layer with interrupted subcuticular stitches of 7-0 PDS, followed by a second running layer of the same material. The suture line should be covered with a well-vascularized dartos flap harvested from the dorsal prepuce, or with a tunica vaginalis flap.

If the urethral plate cannot be preserved, a multistage repair is indicated. In some cases resection of the ventral tethering tissue and division of the urethral plate may not fully correct the ventral curvature; in these patients a dermal graft harvested from a non-hair-bearing donor is defatted and placed in normal saline solution. A transverse incision is made at the site of maximal concavity, and the inserted graft

is sutured to the edges of the defect while preserving the distal urethral plate. The second stage, composite repair, is performed 6 to 9 months later using an anterior, tubularized, incised plate urethroplasty combined with a posterior Thiersch-Duplay procedure. Also, the use of a buccal mucosa graft or an onlay island flap gives satisfactory results at this stage.

## Penoscrotal Transposition

Partial or complete penoscrotal transposition is often found in cases with penoscrotal and perineal hypospadias (see Fig. 123-18). The least severe forms are known as *bifid scrotum, pre-penile scrotum,* and *shawl scrotum.* The scrotoplasty should be delayed until after the hypospadias repair is

completed because the base of the flaps needed for the hypospadias repair must be divided and displaced during correction of the prepenile scrotum. Six months or more should elapse between the urethroplasty and correction of the prepenile deformity. A square flap that circumscribes the base of the penis is displaced in a caudal direction, where it serves to lengthen the scrotum and further correct the bifid scrotal defect. The base of the penis is then advanced and held in place in a cephalad direction while the abdominal flaps are rotated in a posterior direction to the ventral base of the penis. During the forward, upward displacement of the penis, this is done to give it a more erect appearance. Rotation of the abdominal flaps, posterior and caudally, is extremely important. Otherwise, the base of the shaft skin will simply pull away from the apical position on the mons, creating an unacceptable tented appearance. The rotated abdominal flap must be of sufficient length to create half a diameter around the base of the penis to meet the flap from the other side without tension. Midline and lateral closure of the now-lengthened scrotum completes the repair and corrects the bifid scrotum. It is important that these patients stay on bed rest with urine diversion until the ventral base of the penis has effectively healed (Fig. 123-20, *A* to *F*).

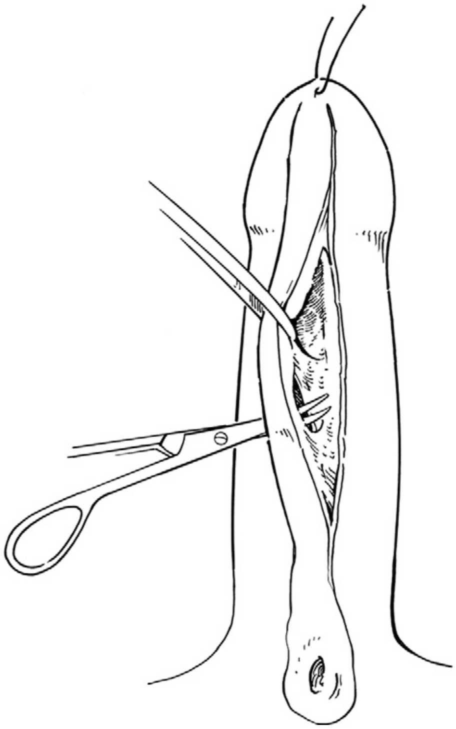

**FIGURE 123-19** Elevating the preserved urethral plate from the corpora cavernosa down to normal urethra for additional chordee correction.

## Müllerian Duct Remnants

In patients with severe hypospadias, ovotesticular disease, or MGD who have been assigned the male gender, the retained müllerian ducts can become quite enlarged, leading to recurrent urinary tract infections, epididymo-orchitis, urinary retention, secondary incontinence due to urine trapping, and infertility (Fig. 123-21). Also, malignant transformation has been reported. In such cases the müllerian duct remnant should be removed.

Surgical treatment of müllerian duct remnants is challenging because of their close proximity to the ejaculatory ducts, pelvic nerves, rectum, vas deferens, and ureters. A number of surgical approaches have been described including transperitoneal, posterior with rectal retraction, anterior and posterior saggital transrectal, transtrigonal, perineal, transurethral fulguration, laparoscopic, and robotic. We have successfully used the transtrigonal technique; however, the laparoscopic- or robotic-assisted procedures are less invasive and minimize possible damage to adjacent anatomic structures. The case shown in Figure 123-21 was successfully treated by a robotic-assisted laparoscopy.

One of the authors (Dr. Patricia Donahoe) has preserved the vas deferens as it courses within the outer wall of the dilated vagina.[122] Its position must be estimated until it exits at the site of the verumontanum. Lateral incisions are made on both sides of the predicted course of the vas deferens. The remainders of the müllerian structures are removed including the sometimes markedly dilated vagina. The strip of vaginal wall containing the vas deferens is tubularized with its mucosa internalized from the urogenital sinus to the point of entry of the vas deferens. Running absorbable suture can be used; one layer usually suffices (Fig. 123-22, *A* to *C*).

## Penile Agenesis

Penile agenesis is a rare condition occurring in 1 in 30 million births (Fig. 123-23).[123,124] It seems to be the result of a development failure of the genital tubercle during the fourth week of embryogenesis; the scrotum appears normal and contains normal testicles.[125] Patients can present with an imperforate anus and a recto-urethral fistula (Fig. 123-24), a recto-urethral fistula with a normal anus, or with the urethra located in the perineum inside a skin tag, resembling a foreskin.[123] Patients are otherwise normal 46,XY males.

Parents of affected children face a stressful decision, and for the surgeons penile agenesis is one of the most challenging conditions. In the past gender reassignment was the most frequent choice for these patients. Initial surgical treatment of female-assigned patients requires bilateral orchiectomy. Cases with an associated imperforate anus and recto-urethral fistula require an urgent colostomy and a vesicostomy. Those babies assigned to the female sex require the creation of a neovagina, which is most frequently performed with a sleeve of sigmoid colon. However, patients have been unhappy with the assigned female sex and prefer to be males.[126]

The diagnostic evaluation of patients with penile agenesis includes a renal ultrasound, pelvic MRI, retrograde urethrogram, and in cases associated with an imperforate anus a distal colonogram through the mucous fistula, using hydro-soluble contrast material combined with an antegrade VCUG via the cutaneous vesicostomy (see Fig. 123-24). Newborns with penile agenesis must be evaluated by a multidisciplinary team composed of surgeons, radiologists, geneticists, psychologists, endocrinologists, and pediatricians. Families must be given all available information regarding sex assignment, surgical procedures, and immediate and long-term results so that they can make a decision in the best interest of their child.

In adolescents and adults the most frequently used phalloplasty procedure is the microvascular transfer radial forearm flap, which is a complex and rare operation performed only in highly specialized centers. The recent description by De Castro of a phalloplasty technique and complete urethroplasty using a quadrangle lower abdominal flap can bridge the interval between childhood and adolescence until a more definitive procedure can be undertaken. In this procedure a quadrangle of lower abdominal flap is created, 4 × 5 cm for babies, and slightly larger in an older child to fashion the new penis (Fig. 123-25, *A* to *C*). De Castro recommends the use of oral or bladder mucosa for the urethroplasty,[127] although the single-stage buccal mucosa urethroplasty has had a high complication rate.

We favor staging the surgical reconstruction. As mentioned earlier, cases with an imperforate anus and a rectourethral fistula require an urgent colostomy with a mucous fistula and a vesicostomy, followed a few months later by a posterior saggital rectourethral pull-through, with subsequent closure of both the vesicostomy and colostomy. Patients born with a normal anus and a rectourethral fistula can be operated through a transperineal approach. We have used the quadrangle lower abdominal flap to fashion the neopenis in three patients, but we prefer a two-stage buccal mucosa urethroplasty to avoid or minimize complications.

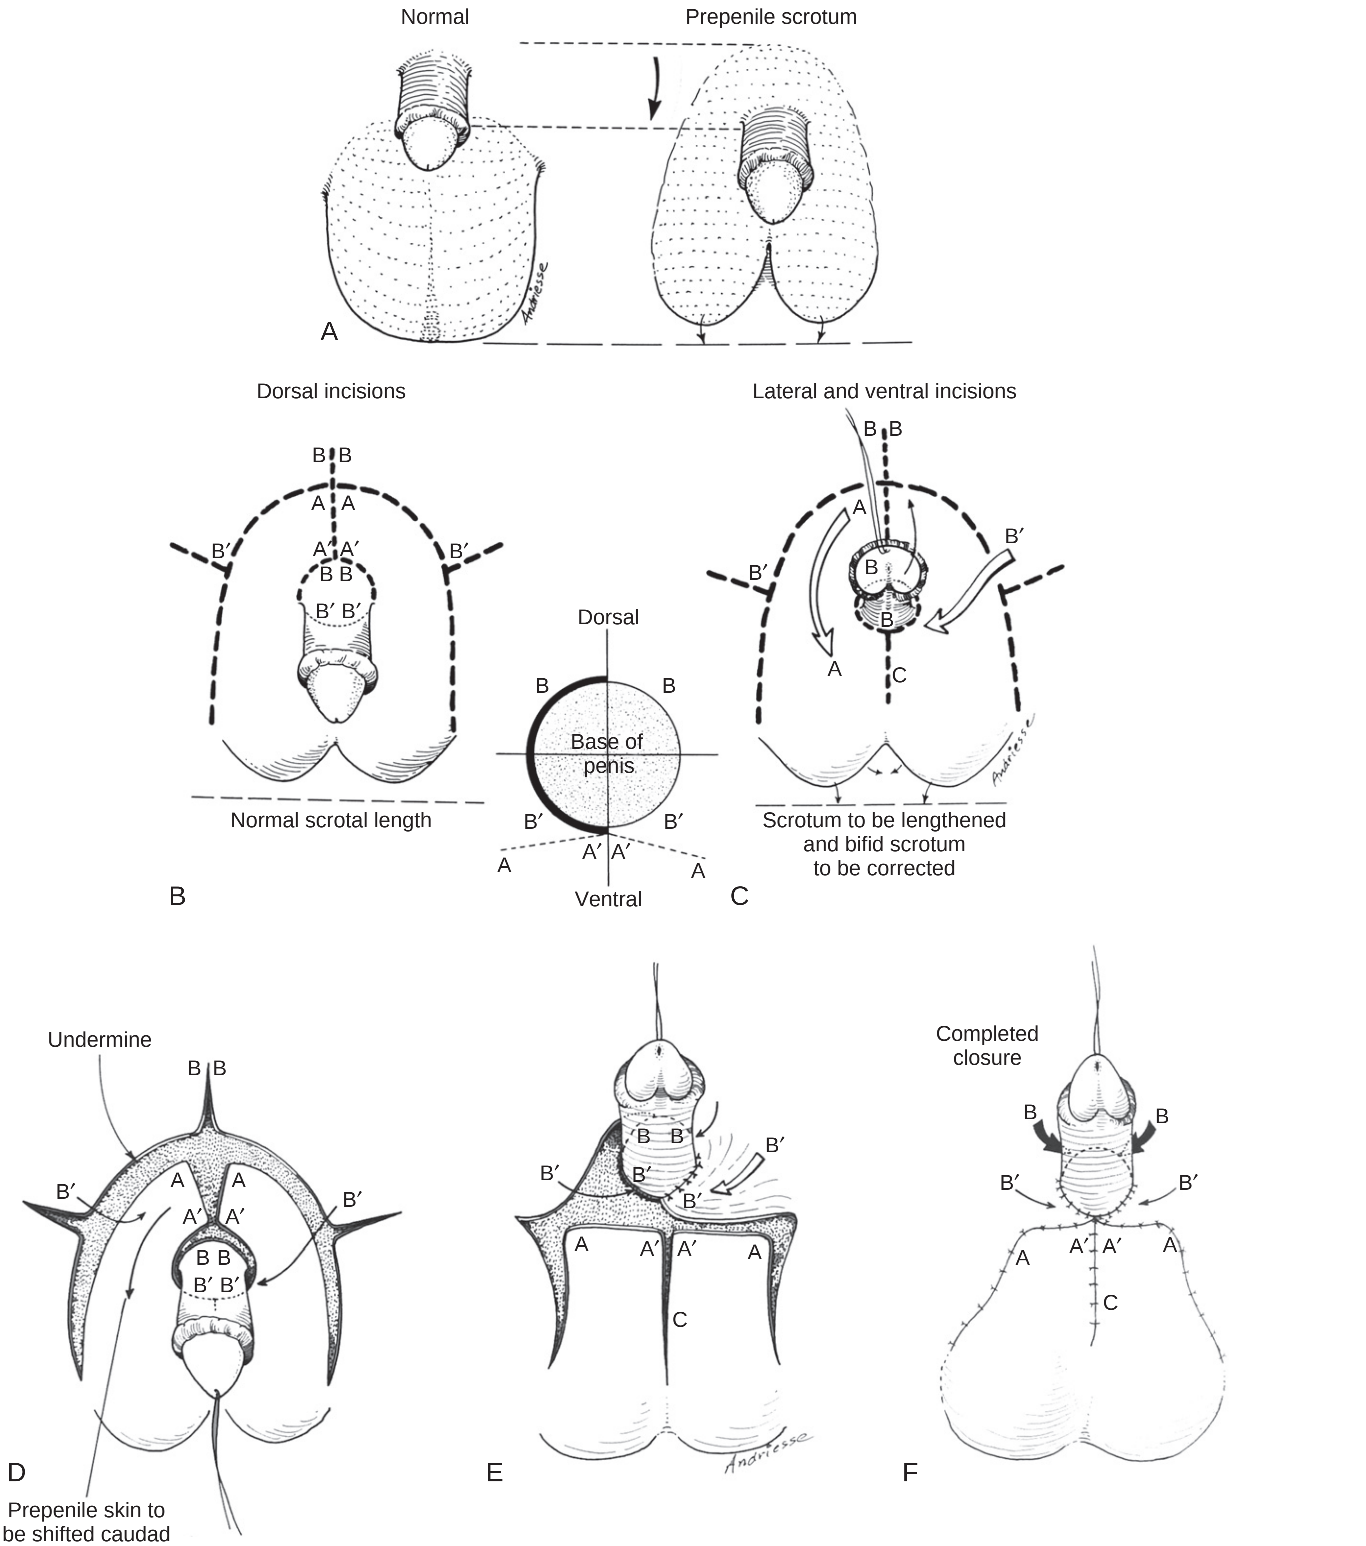

**FIGURE 123-20** Surgical correction of prepenile and bifid scrotum. **A,** Correction is reserved for phenotypic patients in whom abundant scrotal tissue lies in an anterior direction to the dorsal base of the penis in association with a bifid scrotum. **B** and **C,** Posterior transposition of the scrotum and anterior transposition of the penis are accomplished through a series of dorsal, lateral, and ventral incisions and the movement of anterior tissue. **D,** Generous abdominal skin flaps are raised with broad bases to retain blood supply. **E,** The anterior abdominal wall flaps are mobilized sufficiently to advance to the ventral base of the penis with no tension. This is necessary to prevent unsatisfactory tenting of the anterior or dorsal base of the penis. **F,** The remaining incisions are closed using fine absorbable suture. The transposed scrotalized skin, now in a caudal position, lengthens the scrotum and corrects the bifid appearance.

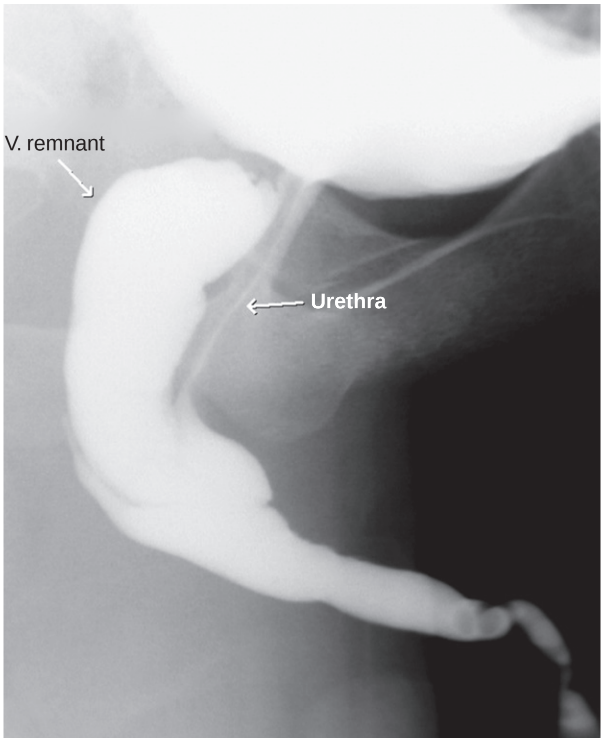

**FIGURE 123-21** Retrograde urethrogram showing an enlarged vaginal remnant in a patient with mixed gonadal dysgenesis reared as a male.

## Vaginal Agenesis

Vaginal agenesis, known as the *Mayer-Rokitansky-Kuster-Hauser syndrome,* is a rare abnormality affecting approximately 1 in 5000 to 10,000 females. In this condition there is absence of the proximal portion of the vagina, resulting from failure of the sinovaginal bulbs to develop and form the vaginal plate.

Two different types of Mayer-Rokitansky-Kuster-Hauser syndrome have been described; in the typical variety (type A) patients have symmetric uterine remnants and normal Fallopian tubes. Cases with the atypical form (type B) present with asymmetric uterine buds or abnormally developed fallopian tubes. The surgeon must be aware of the differences between the two types because the majority of associated findings in other organs or systems occur in type B patients.[128,129]

Skeletal anomalies are present in up to 12% of females affected with this condition, most commonly in type B cases including patients with congenital fusion of the cervical vertebra known as the *Klippel-Feil syndrome*.[130] Duncan proposed the term *MURCS association* to describe the combination of müllerian duct aplasia, renal aplasia, and cervicothoracic somite dysplasia.[131]

Renal anomalies present most frequently in patients with the type B variety[129]; these anomalies consist of either unilateral renal agenesis, horseshoe kidney, or ectopia of one or both kidneys, which occurs in 74% of affected patients.[132]

This condition can be discovered at birth when the examination does not reveal a vaginal opening, but most cases present with primary amenorrhea. A few patients complain of dyspareunia or failed intercourse. Physical examination reveals an absent vagina, but the hymen and a distal vaginal dimple or even an introitus are present because these structures are derived from the urogenital sinus. The diagnosis can be confirmed by pelvic ultrasound and MRI.

## Surgical Treatment of Vaginal Agenesis

Vaginal dilatation is a valid alternative in patients with a vaginal dimple or introitus. A program of daily, graduated dilatations over several months, using Hegar or similar sounds, can result in a good-sized vagina to allow intercourse. Once a satisfactory vaginal size is obtained, regular sexual intercourse maintains an adequate vaginal cavity.

Different techniques for vaginal construction in patients with vaginal agenesis have been used including the construction of a skin neovagina and the creation of an intestinal neovagina using sigmoid, cecum, and small intestine. Our preferred technique for vaginal replacement is the use of a 10-cm segment of distal sigmoid colon based on the left colic or superior hemorrhoidal vessels (Fig. 123-26, *A* and *B*). Mechanical and antibiotic bowel preparation must be done before the procedure. A lower transverse abdominal incision gives adequate exposure. A supine position with legs spread and the knees slightly bent, using Allen stirrups, is recommended.

The sleeve of sigmoid is selected between noncrushing clamps; a short distal sigmoid segment can be discarded to increase the length on the mesenteric vasculature for the neovagina. The sigmoid sleeve can be rotated 180 degrees to allow placement in the perineum. The proximal end is closed with two layers of absorbable suture material. Either a cruciate or H-shaped large perineal opening is made; the rectovesical space is dissected to create a large tunnel that will allow the easy introduction of two fingers in the perineum (Fig. 123-27). The sigmoid segment is pulled through the perineal channel and anastomosed directly to the perineum with absorbable sutures. Two-point fixation between the proximal end of the neovagina and the presacral fascia prevents prolapse of the bowel. We do not elevate the proximal vaginal dimple into the cul-de-sac to perform the anastomosis because in our experience, it results in a higher frequency of strictures. Alternatively, a laparoscopic-assisted procedure can be done with a satisfactory outcome.

The creation of a sigmoid neovagina has several advantages such as natural lubrication without excessive mucous production; long-term use of a stent is avoided, stenosis is infrequent, and most patients have normal sexual intercourse.

## Summary

The medical and surgical management of DSD should be undertaken by a multidisciplinary specialized team. The treatment plan must be thoroughly discussed with parents, with the goal of giving the child, thereafter, the most satisfactory quality of life possible. However, long-term studies are necessary to assess the functional and sensory outcomes of newer surgical techniques.

We recommend that surgeons taking care of these complex cases be familiar with all the available techniques so that satisfactory repairs can be performed either to support the male of female gender.

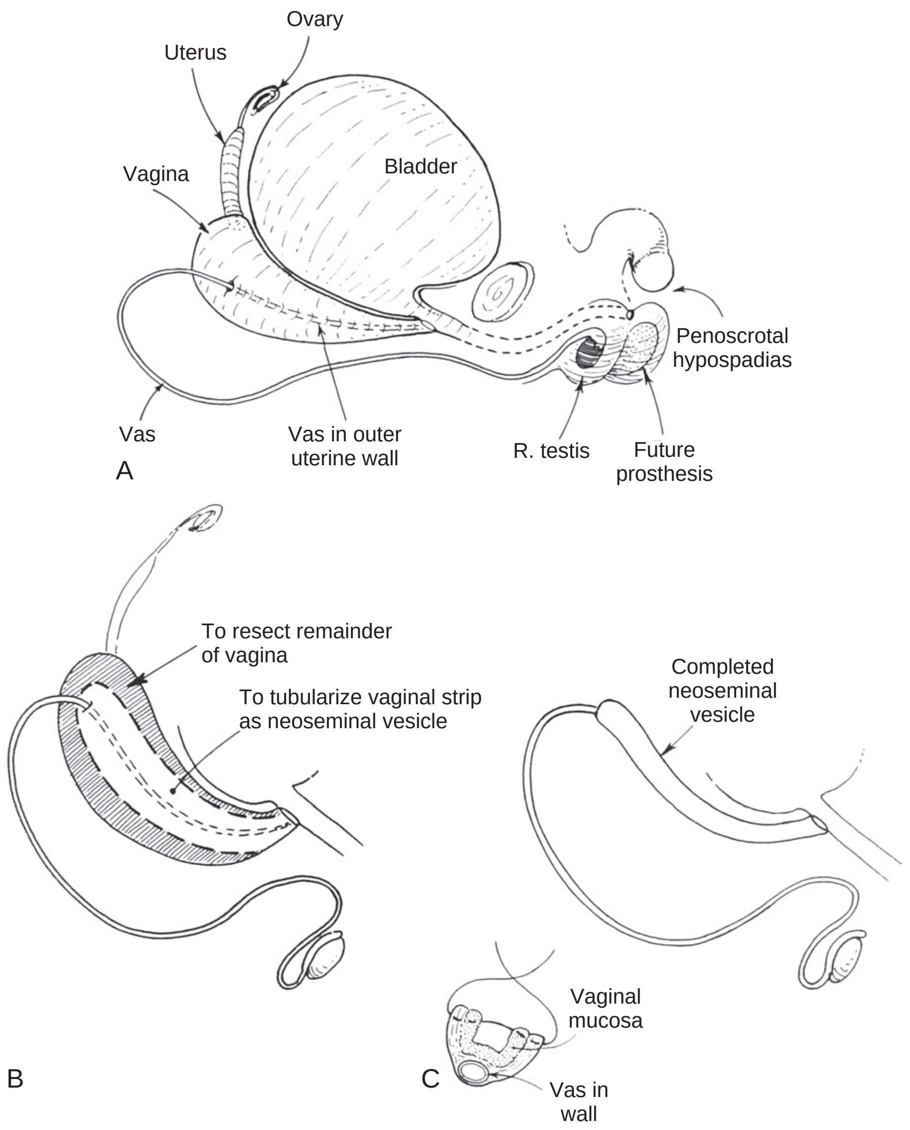

**FIGURE 123-22** Surgical management of retained müllerian ducts. **A,** In males with retained müllerian structures, every attempt is made to preserve the vas deferens, which often enters the side wall of the enlarged vagina and travels between the mucosa and muscularis or in the muscularis, as shown. **B,** A strip of vaginal wall containing the vas is preserved and tubularized, and the remaining vagina and uterus are removed. **C,** The remaining strip of vagina is closed from the entrance of the vas into the wall of the vagina to the narrowed neck, where the vas deferens joins the urethra.

CHAPTER 124

# Abnormalities of the Female Genital Tract

Marc R. Laufer

Abnormalities of the reproductive tract can present and be identified at birth through adulthood. Most genital anomalies in female infants present at birth and are congenital. In some instances, the abnormalities are discovered during evaluation of coexisting urologic problems or as the result of an association with a specific pattern of anomalies. Advances in perinatology, obstetrics, neonatology, and pediatric radiology have improved the recognition and subsequent care of female infants, children, and adolescents with genital tract anomalies. Many of these conditions are now being diagnosed during fetal life by prenatal maternal ultrasonography. A large number of these patients may also present at puberty with primary amenorrhea, pelvic/abdominal pain, and difficulty using a tampon or having sex.

In addition, females present with reproductive tract acquired conditions such as those related to infection, foreign bodies, trauma, and neoplasia. A thorough appreciation of normal anatomy and an understanding of the embryologic development of the female urogenital tract are necessary to understand the multiplicity of congenital anomalies and acquired conditions that may occur.

## Embryology

The female reproductive system is derived primarily from the müllerian or paramesonephric ducts. The ureteral bud arises from the mesonephric (wolffian) duct during the third week of gestation, interacting with the metanephric blastema to ultimately form the kidney and ureter. In the absence of a fetal testis, there is no production of androgen or müllerian-inhibiting substance (MIS), and consequently the wolffian duct distal to the ureteral bud is absorbed into the urogenital sinus. During the sixth week the paired paramesonephric (müllerian) ducts appear alongside the wolffian ducts with which they are intimately related. Between the sixth and eighth weeks of gestation, the paired müllerian ducts develop lateral to the wolffian ducts and then cross over the mesonephric ducts medially to fuse in the midline. Fusion occurs in a caudal to cranial direction, forming a single lumen. These fused müllerian ducts then join the urogenital sinus at the müllerian tubercle. By the 10th week of gestation, the ducts form a single midline tubular structure called the *uterovaginal canal.* The lateral aspect of the müllerian ducts, which remain separate (unfused), ultimately become the fallopian tubes. The caudal fused portion thickens and forms the uterus (fundus and body) and cervix.

The exact embryologic origin of the vagina is somewhat uncertain. Koff[1] suggested that the upper two thirds to four fifths of the vagina are probably formed from the fused müllerian duct, whereas the lower one third to one fifth is formed from the urogenital sinus. Although evidence supports the dual origin of the vagina, the exact contribution from each source is still unknown. By the ninth week of gestation, the fused müllerian ducts push the urogenital sinus caudad, creating the Müller tubercle. Vaginal development begins at the müllerian tubercle, where the uterovaginal canal joins the urogenital sinus. The tubercle thickens and elongates during the third to fifth months of gestation, forming bilateral endodermal invaginations called the *sinovaginal bulbs.* The bulbs grow, the müllerian tubercle regresses, and the distance between the uterovaginal lumen and the urogenital sinus increases. The sinovaginal bulb completes its growth by the 15th to 26th weeks of gestation, giving rise to a solid cord of tissue called the *primitive vaginal plate.* Canalization of this cord of cells begins at the urogenital sinus and progresses in a cephalad direction to form the distal third of the vagina. By the fifth month of gestation, continuity between the proximal and distal vaginal lumens is complete. Defects can occur during development, fusion, and canalization.

Failure of development may result in agenesis, failure of fusion leads to a variety of anomalies including duplication, and failure of the canalization phase results in formation of vaginal septa.[2] The close association and interaction between the müllerian and wolffian duct structures during embryogenesis may lead to associated anomalies between the genital and urinary systems.

Differentiation of the female external genitalia occurs between 12 and 16 weeks of gestation. In the absence of fetal androgen (particularly, dihydrotestosterone, and androgen receptor), the genital anlage develops passively into the external genitalia of the female. The genital tubercle elongates slightly and becomes the clitoris. The urethral folds form the labia minora and do not fuse; the unfused genital swellings form the labia majora. The urogenital groove remains open and forms the vestibule of the vagina.

# Vaginal Agenesis

Complete absence or agenesis of the vagina occurs with differing clinical situations. There can be pure müllerian agenesis with normal chromosomal and gonadal development with normal female hormonal production and variable uterine structures. There can also be androgen insensitivity with a defect in the androgen receptor in 46,XY individuals who develop female external genitalia, and because they make müllerian inhibiting substance, they have no uterus, cervix, or upper two thirds of the vagina.

Müllerian agenesis (also known as *Mayer-Rokitansky-Küster-Hauser [MRKH] syndrome*) probably results from a failure of the müllerian ducts to reach the urogenital sinus due to a disorder involving the ureterovaginal canal or the vaginal plate. The condition appears to be a sporadic polygenic multifactorial disorder occurring between the 4th and 12th weeks of gestation.[3] No specific genetic abnormality has been identified. Mayer[4] first reported vaginal agenesis in stillborn infants with multiple birth defects in 1829. Rokitansky[5] (in 1838) and Küster[6,7] (in 1910) further described this clinical entity and recognized the presence of a rudimentary uterus with normal ovaries and normal external genitalia (Fig. 124-1). Subsequently, in 1961 Hauser and colleagues[8] described the frequent association of renal and skeletal anomalies. Thus the combination of names as MRKH syndrome is used to describe this disorder. The incidence of vaginal agenesis varies from 1 in 4000 to 1 in 5000 live female births.[9–11] By definition, patients are 46,XX females with normal secondary sex characteristics that commonly present with amenorrhea.[11] Uterine development in these patients may vary from normal to the more characteristic rudimentary uteri with or without a lumen/endometrial cavity. Because of the lack of a vagina, they do not have menstrual bleeding but may present with cyclic cramping abdominal pain because of rudimentary functioning endometrium and retrograde menses. In addition, there can be a normal midline uterus with cervical and vaginal agenesis. The vagina is completely absent in 75% of cases, whereas 25% have a short vaginal pouch (often < 2.5 cm).

**FIGURE 124-1** External genitalia of vaginal agenesis. The normal appearance indicates how readily this diagnosis can be overlooked. (From Laufer MR. Structural abnormalities of the female reproductive tract. In Emans SJ, Laufer MR [eds]: Emans, Laufer, Goldstein's Pediatric and Adolescent Gynecology, 6th ed. Philadelphia, Lippincott Williams & Wilkins, 2011.)

Most patients have distal fallopian tubes[12] and ovaries. However, unilateral[13] and bilateral gonadal agenesis[14] have occasionally been observed in MRKH syndrome.

The association between congenital absence of the vagina and anomalies of the urinary tract is common, with approximately one third of these patients having renal abnormalities.[15,16] The most common abnormality is agenesis of one kidney or ectopia of one or both kidneys. Fusion anomalies such as horseshoe kidney and crossed renal ectopia are also commonly observed.[17]

Griffin and colleagues[16] reported skeletal anomalies in approximately 12% of MRKH patients. Two thirds of the patients with skeletal anomalies have spine, limb, or rib anomalies. Six percent of the skeletal malformations were of the Klippel-Feil type, which reflects an aberration in cervical thoracic somite development.[18] In 1979 Duncan and colleagues[19] reported on the frequency of these associated events and suggested that this combination of malformations be called the *MURCS association*. This is an acronym for müllerian duct aplasia, renal aplasia, and cervicothoracic somite association. MRKH syndrome may also occur in association with the TAR syndrome (thrombocytopenia-absent radius)[20,21] and rarely with anorectal malformations.[22] Radiographic abnormalities of the hand and hearing loss also have been observed.[23,24]

The McKusick-Kaufman syndrome (MKS) was described in 1964 in an Amish population and includes hydrometrocolpos due to vaginal atresia or aplasia, postaxial poly-dactyly, and congenital heart disease.[25–27] This is inherited in an autosomal recessive pattern, and a mutation in the *MKKS* gene has been identified in these cases.[28,29] Patients with MKS may have an overlap with the Bardet-Biedl syndrome (BBS).[27] Children with BBS have genital abnormalities and polydactyly in addition to retinitis pigmentosa, learning disabilities, central obesity, and cardiac abnormalities. Mutations in the *MKKS* gene occur in 10% to 15% of BBS patients. BBS can also be caused by the *BBS6* gene on chromosome 20p12, demonstrating heterogeneity.

Although some specific syndromes with known genetic inheritance have MRKH, the genetics/inheritance is not understood. Monochorionic monoamniotic twins have been reported to be discordant for MRKH.[30] In addition, assistant reproductive technologies have been successful in offering fertility options to MRKH patients with the assistance of a gestational carrier and the offspring have not been found to have MRKH.[31]

## DIAGNOSIS

Diagnosis of vaginal agenesis is most frequently made at the time of an evaluation of primary amenorrhea. Approximately 15% of girls presenting with primary amenorrhea will have MRKH syndrome. The diagnosis should be suspected when commonly associated defects (e.g., skeletal, renal, inguinal hernias) are identified in a young woman with amenorrhea.

A diagnosis of vaginal agenesis is emotional for the patient and the family. It is important to have educational information available.[32] Support for patients and their family can be provided from www.mrkh.org and www.youngwomenshealth.org. We have also found it greatly beneficial to have Social Work Service support for patients and families.

It is important to differentiate MRKH and androgen insensitivity syndrome (AIS), both of which present with primary

amenorrhea and absence of a functional vagina. With AIS there is absent or scant pubic hair, and in the postpubertal time period a normal "male range" serum testosterone is present. In the prepubertal time period, before elevation of testosterone, a chromosomal analysis is necessary to confirm the diagnosis. The presence of a Y chromosome increases the risk of dysgerminoma in the gonadal tissue, and thus removal of gonadal tissue is indicated. Women with AIS have a lack of müllerian structures (uterus, cervix, and upper vagina), due to the presence of müllerian inhibiting substance (MIS). Women with AIS tend to have the presence of the lower vagina, with 1 to 3 cm of a lower vagina. In contrast, women with MRKH have absence of müllerian structures with normal functioning ovaries and hormones. In addition, as noted earlier, these women have the ability to use their oocytes for assisted reproductive technologies (ART) and pregnancy with the use of a gestational carrier.

In recent years, instances of hydrocolpos have been noted on prenatal ultrasound studies. Prenatal magnetic resonance imaging (MRI) may also document such cases. Occasionally, the disorder can be diagnosed in the neonatal period in infants with an associated abdominal mass. In infants and older patients, a complete physical examination including vaginoscopy and cystoscopy, pelvic ultrasonography, computed tomography (CT), MRI,[33] and laparoscopy are the best means of making an accurate diagnosis and identifying associated urinary tract abnormalities. Ultrasound, MRI, and endoscopy avoid unnecessary exposure to radiation.

It is extremely important to adequately define the anatomy. From a gynecologic standpoint, this is best accomplished in the postpubertal period. For example, it is possible that a uterus, cervix, and upper vagina are present (agenesis of the lower vagina), and this is addressed differently than the presence of a midline uterus with cervical and vaginal agenesis. In the prepubertal time period, when the uterus, cervix, and upper vagina are not estrogenized and fully developed, the small structures may be unappreciated and thus an incorrect surgical procedure/management may be undertaken. Thus if there is no surgically pressing issue for a prepubertal intervention, then evaluation and treatment is best delayed until after puberty.

## TREATMENT

Treatment of vaginal agenesis depends on the anatomy of the individual patient. Functional, reproductive, and psychologic issues must be carefully evaluated and addressed, taking into account both the physical and intellectual maturity of the patient.[34–36] The goal of therapy is to provide adequate sexual function and deal with the psychologic impact that the patient has no uterus or vagina. Fertility is possible and is an option that should be offered to these patients because both ovaries are usually normal and successful in vitro fertilization with surrogate pregnancy has been achieved.[31,37] Psychologic studies have shown that infertility rather than expected difficulty with intercourse was the most problematic issue for MRKH syndrome patients to deal with.[38,39] Proper counseling of the patient and family members is essential. Patients and families need to be educated in all options for creation of a functional vagina, not just the technique preferred by or most familiar to the treating clinician.

The timing of creation of a functional vagina is important. In cases of MRKH and AIS it is best to wait for intervention until the patient is postpubertal and the young woman is interested in creating a functional vagina. It can be challenging to definitively identify the anatomy in an unestrogenized, prepubertal state. The surgeon may believe that the prepubescent patient has MRKH and create a vagina surgically only to find out later that there is a uterus, cervix, and upper vagina present and that the patient could have had a pull-through vaginoplasty with her native vagina and never needed a bowel vaginoplasty (see "Agenesis of the Lower Vagina" later). It is of utmost importance that the affected young woman decides which treatment plan to pursue and when to move ahead with it.

If uterine tissue is present, it is important to determine the size and location of the tissue and the presence or absence of a cervix. This can best be accomplished with MRI or three-dimensional ultrasound. If a cervix is absent, with the presence of a midline uterus, then we do not recommend attempts to connect the obstructed uterus to a created vagina due to the risk of ascending infection, sepsis, and death.[40] A patient with a midline uterus without a cervix should be maintained on hormonal therapy for menstrual suppression to decrease pelvic pain and endometriosis and maintain the options for the use of GIFT or ZIFT for conception, pregnancy, and a cesarean delivery.

In the majority of cases of müllerian agenesis, there is no uterus or cervix present and creation of a functional vagina should be undertaken when the young woman desires creation of a functional vagina.

The goal for creation of a functional vagina is pleasurable sexual intercourse with acceptable cosmesis of the external genitalia with minimal short- and long-term morbidity.

Over the years a variety of techniques have been used to develop a functional vagina. A native vagina is lined with stratified nonkeratinized squamous epithelium, is inclined posterosuperiorly, and has an average length of 9 cm on the posterior wall and 7.5 cm on the anterior wall. Ideally, the neovagina should be located appropriately (posterosuperiorly), be of adequate dimensions, be lined by elastile tissue (either mucosa or skin), be neither constantly moist nor malodorous, be hairless, and be sensate at least at the introitus.[41] The method of vaginoplasty used should be a simple, one-staged, easily reproducible procedure, with low morbidity and good outcomes (i.e., achieving painless sexual satisfaction). The ideal procedure has been elusive, and there are differences of opinion among various specialists concerning the most appropriate technique for neovaginal construction in patients with MRKH.[2,10,34,42–44]

### Nonoperative Management

A policy statement from the American College of Obstetrics and Gynecology in both 2002 and 2006 suggested that nonoperative management using vaginal dilators is the first line of treatment.[42,45] In 1938 Frank described the use of daily dilatation of the vaginal dimple for 20 minutes using Pyrex tubes in six patients with MRKH syndrome.[46] In 1983 Rock and colleagues reported that only 43% of patients were successfully managed by dilatation with identification of lack of patient compliance affecting the results.[47] Our team in Boston has shown 88% successful creation of a functional vagina. The length of time to success was found to depend on the number

of times per day that the dilator was used, with those using dilators at least once daily for 20 minutes being able to create a vagina in 4.3 ± 2.4 months.[48] We have found success with the use of hard dilators regardless of the depth of the native lower vagina. Because the native vaginal mucosa is stretched, there is normal lubrication and texture to the created vagina.

The dilation technique is best managed by a team of nurse and physician. Educational materials are the key to success. The young woman is instructed on the use of the hard dilator with constant pressure to the appropriate area twice daily. The angle of insertion of the dilator is a key to success (Fig. 124-2). Patients are asked to return monthly for examination to assure that the vagina is being created in the appropriate location and at the appropriate angle. The next size dilator is dispensed when appropriate. If the patient elects to cease or hold off on the process, she can resume when ready.

The vast advantages of this technique support the rationale for being the first-line therapy for vaginal agenesis in cases of MRKH and AIS. The advantages include the fact that this technique is under the control of the young woman, so if she elects to proceed at a faster or slower rate depending on circumstances in her life, she can easily adapt. In addition, it does not require anesthesia or a surgical procedure. Creation of a vagina with the use of dilators is also more cost effective than other treatment options.[49] Critics have concerns regarding adequate length of the vagina, poor lubrication, and dyspareunia during intercourse.

### Operative Management

A number of operative procedures have been advocated for creation of the neovagina including insertion of a skin-covered vaginal mold (Abbe-McIndoe procedure),[50,51] artificial skin grafts,[52] various fasciocutaneous[53] and myocutaneous flaps (gluteal-thigh flap, gracilis, rectus abdominis,[54] Malaga flap,[55] Singapore flap,[56,57] vulvovaginoplasty of Williams,[58] vulvovaginal flap (lotus petal labia majora flap),[59] horseshoe flap using labia minora,[60] labial flaps using tissue expanders,[61] full-thickness skin grafts with vacuum-assisted wound closure,[62] and the use of amnion[7,63] and peritoneum.[64] Varying laparoscopic techniques have been described.[65–67] The Vecchietti[68] procedure consists of intra-abdominal traction on the perineal membrane causing invagination of the shallow vaginal dimple. This requires a laparoscopic approach and long-term dilatation, and there have been reports of modifications and the development of revised instrumentation.[69] The Wharton procedure[70,71] simply places a condom-covered mold in a created space that is left in place for many months. Bowel vaginoplasty using cecum, small bowel, and sigmoid colon has been recommended as an alternative to these other procedures.[2,43,72,73] Some of the more popular procedures are presented here in more detail.

The most popular tissue for vaginal replacement during the past 3 decades has been the split-thickness skin graft as described by McIndoe.[51] The McIndoe procedure uses several split-thickness skin grafts, which are usually harvested from the buttocks (Fig. 124-3). The grafts are then refashioned over a vaginal mold that serves as a stent to form a neovagina. The neovagina is then transferred to its normal anatomic position in a space surgically created through an incision in the apex of the vaginal dimple with dissection superiorly between the urethra and bladder anteriorly and the rectum posteriorly. The dissection is carried up to the pelvic peritoneum to provide length and to avoid postoperative contracture. The labia are sutured over the mold to hold it in position. After 7 days of bedrest the patient is taken back to the operating room for cutting of the labial sutures, removal of the mold, and sewing of the edge of the perineal skin to the skin grafts. Postoperative hematoma and fistula due to pressure necrosis related to the mold are early complications. Use of an inflatable soft vaginal mold has been considered to reduce these risks. The reported complication rate is less than 10%. Follow-up reports have been encouraging,[74,75] but as with most surgical techniques, use of an inflatable mold is hampered by the need for regular and long-term home dilatation. Due to the use of dermis, lubricants are required, and a significant incidence of

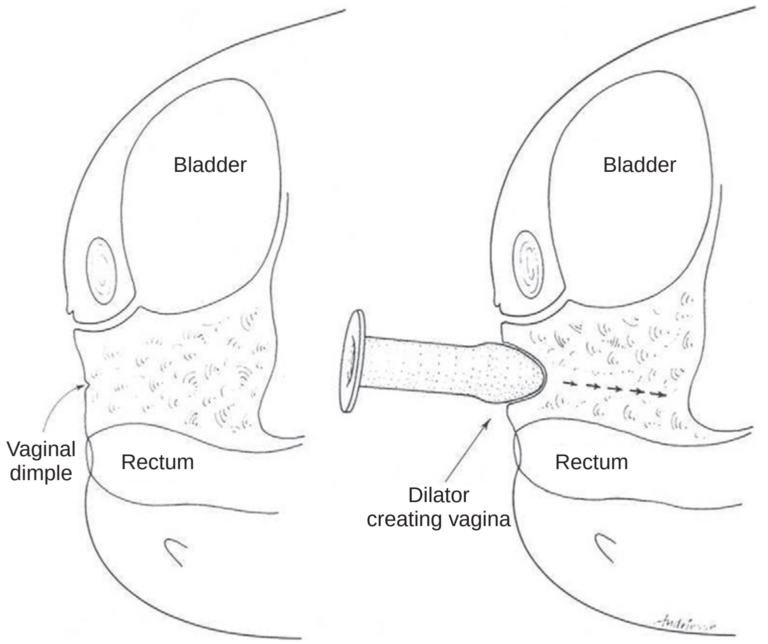

**FIGURE 124-2** Creation of a vaginal with the use of progressive perineal dilation. (From Laufer MR. Structural abnormalities of the female reproductive tract. In Emans SJ, Laufer MR [eds]: Emans, Laufer, Goldstein's Pediatric and Adolescent Gynecology, 6th ed. Philadelphia, Lippincott Williams & Wilkins, 2011.)

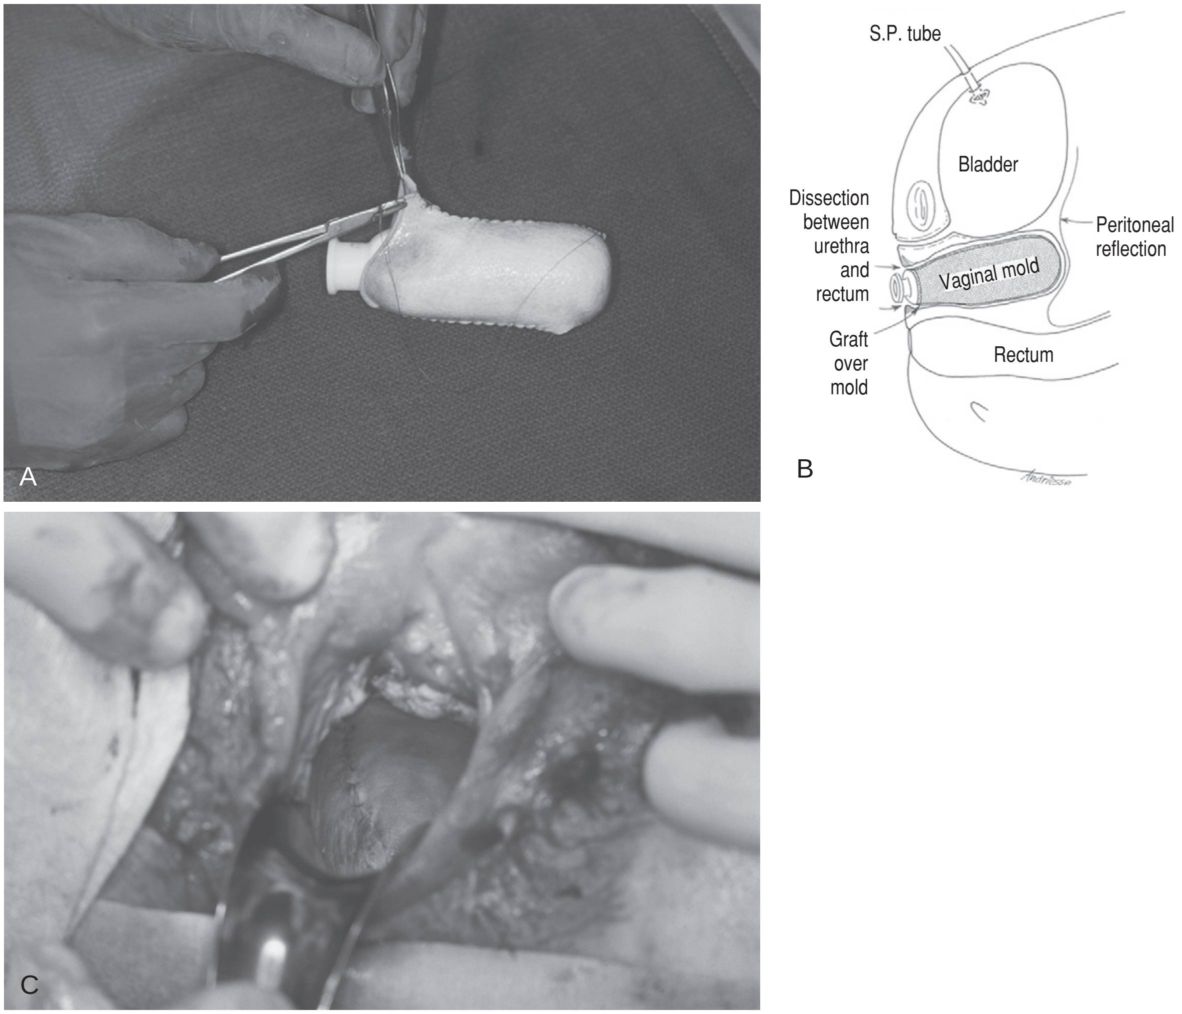

**FIGURE 124-3** The McIndoe procedure. **A,** Split-thickness skin graft sutured over a vaginal mold. **B,** The mold is placed in a surgically created space between the bladder and rectum. **C,** After the mold is removed, the skin graft can be seen in place. Philadelphia, Lippincott Williams & Wilkins, 2011.)

inadequate vaginal length, vaginal stenosis, and dyspareunia due to contraction of the split-thickness skin graft are drawbacks of this procedure.[76] Antibiotics and analgesics are necessary, and the mold requires changing under an anesthetic and replacement with a larger-sized stent.

In order to avoid the need for a skin graft donor site, the use of an acellular human dermal allograft has been reported.[52] Other substances have been recommended as variations on the technique. Amnion has been used to avoid the need for autologous graft sites; however, acquiring amnion requires scheduled cesarean section and tissue banking and donors must be carefully screened for HIV infection and Creutzfeldt-Jakob disease.[77] In order to avoid the issues of infection transmission, chemically processed and freeze-dried human amnion has been used.[78] The peritoneum has been used, as described in the Davydov procedure, to line the neovaginal space, but this requires laparotomy or laparoscopy.[64,67,79] A long-term follow-up study on the use of the Davydov procedure reports that sexuality approaches so-called "normal sexuality."[80]

As noted earlier, a variety of full-thickness skin flaps have been used to obviate the problem of contracture noted with split-thickness grafts. The disadvantage of using hair-bearing areas as the donor source of the flap for vaginal reconstruction is that hair growth results in neovaginal discharge and is associated with dyspareunia. These procedures also result in additional wounds at the donor sites.

Use of vulvar tissues to create a vagina grossly change the appearance of the external genitalia, and in the Williams vulvovaginoplasty (Fig. 124-4), an abnormal angle for intercourse is problematic, resulting in dyspareunia and making this operation undesirable.[58,77] Modifications to the Williams vaginoplasty have been proposed with the report of 200 patients with the Creatsas modification.[81,82]

Use of tissue expanders to create more tissue for a labia minora graft may prove useful, but late results are not yet available to ensure that labia minora flaps will result in adequate vaginal length and will endure.[60,61] Autologous buccal mucosa has been used successfully for vaginoplasty.[83,84] Lin and colleagues[85] described eight cases using buccal mucosal grafts. This technique requires a vaginal stent mold and dilatation. Complications included vaginal bleeding presumably from granulation tissue in one patient and a bladder injury in another. Baker and colleagues[84] reported on 21 patients

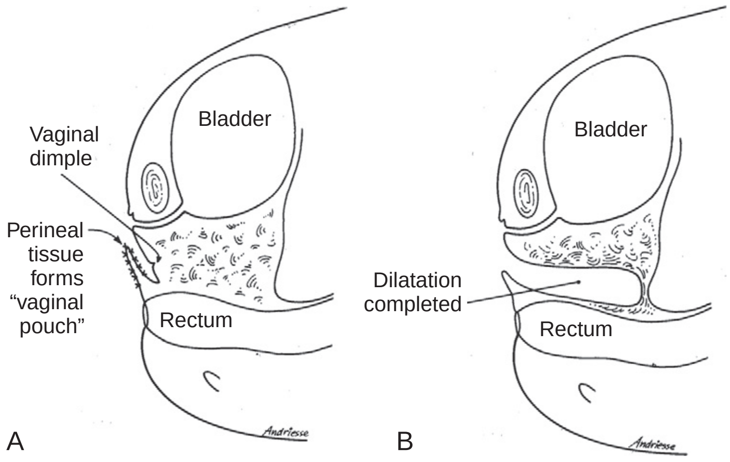

**FIGURE 124-4 A,** Schematic drawing at the completion of the Williams procedure. **B,** Schematic drawing months after completion of the Williams procedure with the creation of a vagina with the use of dilators and vaginal intercourse. (From Laufer MR. Structural abnormalities of the female reproductive tract. In Emans SJ, Laufer MR [eds]: Emans, Laufer, Goldstein's Pediatric and Adolescent Gynecology, 6th ed. Philadelphia, Lippincott Williams & Wilkins, 2011.)

with 5-year follow-up from buccal mucosa graft vaginoplasty. Artificial dermis and recombinant basic fibroblast growth factor (bFGF) have also been used to create a neovagina in hopes of accelerating epithelialization and reducing the incidence of bloody discharge from granulation tissue.[86] Because of the small numbers of patients involved in these studies, no conclusions can be made at this time regarding the efficacy of these techniques.

In the Vecchietti procedure,[68] at laparotomy (or laparoscopy[87]) and with modifications,[69] a suture is passed through the perineal membrane from above and then through a plastic olive and back up through the abdomen. The suture is then attached to a traction device strapped to the patient's abdomen for a week to 10 days, with pressure on the olive causing invagination of the vaginal dimple, creating a vaginal vault. Claims of early vaginal length of 10 to 12 cm and a 100% anatomic and functional success rate have been reported.[88] Complications include bladder and rectal fistula in a small percentage of cases. The traction method is associated with some degree of patient discomfort, is cumbersome, still requires long-term vaginal dilatation, and has not been widely adopted in the United States. Recent revisions to the technique and refinements to the surgical equipment have resulted in U.S. Food and Drug Administration approval and wider availability of the equipment for this technique.[69] It should be realized that this technique must be followed by the patient's use of manual dilation.

The Wharton procedure[71] involves placing a condom-covered mold in the neovagina to epithelialize vaginal granulation tissue. The process is lengthy because epithelialization may take 3 to 6 months to occur and is associated with prolonged bloody vaginal discharge owing to the presence of granulation tissue.

Schätz and colleagues[89] described initial dilatation of rudimentary müllerian ducts in three patients by gradually increasing the Hegar dilator size. The two cavities formed were joined into one by diathermy, and the resultant space is lined by smooth tissue. The dome of the space is composed of the peritoneum reflected from the bladder to the rectum. Sheares' modification of the Wharton technique[70] was applied, and an adjustable vaginal stent was placed in the space. Antibiotics and analgesics were administered for 8 days, and a Foley catheter was left in place for 1 week to avoid urinary retention. The vaginal mold was changed under anesthesia after 1 week, and a new mold was inserted. The mold remained in place 24 hours per day for 3 months and then at night thereafter until regular sexual intercourse was initiated. Periodic changing of the mold required general anesthesia. Subsequent neovaginal length was 7 to 10 cm, and the width was described as two fingerbreadths. Insufficient lubrication and dyspareunia were noted initially with sexual intercourse but resolved using lubricating gels. The two girls who experienced sexual relations expressed satisfaction with the procedure.[89] The extended period of time required to maintain the mold in place, the need for general anesthesia to repeatedly change the mold, inadequate lubrication, and lack of long-term follow-up data are drawbacks of this procedure.

### Bowel Vaginoplasty

The use of isolated bowel segments for vaginal replacement has historically been popular with pediatric surgeons and pediatric urologists. The use of rectum for the creation of a vagina was reported as early as 1892 but was not popular due to the need for a colostomy.[90] The use of isolated segments of small intestine for vaginal replacement was first described by Baldwin[91] in 1904 and performed in 1907.[92] Ruge was the first to use the sigmoid colon to replace the vagina in 1914.[93] Experience with this technique was reported by Fall[94] in 1940, but efforts were abandoned because of an unacceptably high mortality rate in the preantibiotic era. Attention was refocused on the use of small bowel and colon for vaginal replacement in 1972 by Pratt,[41] and there have been scattered reports in the literature ever since.[2,44,72,73,95–108]

Bowel vaginoplasty uses a section of bowel approximately 10 cm that is mobilized and retains its vascular pedicle to reach the perineum without compromise to the graft or the pedicle. A neovaginal space is dissected below the bladder and above the rectum from the perineum to the pouch of Douglas, and the bowel segment is sewn in place in an isoperistaltic or antiperistaltic orientation.[103–105] Most surgeons advocate anchoring the proximal bowel segment in order to decrease the risk of prolapse of the bowel vagina.[106–108]

Currently, an interposed segment of the sigmoid colon is preferred for vaginal replacement. When the use of this segment is unavailable because of previous surgery, the cecum is an acceptable alternative. Although small intestine has occasionally been used, results are not as gratifying because

of excessive mucus formation and friability of small bowel mucosa with intercourse.

Patients require mechanical bowel preparation for 24 hours before surgery. Perioperative systemic antibiotics are administered 30 to 45 minutes before the incision. The operation is accomplished with the patient in the lithotomy position with the legs positioned in stirrups so that the abdomen and perineum can be prepared in the same field. A Foley catheter is placed in the bladder, and the abdomen and pelvis can be approached through a Pfannenstiel or lower midline abdominal incision. Alternatively, the procedure has been carried out using a minimally invasive laparoscopic approach.[99,100,109] The peritoneal cavity is explored, and the genital organs are evaluated. If small rudimentary bicornuate uteri are noted, these are excised. Uncommonly, if a relatively normal uterus is observed, this is maintained (see options for uterus with cervical and vaginal agenesis later). The ovaries should be left in place to maintain the potential for in vitro fertilization with a gestational carrier should the patient desire to pursue this in the future.[37,35,36]

A 10- to 15-cm sleeve of sigmoid colon, based on the left colic or superior hemorrhoidal vessels, is sufficient to provide a functional neovagina. Keeping the segment short avoids excess mucus production, which can be associated with longer segments. The sigmoid segment is divided, and intestinal continuity is reestablished with either a stapled or hand-sewn end-to-end colocolostomy (Fig. 124-5). In patients with Mayer-Rokitansky syndrome or those with a hypoplastic vagina, an incision is made in the vertex of the vaginal dimple and a space is created between the bladder anteriorly and the rectum posteriorly up to the peritoneal reflection. Depending on the length of mesentery, the isolated segment is usually brought down to the perineum in an isoperistaltic fashion or rotated 180 degrees. The proximal end of the neovagina is then closed in two layers, with absorbable suture to form the vertex of the neovagina. An unrestricted one-layer anastomosis of the perineal opening to the distal end of the interposed colon segment using interrupted absorbable sutures (3-0 Vicryl or polydioxanone sutures) is then performed. A three-point fixation of the interposed segment to the

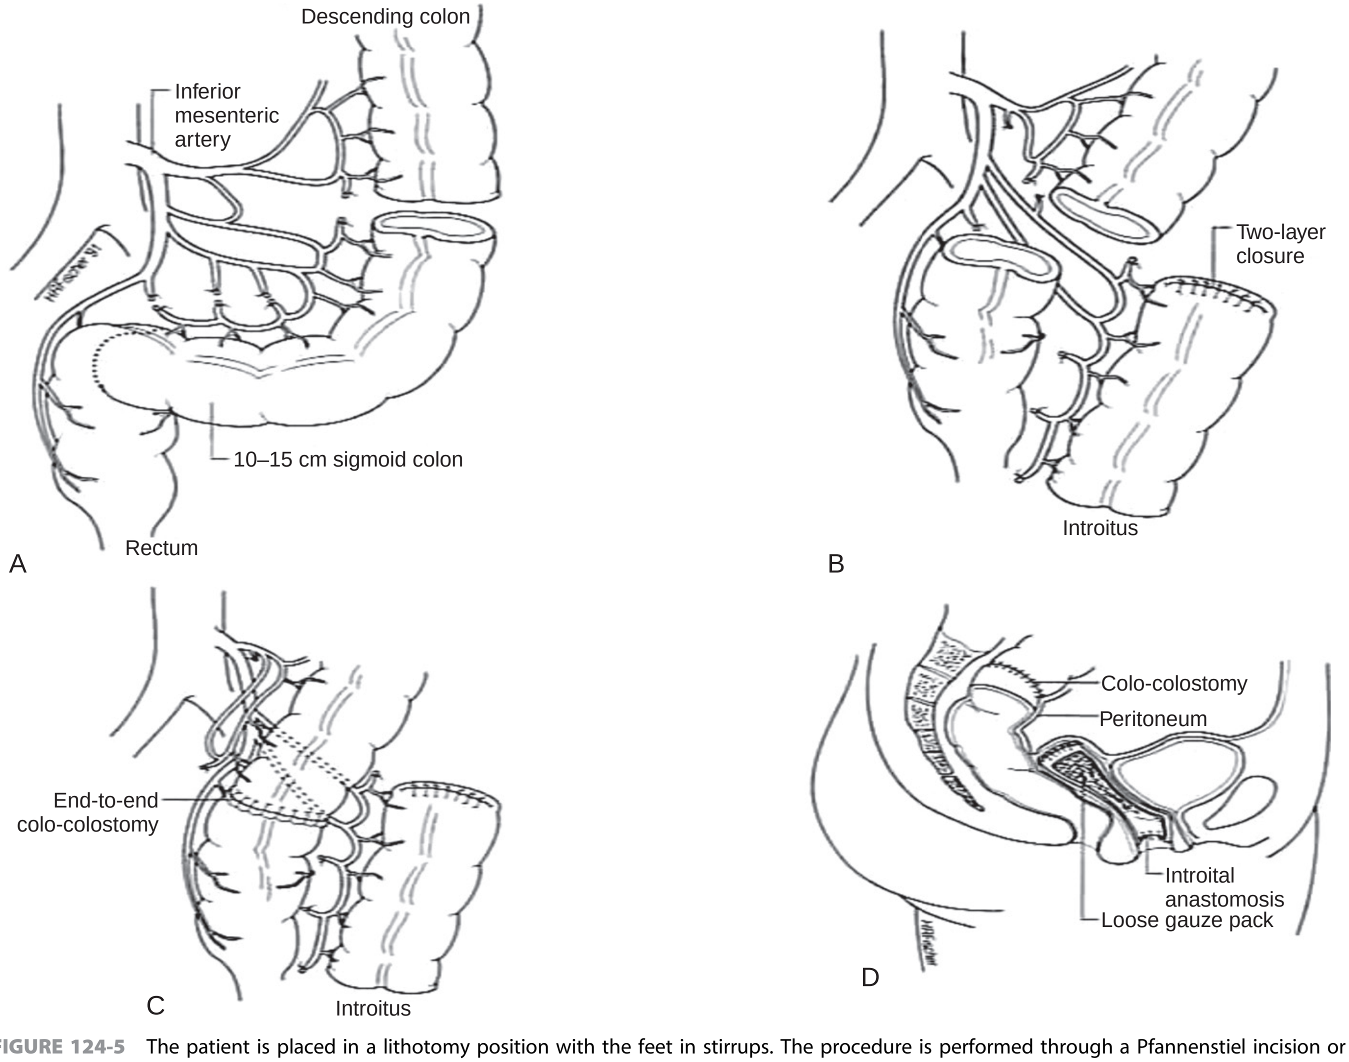

**FIGURE 124-5** The patient is placed in a lithotomy position with the feet in stirrups. The procedure is performed through a Pfannenstiel incision or laparoscopically. **A,** A 10- to 15-cm sigmoid colon segment is isolated. **B** and **C,** The proximal portion of the sigmoid neovagina is closed in two layers, and bowel continuity is restored by an end-to-end colon anastomosis. **D,** The isolated neovagina is then brought into the cul-de-sac, and the distal end of the sigmoid vagina is anastomosed to the vaginal remnant, if present, or to the small introital cuff with one layer of interrupted absorbable sutures. The interposed colon is sutured to the retroperitoneal tissues to prevent prolapse. A Vaseline gauze pack is placed in the new orifice.

retroperitoneum with nonabsorbable suture is essential to prevent prolapse.

Perioperative systemic antibiotics are discontinued after 24 hours. Analgesics are administered for 48 hours and discontinued after that time. Oral pain medication is available on request. The neovagina is stented for 5 days after the procedure with petrolatum gauze. A Foley catheter drains the bladder during the period of vaginal stenting. Patients are discharged when they are ambulating and tolerating a diet, usually on the fifth postoperative day. Patients are examined at 3 weeks and 3 months. If a stenosis is evident, dilatation under anesthesia is performed. Home dilatation is usually unnecessary. Bicycling should be avoided for a 6-week period. Other exercises are permitted as tolerated. Figure 124-6 shows the postoperative view after healing.

## RESULTS

Long-term follow-up and sexual satisfaction have been assessed in a few series of patients who have undergone bowel vaginoplasty. Communal and colleagues[106] used the standardized Female Sexual Function Index in 16 patients, and of the 11 who were sexually active and who responded, 8 (75%) reported satisfactory sexual function results after sigmoid vaginoplasty. Hensle and colleagues described their experience with intestinal-vaginal replacement in 44 patients ranging in age from 1 to 20 years.[44,72,110] Long-term results were assessed by a validated Female Sexual Dysfunction Questionnaire, and 78% of the 36 who responded reported sexual satisfaction.

Syed and colleagues[111] described the occurrence of diversion colitis in 3 of 18 children who had undergone sigmoid vaginoplasty between 18 months and 8 years of age. On the basis of the report by Syed and colleagues,[111] Edmonds[77] has suggested that the procedure not be performed in this young age group. Hiroi and colleagues[112] in Japan described the only case of malignancy occurring in a sigmoid vaginoplasty. A mucinous adenocarcinoma of the colovaginoplasty was observed 30 years after the procedure.

A 7-year follow-up study of 29 patients who underwent intestinal vaginoplasty has shown positive results, and the authors recommend the treatment, especially where there is a cultural moral taboo to the use of vaginal dilators in unmarried women.[104]

Pediatric surgeons have generally felt that the sigmoid colon is an ideal tissue for vaginal replacement. Unlike other methods of vaginoplasty, this procedure creates a vagina that is capable of providing natural lubrication during sexual activity. Many women do complain of the natural mucus production and state that they need to wear a pad daily. Limiting the length of the interposed segment to the usual vaginal length of 9 to 10 cm will reduce the risk of excessive mucus production. Recognized complications such as prolapse can be avoided by retroperitoneal fixation of the sigmoid segment. Use of the sigmoid colon rather than the small intestine will obviate some of the other complications including stenosis and excessive mucus production that were seen in the past. The fact that the procedure can be performed laparoscopically will reduce the risk of wound complications and intra-abdominal adhesions and make this procedure a more attractive alternative in the future.[99,109,113] It should be noted that the intestinal procedures do not eliminate the need for vaginal dilation because patients commonly complain of stenosis at the site of the anastomosis.

## REPRODUCTIVE ISSUES

Reproductive issues relating to MRKH can create emotional hardship for the affected young woman and her family.[35,36,38,114] In cases of MRKH, ovarian function is normal. Women may experience pain with ovulation or with ovarian cyst formation. The possibility for the use of Assisted

**FIGURE 124-6** **A,** Postoperative view of the perineum with the sigmoid vagina anastomosed to vaginal introitus. **B,** No. 26 Hegar dilator (6 inches long) reveals normal vaginal caliber and depth. Patients are advised to pass the dilator periodically to ensure continuation of adequate caliber. This procedure is not as important as it would be for a skin graft vagina, which will contract if not periodically dilated in this fashion or by coitus. (From Hendren WH, Atala A: Use of bowel for vaginal reconstruction. J Urol 1994;152:752.)

Reproductive Technologies (ART) has shown that there is normal response of the ovaries to controlled ovarian hyperstimulation for the retrieval of oocytes.[35,36,115,116]

If there is a midline uterus present with the absence of a cervix and vagina, the uterus can be maintained but it should not be attached to the neovagina due to the risk of ascending infection, sepsis, and death.[40] Instead, the vagina can be created by the selected modality and the uterus can be maintained for ART. In order to maintain the uterus and avoid pain with retrograde menstruation and the risk of the development of endometriosis, the patient should be treated with continuous monophasic combination hormonal therapy. The patient is asked to take the monophasic progesterone dominant oral contraceptive pill daily without breaks or placebos for the suppression of retrograde menses. This treatment plan maintains the uterus without risk of ascending infection and preserves the option for fertility. In this clinical scenario, pregnancies have been reported.[117]

The etiology of MRKH is unknown, but reports have shown that a specific genetic abnormality has not been identified. We recently reported a case of monozygotic (monoamniotic/monochorionic) twins in which only one twin exhibited MRKH.[30] In addition, in 58 women with MRKH undergoing ART with gestational carriers, none of the 17 female offspring had MRKH.[31] Thus women with MRKH who desire fertility can use their oocytes, fertilized with a partner's or donor's sperm, and the conceptus is implanted and carried in a gestational carrier.

# Congenital Vaginal Obstruction

Congenital vaginal obstruction is probably caused by incomplete canalization of the vagina and can occur at differing levels. The obstruction can result from an imperforate hymen, agenesis of the lower vagina, or a transverse vaginal septum. It is important to differentiate these anomalies because the appropriate surgical management varies greatly.

## IMPERFORATE HYMEN

Perforation of the hymen usually occurs during the fifth month of gestation. The hymen occurs at the junction of the sinovaginal bulbs with the urogenital sinus and is usually perforated during fetal life. Failure of perforation to occur results in an imperforate hymen.[11,77] Different types of hymens are shown in Figure 124-7. An imperforate hymen can result in gross distention of the vagina, which can be filled with fluid (hydrocolpos), mucus (mucocolpos), pus (pyocolpos), or blood (hematocolpos), or in distention of both the vagina and uterus, which is termed hydrometrocolpos, mucometrocolpos, pyometrocolpos, or hematometrocolpos.

Congenital vaginal obstruction is most commonly caused by simple obstructive anomalies and can include agenesis of the lower vagina, segmental agenesis, or transverse vaginal septum.

## DIAGNOSIS

Imperforate hymen usually presents in the newborn period when there is increased mucus production from maternal estradiol production or at the time of menarche.[100] The mucus distention will usually resolve with time because there is cessation of the estradiol stimulation. The imperforate hymen that is asymptomatic (not causing compromise of urination or other issue) can be observed and addressed as an adolescent or surgically addressed in the newborn period of time.

An imperforate hymen can be suspected on prenatal ultrasound.[118] In the fetus, the imperforate hymen appears as a thin membrane associated with a distended vagina (sonolucent mass) and spread labia majora. Imperforate hymen and hydrocolpos can be diagnosed as early as the second trimester. Neonates with vaginal obstruction can present with a lower midline abdominal mass. Frequently, these infants have associated urinary tract obstruction. The abdominal mass is the distended vagina, which results from continued collection of cervical gland secretions in response to maternal estrogens. Abdominal ultrasonography reveals a large midline

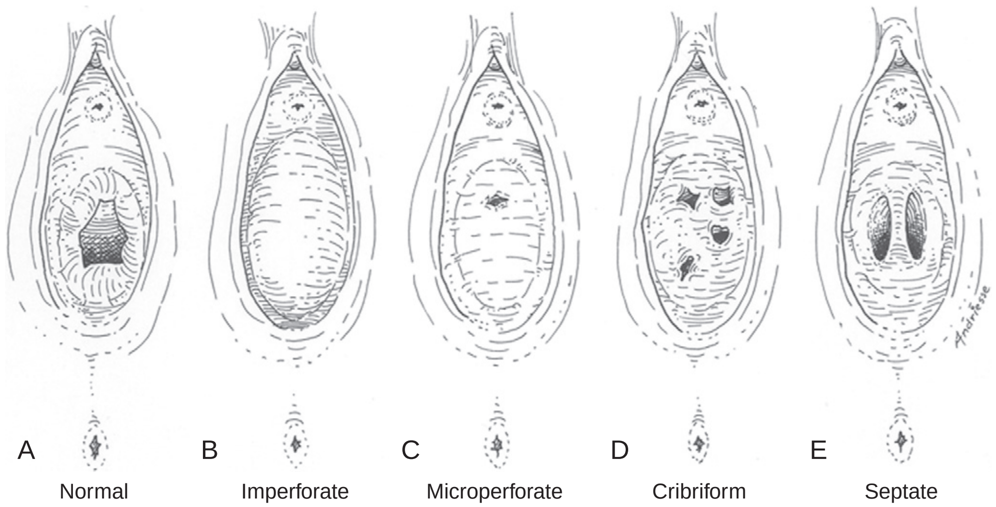

FIGURE 124-7 Types of hymens: **A,** normal, **B,** imperforate, **C,** microperforate, **D,** cribriform or complex, and **E,** septate. (From Emans SJ. Office evaluation of the child and adolescent. In Emans SJ, Laufer MR [eds]: Emans, Laufer, Goldstein's Pediatric and Adolescent Gynecology, 6th ed. Philadelphia, Lippincott Williams & Wilkins, 2011.)

sonolucent mass. This mass causes forward displacement of the bladder and posterior displacement of the rectum. Percutaneous needle aspiration and injection of contrast medium may aid in the diagnosis and can be done through the perineum or the anterior abdominal wall (Fig. 124-8). If no abdominal mass is present at birth, the condition is often not detected until early adolescence. At the time of puberty, symptoms may include amenorrhea, cyclic abdominal pain, and an abdominal mass secondary to hematocolpos or hydrometrocolpos (Fig. 124-9). Introital examination may show a bulging membrane with bluish discoloration behind it due to hematocolpos.

### TREATMENT

An imperforate hymen in neonates that bulges at the introitus can be easily incised, but there is a risk that when the hymenal tissue is no longer bulging, the edges of incised tissue will adhere, resulting in a persistent structural issue. That is the rationale for not performing a cruciate incision type procedure in either the infant or adolescent (Fig. 124-10). This technique will result in achieving adequate drainage, but there is high risk of reobstruction. We thus recommend the use of an elliptical incision and removal of the excess hymenal tissue. It is necessary to clearly identify the anatomy at the time of the drainage/corrective procedure to ensure that a common urogenital sinus or other urinary tract anomaly is not associated with the obstructive anomaly.

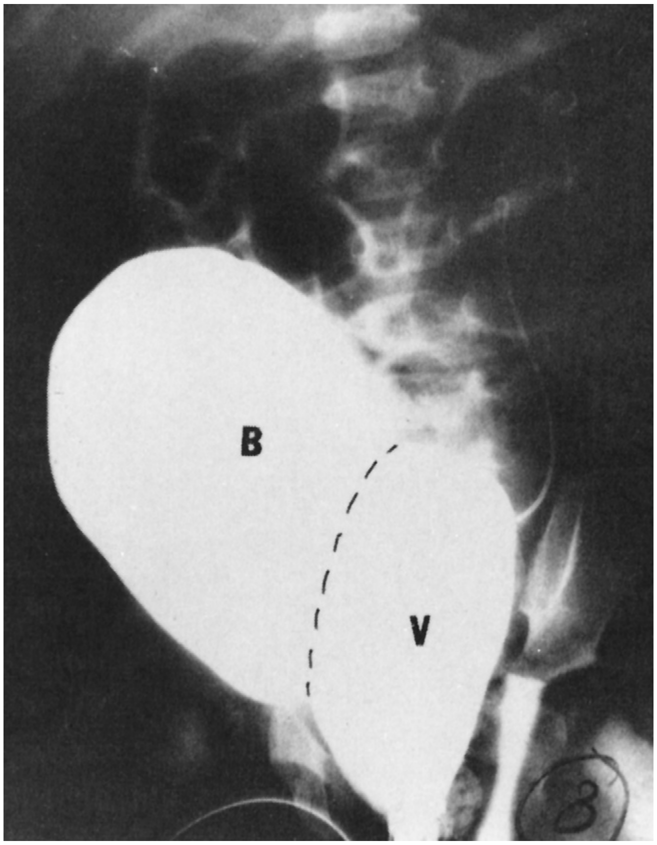

**FIGURE 124-8** Percutaneous injection of an obstructed vagina *(V)* in a newborn, with simultaneous cystogram of bladder *(B)* and retrograde catheterization of a solitary left ureter and kidney.

## Agenesis of the Lower Vagina

Agenesis of the lower vagina (ALV) (Fig. 124-11) occurs with a normal upper vagina in patients with a uterus and cervix. The presentation is similar to an imperforate hymen, and the diagnosis is determined by physical examination and imaging studies.

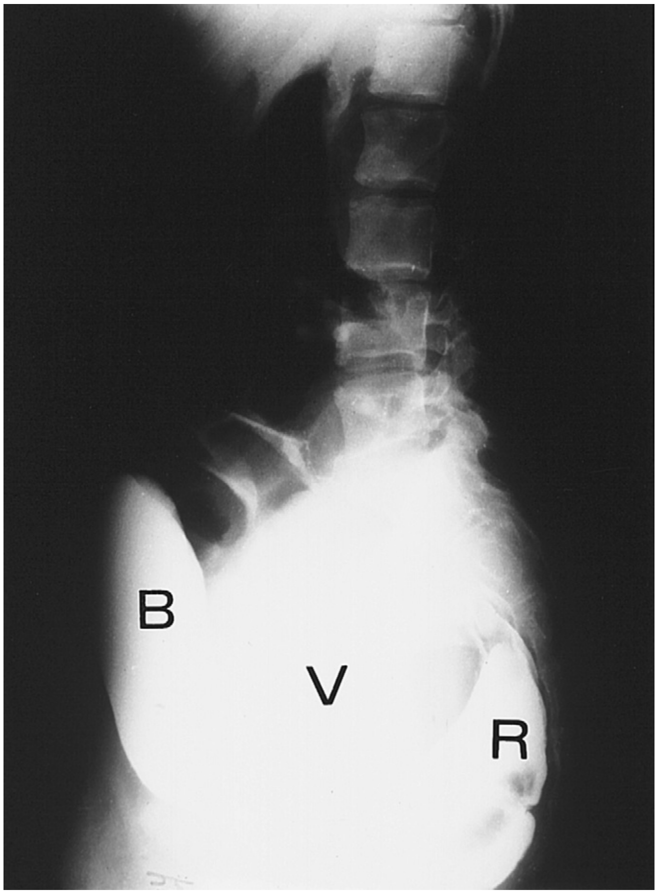

**FIGURE 124-9** Lateral view of a contrast study in a patient with a midline mass pushing the bladder *(B)* forward and the rectum *(R)* in a posterior direction. *V* indicates the obstructed vagina.

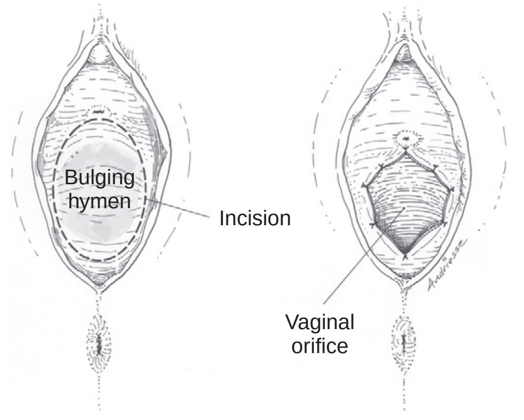

**FIGURE 124-10** Surgical correction of imperforate hymen. (From Laufer MR. Structural abnormalities of the female reproductive tract. In Emans SJ, Laufer MR [eds]: Emans, Laufer, Goldstein's Pediatric and Adolescent Gynecology, 6th ed. Philadelphia, Lippincott Williams & Wilkins, 2011.)

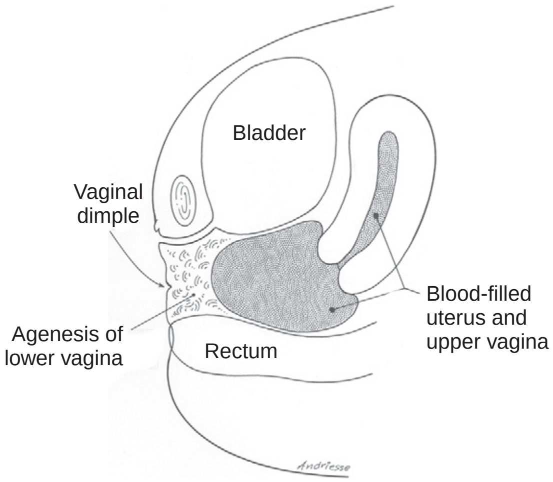

**FIGURE 124-11** Agenesis of the lower vagina with a blood-filled upper vagina. (From Laufer MR. Structural abnormalities of the female reproductive tract. In Emans SJ, Laufer MR [eds]: Emans, Laufer, Goldstein's Pediatric and Adolescent Gynecology, 6th ed. Philadelphia, Lippincott Williams & Wilkins, 2011.)

### DIAGNOSIS

The external appearance of ALV can easily be confused with an imperforate hymen. The key means to a correct diagnosis include the observation that there are normal fronds of hymen and there is not just a membrane of tissue. In addition, the examiner may be able to insert a finger in the rectum (with the patient in the dorsal supine position) and appreciate a space between the obstructed vagina and the location for the introitus (see Fig. 124-11). The surgeon may not appreciate the difference until an operation is in progress. If there is some amount of areolar tissue until the obstructed vagina is reached, then this is ALV and not an imperforate hymen. Note the distance that has been dissected before reaching the vaginal mucosa in Figure 124-12, *A*. This is an important differential because if the upper vagina is distended and pointing toward the introitus, the blood acts as a natural tissue expander and increases the amount of native vaginal tissue. Once the obstruction is relieved and the old blood is evacuated, the native upper vagina will tend to retract back up toward the uterus. This is the reason the native vaginal tissue must be sewn to the newly created introitus (Fig. 124-12, *B* and *C*). A flexible vaginal dilator should be used 24 hours a day 7 days a week for some number of months so that stenosis of the vaginal orifice will not occur and a fistulous tract will not form if the upper vagina retracts after the pull-through vaginoplasty.

## Transverse Vaginal Septum

Transverse vaginal septum (TVS) can occur at varying levels of the vagina (Fig. 124-13) and is referred to as low, middle, and high transverse vaginal septum. Although highly variable, it

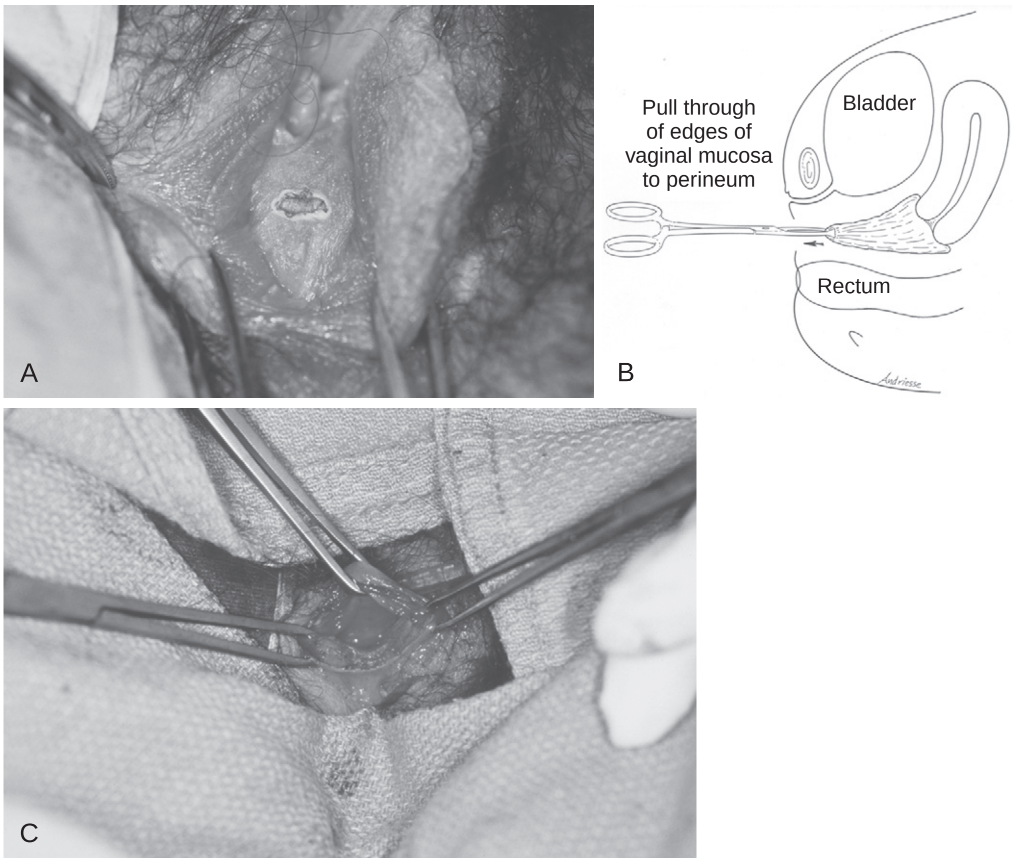

**FIGURE 124-12** **A,** Transverse incision is made to create the vaginal orifice. The dissection is carried through the areolar type tissue to reach the obstructed vagina. **B,** After drainage, the previously obstructed upper vaginal tissue is pulled through to the perineum to create a patent tract. **C,** The normal upper vagina has been pulled down and will now be sewn in place. (From Laufer MR. Structural abnormalities of the female reproductive tract. In Emans SJ, Laufer MR [eds]: Emans, Laufer, Goldstein's Pediatric and Adolescent Gynecology, 6th ed. Philadelphia, Lippincott Williams & Wilkins, 2011.)

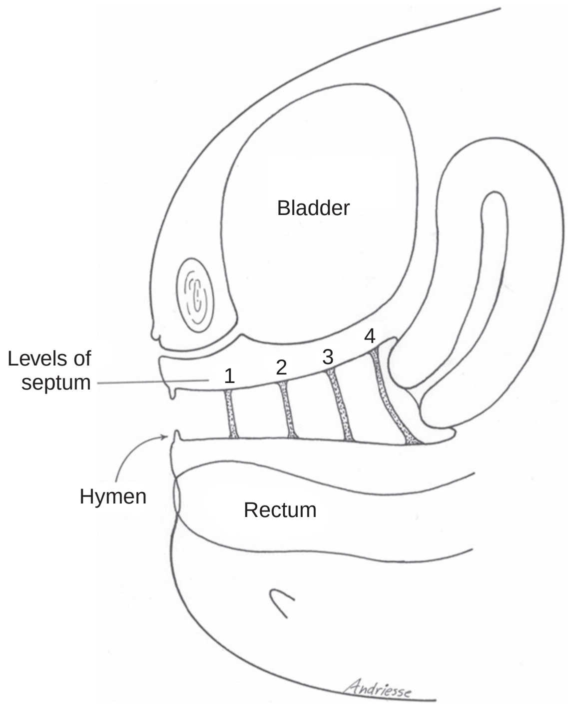

**FIGURE 124-13** Locations of transverse vaginal septum. (From Laufer MR. Structural abnormalities of the female reproductive tract. In Emans SJ, Laufer MR [eds]: Emans, Laufer, Goldstein's Pediatric and Adolescent Gynecology, 6th ed. Philadelphia, Lippincott Williams & Wilkins, 2011.)

has been reported that approximately 46% of vaginal septa occur in the upper vagina, 40% in the middle vagina, and 14% in the lower vagina.[119] The septum can be obstructing or have a small perforation either in the midline or laterally. The presentation will vary depending on whether there is a perforation.

Pelvic ultrasonography is usually diagnostic of hematocolpos. The high transverse vaginal septum is best treated by draining the vagina by cutting into the septum, resecting the septum, and performing a simultaneous transperineal vaginal pull-through procedure attaching the upper and lower vagina using absorbable sutures. This condition is best addressed after menarche, and the patient is asked to wear a flexible vaginal dilator to avoid circumferential stricture.

The results with lower septum defect repair are much better than outcomes achieved with high vaginal septum defects due to difficulty with the use of dilators reaching the area of the high septum.

# Anomalies of Fusion

## VAGINAL DUPLICATION

Disorders of embryogenesis that produce duplication anomalies of the vagina and uterus occur at approximately 9 weeks of gestation and involve a complete or partial failure of union of the two lateral müllerian ducts. These anomalies[120] are common and can include two uteri and two cervices with two separate vaginas (uterus didelphys) or a single vagina (uterus duplex bicollis). They may also consist of two uteri fused with a single cervix and a single vagina (uterus duplex unicollis or bicornuate uterus) (Fig. 124-14).

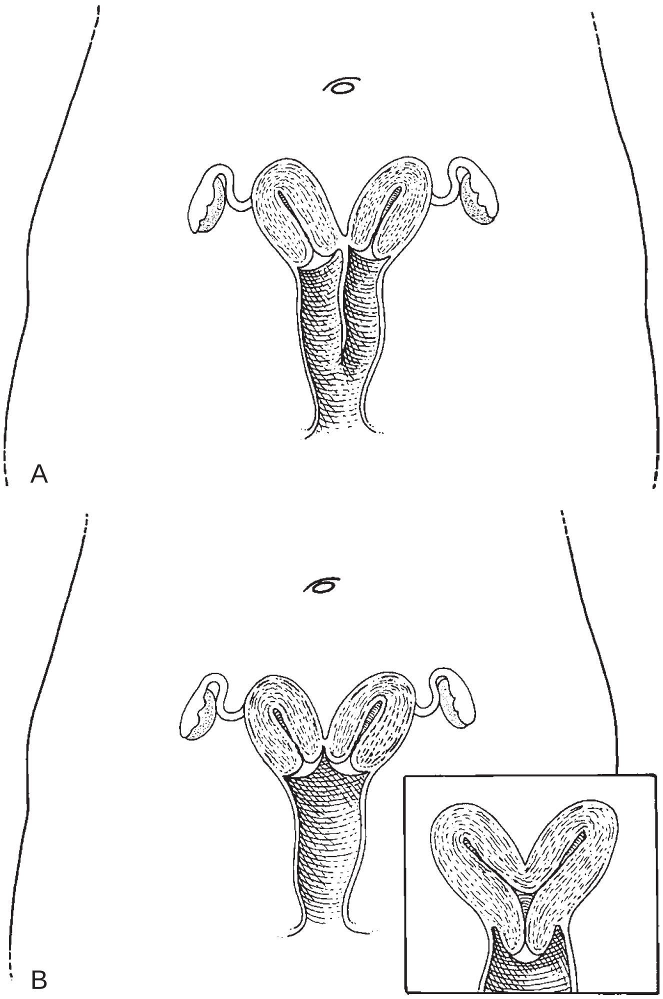

**FIGURE 124-14** Fusion anomalies of the uterus **(A)** and vagina **(B).**

## OHVIRA

In cases of complete vaginal duplication, one vagina can be obstructed and the other can be patent, which is referred to as *obstructed hemivagina with ipsilateral renal anomaly* (OHVIRA)[121] or Herlyn-Werner-Wunderlich syndrome (Fig. 124-15).[122,123] Urinary tract anomalies may confound the situation with an ectopic ureter inserting into a duplicated imperforate hemivagina, resulting in a mass.[13,44,124] The external genitalia will usually appear normal. The diagnosis of uterus didelphys and a unilateral obstructed vagina should be entertained as part of the differential diagnosis in a newborn with a sonolucent abdominal mass. The mass usually pushes the bladder forward and the normal vagina in a posterior direction. Pelvic examination without possible vaginoscopy is helpful in this situation and may reveal a bulging mass high in the vaginal side wall. A simple incision of the obstructing septum with resection of a "window of tissue" often provides adequate drainage; however, further resection of the septum is necessary to prevent possible collection of bacteria on the abnormal side and abscess formation and is usually performed after menarche.[11,121] We advocate a single procedure for OHVIRA during adolescence.[121] Rarely a staged procedure is necessary but is useful when the procedure must be performed on children (due to urinary symptoms, pain, or infection) and when there is a pyocolpos with associated inflammation in the adolescent.

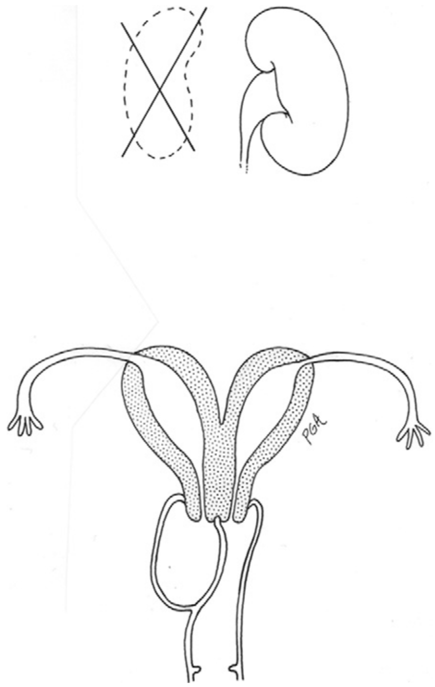

**FIGURE 124-15** Obstructed hemivagina with ipsilateral renal anomaly [OHVIRA]. (From Laufer MR. Structural abnormalities of the female reproductive tract. In Emans SJ, Laufer MR [eds]: Emans, Laufer, Goldstein's Pediatric and Adolescent Gynecology, 6th ed. Philadelphia, Lippincott Williams & Wilkins, 2011.)

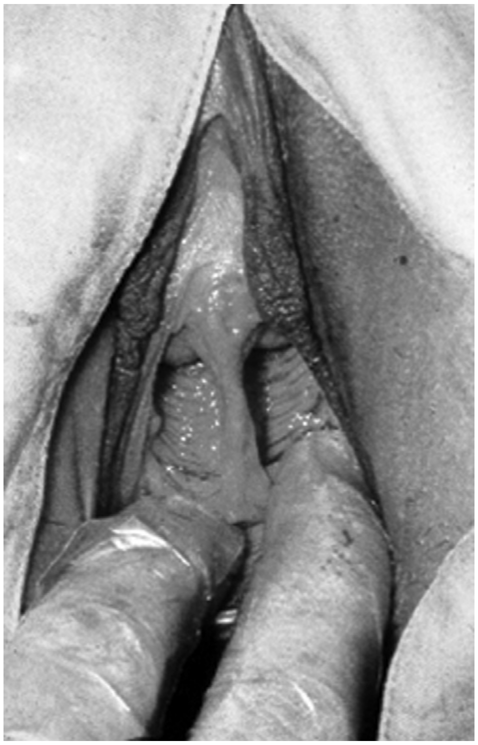

**FIGURE 124-16** Longitudinal vaginal septum. (From Laufer MR. Structural abnormalities of the female reproductive tract. In Emans SJ, Laufer MR [eds]: Emans, Laufer, Goldstein's Pediatric and Adolescent Gynecology, 6th ed. Philadelphia, Lippincott Williams & Wilkins, 2011.)

# Longitudinal Vaginal Septum

For nonobstructed longitudinal vaginal septum (Fig. 124-16), a surgical excision of the septum is required only if the young woman desires such a procedure. Some patients complain that they need to use a pad in addition to a tampon (because the tampon is absorbing menstrual blood from only one of the two vaginas). Some maintain the longitudinal vaginal septum and have no issues with sexual activity or vaginal delivery. Most have two cervices, so a Papanicolaou smear must be obtained from both.

The septum should be excised by "wedging" out the fibrous septal tissue. Great care is necessary to avoid the bladder above, the rectum below, and the septal tissue between the two cervixes at the apex. Once the septal tissue is excised, the normal vaginal mucosa from one vagina is sewn to the other vagina to create a smooth vaginal mucosa and close the resulting defect. Excision of the septal tissue removes the fibrous tissue to avoid dyspareunia.

If there are two systems that are not obstructed, each can function independently, as two unicornuate systems, from a fertility standpoint.[125]

## RUDIMENTARY UTERINE HORNS

A young woman may present with pain and regular menses. The possibility of a patent unicornuate system (Fig. 124-17) and an obstructed hemi uterus (Fig. 124-18) should be considered. The obstructed hemi uterus may be appreciated on ultrasonography or MRI. In cases of MRKH, if rudimentary uteri are present, they may be difficult to appreciate even on MRI.[126]

The obstructed hemi uterus should be removed so that the patient will no longer have retrograde menses and pain. The procedure can be performed laparoscopically. The cervix should be canalized, and blue dye should be injected at the time of the laparoscopy so that it can be confirmed which

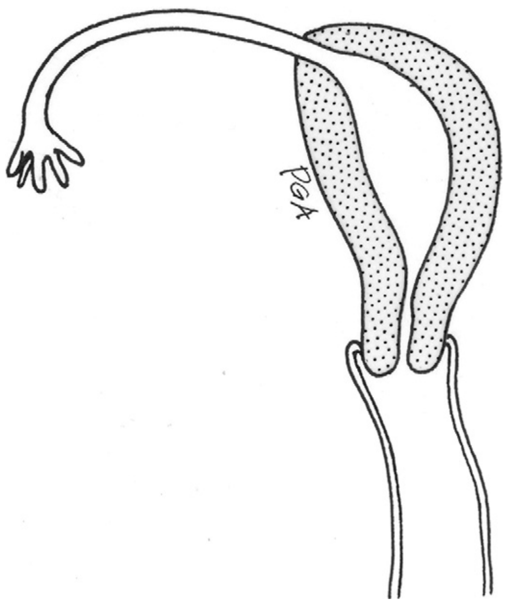

**FIGURE 124-17** Unicornuate system. (From Laufer MR. Structural abnormalities of the female reproductive tract. In Emans SJ, Laufer MR [eds]: Emans, Laufer, Goldstein's Pediatric and Adolescent Gynecology, 6th ed. Philadelphia, Lippincott Williams & Wilkins, 2011.)

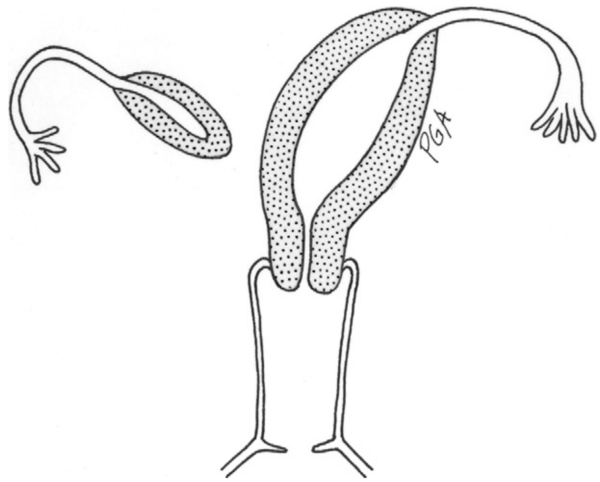

**FIGURE 124-18** Unicornuate system with an obstructed hemiuterus. (From Laufer MR. Structural abnormalities of the female reproductive tract. In Emans SJ, Laufer MR [eds]: Emans, Laufer, Goldstein's Pediatric and Adolescent Gynecology, 6th ed. Philadelphia, Lippincott Williams & Wilkins, 2011.)

uterus communicates with the cervix (Fig. 124-19). The remaining unicornuate system will most likely function normally but has an increased risk of breech presentation and premature labor.[35,125]

## Urogenital Sinus Anomalies

The urogenital sinus is defined as a common channel into which both the urinary and genital tracts open. The common urogenital sinus is a normal stage of embryonic development in both sexes. In normal females, an arrest in development of the müllerian ducts at 9 weeks' gestation, after fusion with the urogenital sinus, manifests as a urovaginal confluence or common urogenital sinus. An arrest of vaginal differentiation at a slightly later date can lead to varying degrees of persistence of the urogenital sinus seen clinically (Fig. 124-20). A long urogenital sinus with a short vagina and high urethral opening will result if the defect occurs at an early stage. Conversely, a short urogenital sinus with an almost normal vaginal vestibule and low urethral orifice will occur if the arrest occurs late in development.[127] Early defects with a high insertion of the vagina and urethra into the urogenital sinus are frequently associated with an anteriorly displaced anus. This indicates poor formation of the urorectal septum.

### DIAGNOSIS

Adequate definition of the patient's anatomy is essential for proper evaluation of any urogenital sinus anomaly. A retrograde genitogram (Fig. 124-21) can assist in the definition of the urogenital sinus by delineating the length of the common channel and identifying the anatomic relationship of the vagina and urethra.[128] This procedure is best done with a blunt adaptor placed against the perineal opening to instill the contrast agent. Cystoscopy and vaginoscopy should be performed in each case.

### TREATMENT

Once the anatomy of the defect has been clearly identified, various treatment options can be considered. A simple U-flap vaginoplasty[129] can be done if the urogenital sinus is low and the common channel is short. In the cases of a urogenital sinus with a high confluence of the bladder and vagina, Donahoe and Gustafson[130] advocate an inverted perineal U-flap in combination with bilateral buttock flaps to augment the vagina. However, the urogenital sinus is frequently associated with an anteriorly placed anus, which requires posterior relocation of the anus before the perineal skin flap vaginoplasty is done.[131] If the vagina enters the urogenital sinus too far proximally, a division of the vaginal moiety from the urogenital sinus in conjunction with a pull-through vaginoplasty will be necessary. A confluence of both the vagina and the bladder high in the urogenital sinus requires a pull-through vaginoplasty and often requires the creation of a neourethra from the anterior vaginal wall.[132]

## Cloacal Malformations

Cloacal malformations result from the combination of a urogenital sinus with an anorectal anomaly.[133] In the early embryo there is a cloacal stage during which there is a single common tract. At 4 to 6 weeks' gestation, the urorectal septum divides the allantois from the hindgut. If this separation does not take place, a common cloaca will result. Infants

with this defect present at birth with abdominal distention and an abnormal perineum. They usually have no anus or vagina but possess a single perineal opening. The phallus-like structure frequently has a hooded appearance, which gives a masculinized gender appearance (Fig. 124-22). The bladder may enter the cloaca immediately inside the perineal opening and may be associated with a relatively normal length urethra. Conversely, the bladder may enter the cloaca very high and be located in proximity to the bladder neck. The entrance of the rectum into the cloaca can similarly be either high or low (Fig. 124-23).[134] Vaginal anomalies are common in patients with a cloaca, and vaginal duplication is seen most often. There may also be significant perineal obstruction in these neonates, resulting in both hydrocolpos and an obstructive uropathy (Fig. 124-24).

## DIAGNOSIS

Diagnosis of a cloacal anomaly is confirmed by a retrograde contrast study through the single perineal opening. Frequently, these studies demonstrate a confluence of both the genitourinary and gastrointestinal systems. Blask and colleagues[135] reported on the usefulness of ultrasonography in nine neonates who had either an obstructed urogenital sinus or a cloacal anomaly. On abdominopelvic ultrasonography, the bladder was often compressed by the distended vagina and difficult to visualize. Typically, the vagina was markedly distended with urine and a vaginal fluid-debris level distinguished the vagina from a distended bladder. However, all components of the cloacal anomaly are often not identified on ultrasonography or retrograde studies. Therefore it is only

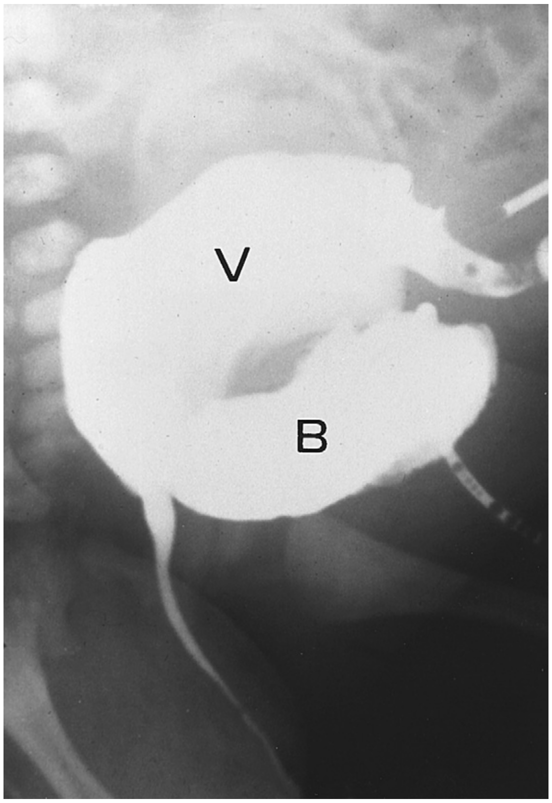

**FIGURE 124-21** Retrograde genitogram of a urogenital sinus showing a high confluence of the bladder *(B)* and vagina *(V)* into a long urogenital sinus.

at the time of panendoscopy or an open surgical procedure that the exact anatomy can be defined. Complete definition of the patient's anatomy is the first principle of treatment.[136] Information concerning cloacal exstrophy can be found in Chapter 119.

# Other Gynecologic Issues

## LABIAL ADHESIONS

Labial fusion is a common finding in infants and young children. Labial fusion may present as a primary skin bridge and may be associated with or identified at the time of an evaluation of a urinary tract infection. The etiology of labial adhesions is unknown. In most cases the adhesions are asymptomatic and do not require an intervention. They will usually resolve completely with exogenous estrogen production with puberty. The adhesions may be symptomatic, causing irritation, pulling sensation, or complaints of wetness due to trapping of urine in the vagina such that the child wipes after urination and then stands, only to have resulting wetness in her underwear from spontaneous evacuation of the trapped vaginal urine. In symptomatic cases the labial adhesions will easily respond to the twice-daily application of topical estrogen cream or a mild corticosteroid such as betamethasone 0.05%. A surgical intervention is rarely necessary and is reserved for cases of complete obstruction and the inability to urinate. If a surgical intervention is required, great care should be taken to make sure that the lysis of adhesions is performed without cutting into the normal labial tissue. If the normal labial tissue is incised, bleeding may occur and resulting scar tissue may not be estrogen responsive in the future. Thus daily topical application of conjugated estrogen cream should be the first line of therapy in almost all cases of labial adhesions.

## MASSES OF THE INTROITUS

A mass presenting at the introitus between the labia is often a diagnostic dilemma. The differential diagnosis includes prolapse of the urethra, prolapsed ectopic ureterocele, prolapsed yolk-sac tumor, and rhabdomyosarcoma (sarcoma botryoides). It is important to recognize each of these clinical entities and to understand the diagnostic and treatment criteria for each.

## URETHRAL PROLAPSE

Prolapse of the urethra (Fig. 124-25) occurs most commonly in the prepubescent years. Affected children frequently present with blood spotting on the underwear and a mass at the introitus. The tissue appears inflamed and friable and represents a prolapsed portion of the anterior or posterior urethra. The cause remains unclear. An accurate diagnosis depends on recognition of the entity. No special diagnostic studies are necessary. Medical treatment with sitz baths and topical estrogen cream is usually successful. Once treated medically with topical estrogen, an examination is necessary to be certain that a urethral polyp is not present. Operative treatment is rarely required, even in cases of distal necrosis. If a surgical procedure is used, it usually involves simple excision of the prolapsed segment, with suturing of the normal urethra to the meatus.[137] With a surgical procedure, complications are uncommon except for mild degrees of meatal stenosis after excision of the prolapsed segment. Valerie and colleagues[138] noted recurrence of prolapse in 1 of 20 patients treated by excision.

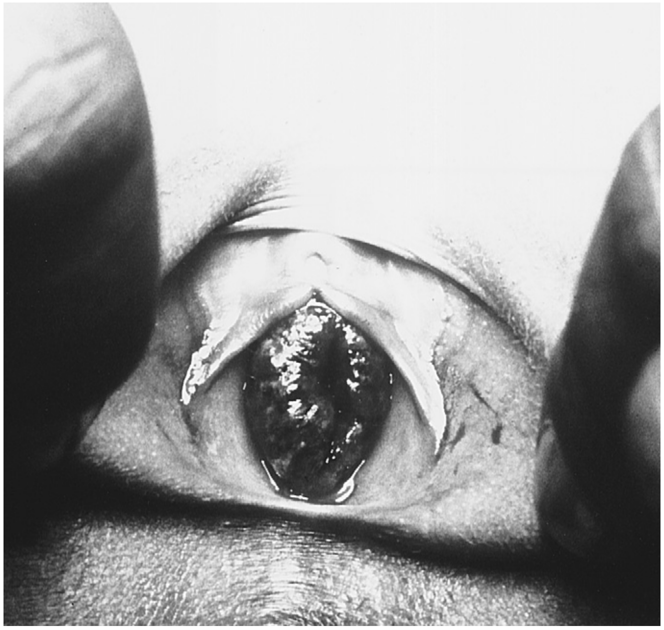

**FIGURE 124-25** Prolapsed urethra in a 9-year-old girl. Note the congested, necrotic appearance of the prolapsed tissue.

## PROLAPSED ECTOPIC URETEROCELE

Prolapsed ectopic ureteroceles can present as an intralabial introital mass (Fig. 124-26).[139] They are usually smooth and white or slightly edematous lesions that extrude from the urethral meatus. The urethral meatus can often be seen above the lesion. The diagnosis can usually be made on intravenous urography, which demonstrates a lower pole collecting system that is pushed laterally and inferiorly (i.e., drooping lily sign). The ureter is displaced away from the midline on the affected side, and the bladder has a filling defect (see Fig. 124-26).[140] Current management of these lesions is presented in Chapter 114.

## SARCOMA BOTRYOIDES

Sarcoma botryoides, or rhabdomyosarcoma of the bladder or vagina, is the most common malignant condition of the lower genitourinary system presenting in infancy.[141] The tumor may be observed protruding from the introitus. It often presents as blood spotting on the undergarments with the diagnosis then achieved by vaginoscopy and biopsy.[142] The lesion, as the name denotes, appears as a lobulated, grapelike mass (Fig. 124-27). The extent of the lesion is best determined by pelvic ultrasonography and CT. Rhabdomyosarcoma occurring at this primary site (vulvovaginal) is associated with an excellent outcome, with more than 90% of patients surviving with limited fertility-preserving surgery (including vaginoscopic resection) and multimodal chemotherapy.[142–146] Further details concerning management can be found in Chapter 34.

## YOLK SAC TUMOR

The vagina is a usual primary site for yolk sac tumors. These neoplasms can present protruding from the introitus or with vaginal spotting or bleeding.[147] These lesions are classified as endodermal sinus tumors (germ cell tumors), and affected patients frequently have an elevated serum alpha fetoprotein

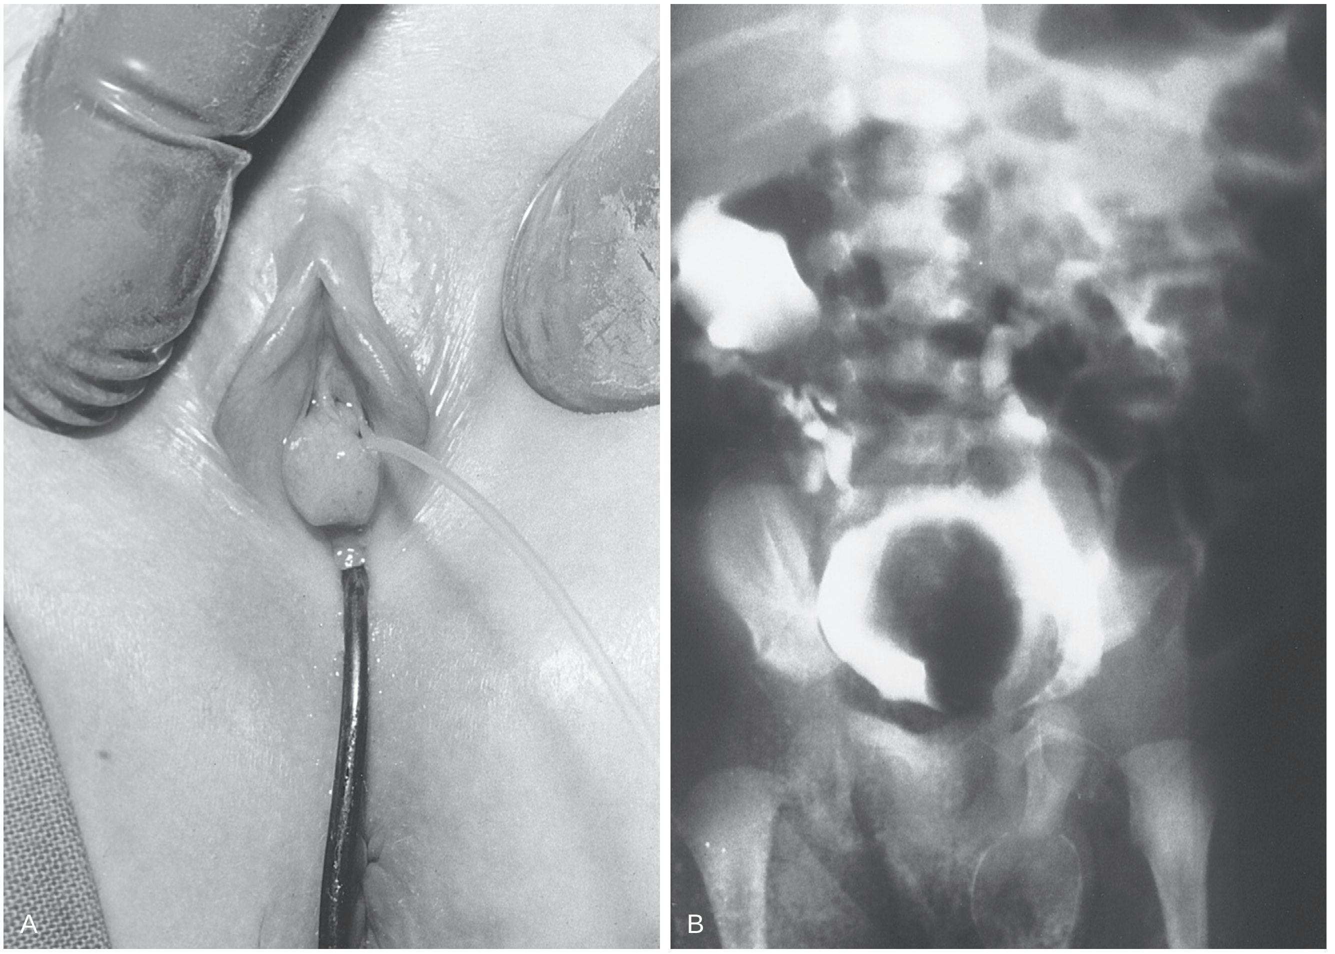

FIGURE 124-26 **A,** Prolapsed ureterocele in a 3-year-old girl. level. Germ cell tumors are treated with platinum-based chemotherapy programs and often have an excellent outcome (85% survival). Fertility-sparing vaginal surgery and adjuvant chemotherapy have been successful in these cases.[148,149] In fact, some cases have demonstrated resolution of the tumor with chemotherapy alone.[150] This topic is presented in depth in Chapter 39.

## MISCELLANEOUS INTROITAL LESIONS

Paraurethral cysts also present as interlabial masses in female infants.[151] They tend to displace the urethral meatus and vaginal introitus to one side. A normal urethra and vaginal introitus can usually be identified (see Fig. 124-20). These cysts are probably embryologic remnants of Skene glands or the Gartner duct. Most of these cysts regress spontaneously and rarely need to be incised and drained. The Gartner duct cysts are remnants of the wolffian duct and may be associated with unilateral renal dysplasia[152] and duplicated collecting system with ectopic ureter emptying into the vagina or rarely the cyst wall.[153,154] Goldstein and colleagues[153] were the first to describe the relationship of the Gartner duct cyst and ipsilateral renal agenesis in 1973. Both patients in that report had a bicornuate uterus. Patients often present with urinary tract infection and incontinence due to the ectopic ureter emptying into the vagina or the Gartner cyst wall.[155,156] Once the urinary tract abnormalities have been addressed, the Gartner cyst can either be excised or marsupialized.

# Other Vaginal Tumors

## HEMANGIOMA

Hemangiomas can occur in the vagina, as they can in many other tissues. Vaginal hemangiomas are occasionally extensive and coexist with hemangiomas affecting the skin and subcutaneous tissues of the perineum and perianal areas and rectal wall.[157] Conservative management is usually recommended because the natural history of these lesions suggests that spontaneous resolution will occur over a period of months to years. Ulceration and bleeding are complications that may require treatment with corticosteroids and interferon-α.[157] Failure of conservative treatment may require excision. Further information regarding hemangiomas is available in Chapter 124.

## ADENOCARCINOMA OF THE CERVIX AND VAGINA

Adenocarcinoma of the cervix and vagina is rare in children. Less than 3% of sexually active adolescents may show evidence of cervical intraepithelial neoplasia, and annual Papanicolaou smears have been recommended. In 1971 Herbst and colleagues[158] described the occurrence of clear cell adenocarcinoma of the vagina in young adolescent girls who were progeny of mothers who had received diethylstilbestrol during pregnancy. Offspring of women with this history are recommended to have a gynecologic examination by age 14 or after menarche and then annually thereafter. Vaginal clear cell adenocarcinoma has been observed in an infant who presented with hematuria.[159] In 2004 McNall and colleagues[160] reviewed 37 patients 18 years of age or younger with vaginal or cervical mesonephric adenocarcinoma and clear cell adenocarcinoma. The patients' ages ranged from 7 months to 18 years. The most common presenting symptoms were vaginal bleeding (89%) and/or discharge (16%). Sixty-two percent were exposed to diethylstilbestrol. Eight of 27 girls (21%) with vaginal tumors had metastases at diagnosis. Delay in diagnosis was common because of the lack of an appropriate pelvic examination in patients younger than 13 years old. Nine patients (36%) had not reached menarche. Seventy-six percent had International Federation of Gynecology and Obstetrics (FIGO) stage I or II disease, whereas 24% had stage III or IV (advanced-stage) disease. Twenty-two girls (58%) underwent a radical operative procedure (radical hysterectomy or pelvic exenteration): 19 had stage I or II disease, and in 3 the stage was undocumented. Seven of these patients received radiation therapy. Seven girls (18%) had tumor excision alone combined with radiation therapy in three and chemotherapy and radiation in one. Seven patients with advanced disease had no surgery. Three received radiation therapy, three had chemotherapy, and one had both. Overall, the 3-year disease-free survival was 71% (27/38). Ten patients died of progressive or recurrent disease. Relapse was an ominous finding. Sites of recurrence were the lungs in six patients, the lymph nodes or soft tissues in two, and the brain in one. The 3-year survival estimate for those undergoing surgical removal of tumor was 85%. Girls with tumor excision (conservative surgery) did better than those with radical surgery (100% 3-year survival vs. 78%), although there were only seven patients with tumor excision and four received adjuvant therapy. The study did not evaluate tumor size. Two of the seven patients with tumor excision had stage III disease, whereas all of those undergoing radical surgery had stage I or II disease. The only statistically significant predictors of survival were surgical resection and the presence of metastases at diagnosis. The data suggest that conservative surgical treatment with adjuvant therapy may obviate the need for radical surgery. A prospective randomized study in a larger number of patients is necessary to confirm these observations. Because of the rarity of the tumor, this may be difficult to achieve. Long-term follow-up is important in these patients because late recurrences have been observed.[161,162]

CHAPTER 125

# Vascular Anomalies

Ann M. Kulungowski and Steven J. Fishman

A reliable classification system for vascular anomalies was developed 30 years ago.[1] Vascular anomalies are divided into two categories, tumors and malformations, on the basis of clinical behavior and cellular kinetics.[2] Vascular tumors are characterized by endothelial hyperplasia; vascular malformations arise due to vascular dysmorphogenesis and exhibit normal endothelial turnover.[2] The classification scheme provides the framework for understanding the pathophysiology, diagnosis, and prognosis of these lesions.

Pediatric surgeons are often called on to assist with diagnosis and treatment of vascular anomalies. The majority of lesions are noted at birth or during infancy because they commonly involve the skin. A thorough history and physical examination leads to the correct diagnosis in more than 90% of patients. Familiarity with the field of vascular anomalies, its classification scheme, and use of correct nomenclature will ultimately improve outcomes for patients affected by these lesions.

## Historical Perspective

Historically, vascular birthmarks were thought to be imprinted on the unborn child due to a mother's emotions.[1,3] The use of adjectives such as "strawberry" and "port wine" are reflected in this doctrine of maternal impressions.[4] Physicians preferred the Latin term *naevus maternus*. In the nineteenth century, Virchow is likely the first to have categorized vascular anomalies on the basis of histologic features.[4]

For centuries, the field has been plagued by overlapping vernacular, clinical, and histopathologic terms resulting in misdiagnosis, inappropriate treatment, and misdirected research. A common example is the continued application of the word "hemangioma" to describe vascular lesions of any kind irrespective of behavior and biology. The biologic classification system in use today was formally accepted in 1996 by the International Society for the Study of Vascular Anomalies (Table 125-1).[5] In addition to classifying tumors and malformations based on cellular and clinical behavior, they also exhibit their own unique radiographic findings and immunohistochemical properties.[2]

## Vascular Tumors

### INFANTILE HEMANGIOMA

Infantile hemangiomas (IHs), benign tumors of the endothelium, are the most common tumor of infancy (Fig. 125-1). It occurs in approximately 4% of white-skinned infants. A frequently quoted study probably overestimated the incidence of 10% by including other vascular lesions.[6] The incidence is lower in dark-skinned babies. There is a female-to-male preponderance of 3:1 to 5:1.[2] Extremely-low-birth-weight infants (<1000 g) have the highest incidence of IHs, approaching 23%.[7] Additional risk factors include advanced maternal age, multiple gestations, and placental abnormalities.[8]

IHs most often occur as a single cutaneous lesion (80%) with a predilection for the head and neck (60%), trunk (25%), and extremities (20%) (see Fig. 125-1).[9] Multiple tumors are present in up to 20% of patients and, when present, may signal involvement of extracutaneous organs such as the liver or gastrointestinal (GI) tract.[2] Median age of onset is 1 to 2 weeks. A premonitory cutaneous mark such as a pale spot or faint macular stain is present at birth in 30% to 50% of cases.[2] The majority (90%) of IHs are small, localized lesions that do not involve aesthetically or functionally vital structures.[2,10]

A hallmark of IH is its predictable life cycle (Fig. 125-2). During the proliferating phase, there is rapid growth of the tumor, which typically lasts until 10 to 12 months of age. Superficial hemangiomas are red; deeper lesions may be noted later as a blue mass visualized through the skin. Around 12 months of age, growth of the IH plateaus, marking the beginning of the involuting phase. Over the next 6 to 7 years, the crimson color fades, the center becomes pale, and the lesion appears to deflate.[2] By 5 years of age, 50% of tumors have completed involution, which increases to 70% at 7 years of age. There is often continued gradual regression of the color and bulk of the tumor until 10 to 12 years of age.[11] When the IH has ceased involuting, it enters the involuted phase. At the end of involution, 50% of patients have nearly normal skin in the area of the prior lesion. Large tumors can leave lax, redundant skin and/or a fibrofatty residuum. Previously ulcerated lesions can leave permanently damaged skin, scars, and discoloration.[2]

Endangering or life-threatening IHs are rare.[12] Recognition of the anatomic distribution of the lesions helps predict possible complications. Cervicofacial and subglottic IHs can be life-threatening due to airway obstruction.[2] Subglottic IHs are characterized initially by hoarseness and later biphasic

stridor around 6 to 12 weeks of age. Ulceration of the eyelid, nasal tip, lip, and ear can be disfiguring. Periorbital IHs can block the visual axis and cause deprivation amblyopia; upper eyelid and supraorbital lesions can distort the cornea, producing astigmatic amblyopia. Infants with periorbital hemangioma should be examined by a pediatric ophthalmologist. GI IHs can cause GI bleeding. Complications of hepatic hemangioma include high-output cardiac failure, hypothyroidism, and abdominal compartment syndrome.

The occurrence of multiple IHs is called hemangiomatosis (see Fig. 125-1, *left, middle*). In this setting, the cutaneous lesions are usually tiny (<5 mm) and domelike, but some may have the more typical appearance of a single tumor. Occult visceral lesions may be present when multiple cutaneous IHs (usually five or more) are found. Screening ultrasonography may be indicated. The liver is the most frequently involved location.

***Etiology and Pathogenesis*** The exact etiology and pathogenesis of IH remains to be elucidated. There is emerging evidence for an endothelial stem/progenitor cell as the cellular origin of hemangioma.[13–15] The source of these endothelial progenitors remains elusive. Some studies suggest a population of resident angioblasts, arrested in an early stage of vascular development, as a source. Hemangioma endothelial cells may be of placental origin because they coexpress several markers: glucose transporter-1 (GLUT-1), type III iodothyronine deiodinase, Fc$\gamma$-RIIb, merosin, and Lewis Y antigen.[16–20] Disruption of the maternal-fetal barrier may allow an embolic nidus of placental endothelial cells to reach fetal tissues through the permissive right to left shunt of fetal circulation.[21] This could explain the increased incidence of IH observed with chorionic villus sampling and prematurity, sometimes a result of placental disorders.[22]

The characteristic growth and involution of IH seen on physical examination parallel the cellular activity of the tumor. During the proliferating phase, angiogenesis occurs as endothelial cells rapidly divide, forming a mass of sinusoidal vascular channels with feeding arteries and draining veins.[23–25] A proangiogenic environment is created by the presence of factors such as basic fibroblast growth factor, vascular endothelial growth factor, and matrix metalloproteinases. In contrast, angiogenesis is decreased during the involuting phase as endothelial cells undergo apoptosis.[26] This coincides with increased expression of angiogenesis inhibitors such as interferon-$\beta$ and tissue inhibitor of metalloproteinase.[23,24]

***Associated Structural Abnormalities*** Congenital abnormalities are rarely associated with IH, but larger hemangiomas and those encountered in the midline merit attention. A subgroup of patients with IH exhibits associated structural anomalies of the brain (e.g., posterior fossa abnormalities), cerebral vasculature (e.g., hypoplasia or absent carotid and vertebral vessels, aneurysms), eye (e.g., cataracts and optic nerve hypoplasia), aorta (e.g., coarctation), and chest wall defects (e.g., sternal clefts) in the neurocutaneous disorder called PHACES syndrome (*P*osterior fossa malformations, *H*emangioma, *A*rterial anomalies, *C*ardiac defects, *E*ye anomalies, and *S*ternal defects).[27–30] Tumors of the lumbosacral region may occur along with spinal dysraphism abnormalities such as a tethered cord or lipomeningocele. Ultrasonography is used to screen infants younger than 4 months of age for the presence of

**FIGURE 125-1** Morphologic variation of infantile hemangioma (IH). Proliferating phase IH on the trunk *(left)*. Multiple cutaneous dome-shaped IHs, which are often seen in association with hepatic hemangioma *(left, middle)*. Proliferating IH in the perineum *(right, middle)*. Reticular IH over the midline *(right)*.

FIGURE 125-2 Progression and involution of infantile hemangioma (IH) in the beard distribution. Proliferating IH at 2 weeks of age *(top, left)*. Corticosteroid treatment initiated. After 2 weeks of therapy *(top, middle)*. Notice ulcerated area in lower lip. Ulceration has healed after 6 weeks of corticosteroid (2 months) *(top, right)*. Continued proliferation of IH despite therapy (3 months) *(bottom, left)*. Corticosteroid was weaned with rebound growth (age 11 months) *(bottom, middle)*. Propranolol therapy was initiated. After 6 months of propranolol therapy *(bottom, right)*. IH has decreased in size (18 months).

occult spinal dysraphism; magnetic resonance imaging (MRI) may be necessary in older children. Anorectal and genitourinary anomalies can occur with IH of the pelvis or perineum, sometimes as part of PELVIS syndrome (*P*elvic hemangioma, *E*xternal genital malformations, *L*ipomeningocele, *V*esicorenal, *I*mperforate anus, *S*kin tags).[31] A macular, network-like hemangioma of the lower extremity has been seen with structural anomalies of the ventral-caudal region, visceral hemangiomas, and cardiac overload.[32]

***Radiologic Features*** Radiographic studies assist with classifying indistinguishable vascular tumors. Ultrasonographic features of proliferating IHs include a focal fast-flow soft tissue mass with increased vessel density.[33,34] MRI is the second-line study and reserved for further clarification in the face of diagnostic uncertainty to confirm the extent and tissue characteristics of the lesion. MRI characteristics of a proliferative-phase IH reveal a solid mass with dilated feeding and draining vessels (Fig. 125-3). IHs are of variable intensity on T1 and are hyperintense on T2.[35] Flow voids are seen around and within the mass.[35] As the IHs involute, vessels decrease in size and number. Involuted IHs are seen as avascular fatty masses on MRI.[36]

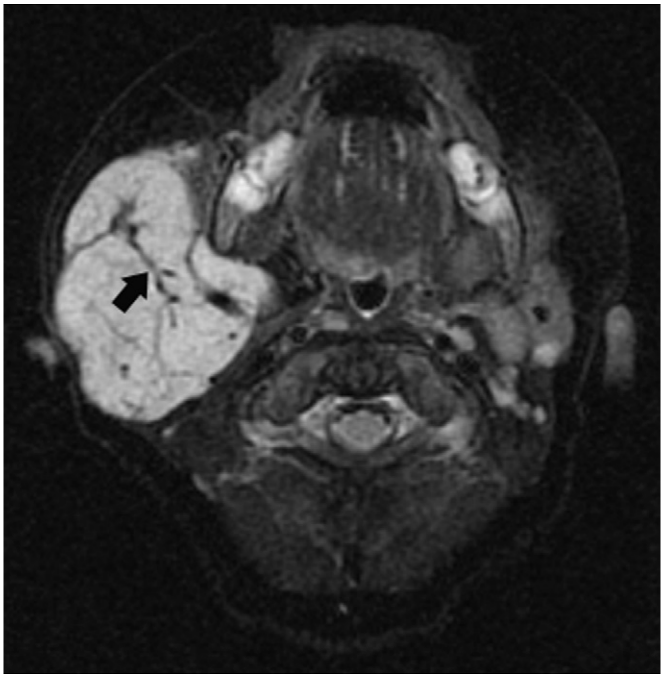

FIGURE 125-3 Magnetic resonance imaging (MRI) of infantile hemangioma (IH). Axial T2 weighted fat-saturation MRI sequence of a parotid IH, which shows a well-circumscribed, uniformly hyperintense mass with dilated feeding and draining vessels *(arrow)*.

***Treatment***

**Observation and Local Treatment** The majority of IHs require no specific treatment other than observation. Even if the proper decision is not to intervene, this does not mean that

nothing should be done.[2] The consultant plays a crucial role in providing guidance and support.[37] Regularly scheduled follow-up is imperative. Serial photographs are useful to document progression, response to treatment, and subsequent regression. Disfiguring hemangiomas, particularly when located on the face, frequently evoke strong parental emotions of loss and grief. Deformity and severe complications occur in 10% cases.[12]

The most frequent complications of proliferating cutaneous IHs include epithelial breakdown, ulceration, bleeding, and pain. The lips, perineum, and parotid area are especially vulnerable to ulceration.[38] Treatment of ulceration includes daily cleansing; application of petrolatum and viscous lidocaine may be used for pain control. Superficial ulceration usually heals within days to weeks, whereas a deep ulceration may take several weeks.[2] Eschars should be debrided and treated with wet-to-dry dressings to stimulate granulation tissue. Total excision of an ulcerated IH is usually reserved for lesions of the chest, scalp, extremity, and rarely for facial lesions when primary closure is possible.

**Pharmacotherapy** Systemic pharmacologic intervention may be necessary for endangering, ulcerating, problematic, or life-threatening IHs. Corticosteroids inhibit the vasculogenic potential of hemangioma-derived stem cells, as well as the expression of vascular endothelial growth factor.[39] Prednisone or prednisolone is administered in the morning at 2 to 3 mg/kg/day for 2 weeks. Initial improvement in color and tension is usually evident in the first 1 to 2 weeks. If the IH stabilizes, the dosage is tapered every 2 to 4 weeks with a goal of discontinuation by 10 to 11 months of age. The overall response rate is 80% to 90%. In some cases the tumor may exhibit rebound growth as the corticosteroid is tapered. A return to the initial dose and slower taper will usually suffice. Possible side effects of corticosteroid include Cushingoid facies, irritability, GI reflux, a slowing in the rate of height and weight gain, steroid-induced cardiomyopathy, and hypertension.[40–42] Nearly all children (88%) return to their pretreatment curves for height and weight within 24 months.[41] Live vaccines (e.g., polio, measles, mumps, rubella, varicella) should not be administered during corticosteroid treatment.

Intralesional injection of corticosteroid for well-localized tumors of the nasal tip, cheek, lip, or eyelid is used to minimize deformity. There are reports of retinal artery occlusion and eyelid necrosis, presumably from embolization of colloidal particles.[43,44] Compression at the periphery of the lesion will help minimize this risk. Triamcinolone (25 mg/mL) is injected slowly at a low pressure with a 3-mL syringe and 25-gauge needle. The dosage is 3 to 5 mg/kg per injection.[45] Additional injections can be done at 6- to 8-week intervals; usually, three to five are necessary.[45] Response rates are similar to that of oral corticosteroid.

Propranolol, a nonselective beta blocker, is being used with increasing frequency for the treatment of IHs.[46] Early reports suggest that propranolol may be as efficacious as corticosteroids for the treatment of problematic IHs.[46–48] The mechanism of action for propranolol is unknown; theories include vasoconstriction of the tumor vasculature or downregulation of angiogenic proteins.[46,48] An ongoing, prospective, randomized controlled trial will help elucidate propranolol's safety, efficacy, and tolerability for the treatment of IHs.

Recombinant interferon-alfa has fallen out of favor as second-line therapy due to the risk of spastic diplegia, which occurs in 5% to 20% of treated infants, particularly those younger than 6 months of age.[49,50] More suitable second-line agents are chemotherapeutic drugs with antiangiogenic properties such as vincristine. The drugs are administered in a low-dose, high-frequency metronomic regimen.

**Embolic Therapy** Rarely, embolization is indicated for IHs that result in congestive heart failure and do not respond to drug therapy. Hepatic hemangiomas are the most common lesions to require embolization. Its effectiveness is determined by the ability to occlude a large percentage of the shunts. Infants are maintained on pharmacotherapy even after an apparently successful embolization.[2]

**Laser Therapy** Flashlamp pulsed-dye laser is not beneficial for nascent or proliferating hemangiomas. It penetrates only the most superficial portion of the dermis and leaves the majority of the lesion untreated. Moreover, a superficial IH is often the tumor that requires no treatment and involutes without a trace. Laser treatment carries the risks of scarring, ulceration, and hypopigmentation. In the involuting/involuted phase, remnant telangiectasias can be effectively treated with pulsed-dye laser. The use of endoscopic continuous-wave carbon dioxide laser can control proliferating, unilateral subglottic IHs.[51]

**Surgical Therapy** Indications for surgical resection vary according to patient age and hemangioma stage. During infancy (proliferating phase), excision may be necessary for IHs causing ulceration, obstruction, and bleeding. Occasionally, a well-localized or pedunculated lesion may be removed when the scar formed would be similar to that if the excision were to occur at a later stage. Sites most amenable to resection during this phase include the scalp, trunk, and extremity due to skin laxity. IHs of the forehead, eyelid, cheek, lips, nose, nasal tip, ear, and neck require surgical expertise.

IHs of the stomach, small intestine, or colon can present with mild or life-threatening GI bleeding during infancy. Endoscopy or laparoscopy, or both, are sometimes necessary to localize lesions of the small bowel.[52] Most infants with GI hemangiomas are medically managed with pharmacotherapy and intermittent blood transfusions. Focal lesions that are not responsive to drug therapy can be treated with endoscopic band ligation or segmental bowel or wedge resections. More commonly, though, GI hemangiomas present with diffuse, patchy involvement, making endoscopic and surgical intervention problematic.[53] Extensive resections should not be performed. These infants should be supported medically. Involution and cessation of bleeding will eventually occur.

Removal of IHs during the involuting phase may be considered for large, protuberant lesions, which are likely later to be associated with excess skin or a large fibrofatty residuum. Indications for resection include inevitable excision, need for staged excision, ability to hide the scar, and desire to avoid an altered self-image.[2] Waiting until the involuted phase to determine the need for resection is reasonable barring any endangering or life-threatening complications. Many IHs involute, leaving normal or minimally blemished skin. Ulceration increases the likelihood of scar. Excision may be considered during late childhood (involuted phase) for damaged skin and contour deformity.

Surgeons would agree that the scar for resection of IH should be minimized irrespective of indication and timing.[54] Lenticular excision with linear closure is the usual method for removal of an ovoid mass. The incisional length often

extends beyond the lesional border into uninvolved skin in an effort to avoid terminal dog-ears. Lenticular excision may be used when a transverse incision is necessary. Convex areas such as the cheek and forehead are susceptible to central flattening when lenticular excision and linear closure are used. Instead, circular excision and intradermal purse-string closure are particularly applicable. Radial folds may be evident initially and usually smooth out rapidly within weeks.[54] Staged excisions are possible with this method.

## CONGENITAL HEMANGIOMA

Unlike IHs, congenital hemangiomas are present at birth and do not exhibit postnatal growth. Two different lesions are recognized: rapidly involuting congenital hemangioma (RICH) and noninvoluting congenital hemangioma (NICH). Most lesions are solitary. There is no gender bias. These lesions are further distinguished from IH by staining negatively for GLUT-1.

RICHs undergo involution early, often beginning before birth. Involution is complete between 6 and 14 months of age.[55] RICHs commonly affect the head/neck and extremities.[55,56] On physical examination, the lesions are raised, firm, pink to violaceous with central depression or ulceration and a surrounding pale rim (Fig. 125-4). Coarse telangiectasias are often present.[55] After involution, the residual area often appears deflated and is not accompanied by the usual fatty residuum of IH.[56] Prenatal detection is possible because RICHs arise in utero.[55,57,58]

NICHs present as bossed, round-to-ovoid shape lesions in shades of pink to purple. The average diameter is 5 cm. There may be overlying coarse telangiectasia.[59] NICHs most commonly affect the head/neck (43%) followed by the limbs (38%) and trunk (19%). As the name implies, NICHs do not undergo involution and persist essentially unchanged.[59] Although they are tumors histologically, the static behavior of NICHs resembles that of a malformation.

RICHs and NICHs are fast-flow by Doppler evaluation. RICHs exhibit large flow voids near the surface and have areas that enhance inhomogenously on MRI. Arterial aneurysms and direct arteriovenous shunts can be seen on angiography.[56] NICHs and IHs are indistinguishable radiographically. The differential diagnosis of congenital hemangioma includes infantile fibrosarcoma.[60] Biopsy must be performed when the diagnosis is in question. The periphery of the lesion should be included in the biopsy specimen because lobular architecture is preserved here in congenital hemangioma.[56]

## HEPATIC HEMANGIOMA

Infantile hepatic hemangiomas (HHs) must be differentiated from so-called “hepatic hemangiomas” that are seen in adulthood. Adult “hepatic hemangiomas,” also referred to as “cavernous hemangiomas,” are actually venous malformations. Conversely, hepatic hemangiomas of infancy are true vascular tumors. HHs present in one of three recognizable patterns: focal, multifocal, and diffuse.[61] The majority of HHs are not life-threatening and involute without long-term sequelae.

Focal HHs are likely the hepatic equivalent of the cutaneous RICHs. Focal HHs are GLUT-1 negative. These tumors are fully grown at birth and involute faster than multifocal or diffuse lesions, which are typical infantile hemangiomas. There is no gender predilection. Cutaneous IHs are rarely present. They can be detected on antenatal ultrasound because they develop antenatally.[62] Transient thrombocytopenia and anemia are observed in some infants due to intralesional thrombosis. Contrary to previous beliefs, true Kasabach-Merritt phenomenon is not observed with focal HH. Most lesions are discovered as an abdominal mass in an otherwise healthy infant. A subset of these focal lesions, however, results in high-output cardiac failure due to the presence of macrovascular high-flow shunts (arteriovenous or portovenous). These shunts can cause steal accounting for blood-flow demands above and beyond the hypervascular tumor parenchyma. As the tumor involutes, the shunts usually close. The benefit of pharmacotherapy is unknown because these lesions are biologically distinct from cutaneous and hepatic infantile hemangiomas and involute rapidly. Nevertheless, medical therapy is attempted when treatment is indicated because it is less invasive and more widely available than embolization. Skilled pediatric interventional radiologists can frequently successfully embolize symptomatic shunts to improve heart failure while protecting major hepatic vessels. Resection is almost never indicated.

Multifocal HH is a true infantile hemangioma. This lesion was formerly known as *infantile hemangioendothelioma* because of histologic similarities with kaposiform hemangioendothelioma, a cutaneous tumor with a more aggressive behavior (see later). Females are more affected than males. These lesions are GLUT-1 positive. Most infants are asymptomatic and require no treatment. Multifocal HHs often come to

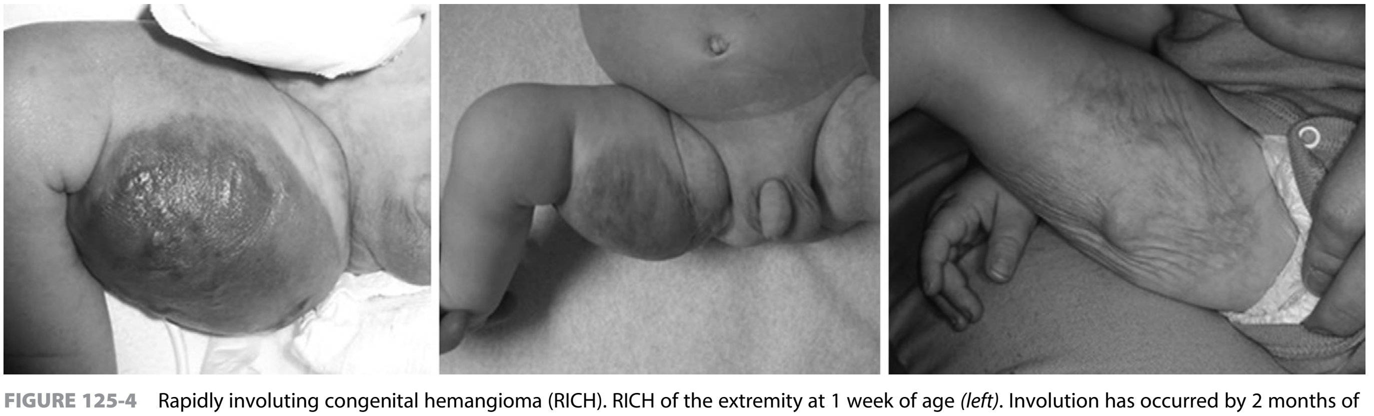

**FIGURE 125-4** Rapidly involuting congenital hemangioma (RICH). RICH of the extremity at 1 week of age *(left)*. Involution has occurred by 2 months of age *(middle)*. By 1 year of life the RICH has completely involuted *(right)*.

clinical attention while screening for visceral hemangioma on the basis of the presence of multiple cutaneous infantile hemangiomas. Occasionally, an infant can present in high-output cardiac failure due to macrovascular shunting. Corticosteroid is used to treat symptomatic infants in an effort to close shunts. Propranolol use is increasing.[63] Asymptomatic infants without shunts do not require therapy. Embolization is sometimes necessary to improve heart failure when the lesions are refractory to pharmacotherapy or if time is insufficient to allow for clinical improvement. Infants with multifocal HHs should be followed closely with serial abdominal ultrasonography until involution of their hemangiomas.

Diffuse HHs are the most feared. These lesions are also true IHs. There is a female gender bias. The normal liver parenchyma is almost completely replaced by innumerable compact, nodular tumors. The massive hepatomegaly can compress the inferior vena cava and thoracic cavity leading to abdominal compartment syndrome, respiratory distress, and multiorgan failure. All IHs express type 3 iodothyronine deiodinase, which converts thyroid hormone to its inactive forms, resulting in an acquired hypothyroidism.[20] This is most prevalent in diffuse HHs but is sometimes seen with multifocal HHs. Levels of type 3 iodothyronine deiodinase are proportional to tumor burden, placing infants with diffuse HHs (and occasionally larger multifocal HHs) at risk for hypothyroidism. Exogenous thyroid hormone replacement, often in large quantities, is necessary to prevent mental retardation and cardiac failure.[20] Serum TSH should be checked in all patients with larger multifocal and diffuse HHs. Hypothyroidism improves with tumor involution. Corticosteroid and increasingly propranolol are given for diffuse HHs to accelerate tumor involution. Hepatic transplantation may occasionally be indicated in some infants in extremis without time to wait for a response to pharmacologic therapy.[61] Other extraordinary maneuvers in the presence of respiratory distress and abdominal compartment syndrome include temporary abdominal enlargement with Silastic sheets or silos and low-dose vincristine treatment.[64,65]

HHs exhibit unique radiographic patterns, which aid in diagnosis. On computed tomography (CT), focal HHs are heterogeneous. Enhancement is usually centripetal with central sparing due to thrombosis or necrosis. Calcifications can also be evident and increase as the tumor involutes.[66] MRI of focal HHs shows a well-defined, solitary, spherical tumor (Fig. 125-5). It is hypointense relative to liver on T1 and hyperintense on T2. Centripetal enhancement is seen on gadolinium sequences. The solid, nonthrombosed portions at the periphery demonstrate intense homogeneous enhancement (see Fig. 125-5). Centrally there is heterogeneous enhancement due to necrosis, thrombosis, or intralesional hemorrhage.[61]

Multifocal and diffuse HHs on CT appear as multiple well-defined, spherical lesions. Multifocal HHs will have intervening normal hepatic parenchyma, whereas diffuse lesions nearly totally replace the liver. Without contrast the lesions are hypodense relative to the liver. They enhance centripetally with contrast. In comparison with focal lesions, there is no thrombosis, necrosis, or central sparing. The supraceliac aorta is usually dilated and tapers distally. Enlarged hepatic arteries and veins may indicate shunting.[66] Flow-voids can be seen in and around the lesions. On MRI, the lesions enhance homogenously and are hypointense relative to liver on T1 and hyperintense on T2 (see Fig. 125-5).[66]

Close follow-up is mandatory, especially in the first few months of life, because clinical deterioration is possible. The differential diagnosis of HH is broad and includes arteriovenous malformation, arterioportal fistula, mesenchymal hamartoma, hepatoblastoma, angiosarcoma, and metastatic neuroblastoma. Percutaneous needle or open biopsy should not be delayed in the face of diagnostic uncertainty.

## PYOGENIC GRANULOMA

Pyogenic granuloma is a benign, acquired vascular lesion of the skin and mucous membranes seen in children and pregnant women.[67] Pyogenic granulomas rarely occur before 6 months of age. The etiology is unknown. Most lesions are not associated with trauma or dermatologic conditions.[67] They develop as small erythematous papules that enlarge to 5 mm to 10 mm, mostly seen in the head and neck area (Fig. 125-6). The lesions bleed easily and are often pedunculated.[68] Treatment options include curettage, full-thickness excision with linear closure, shave excision and cautery, cautery alone, and laser phototherapy.[69] Silver nitrate can be used for small pyogenic granulomas. Larger lesions may require liquid nitrogen. Recurrence is high (45%) when pyogenic granuloma is not completely excised or ablated.[67]

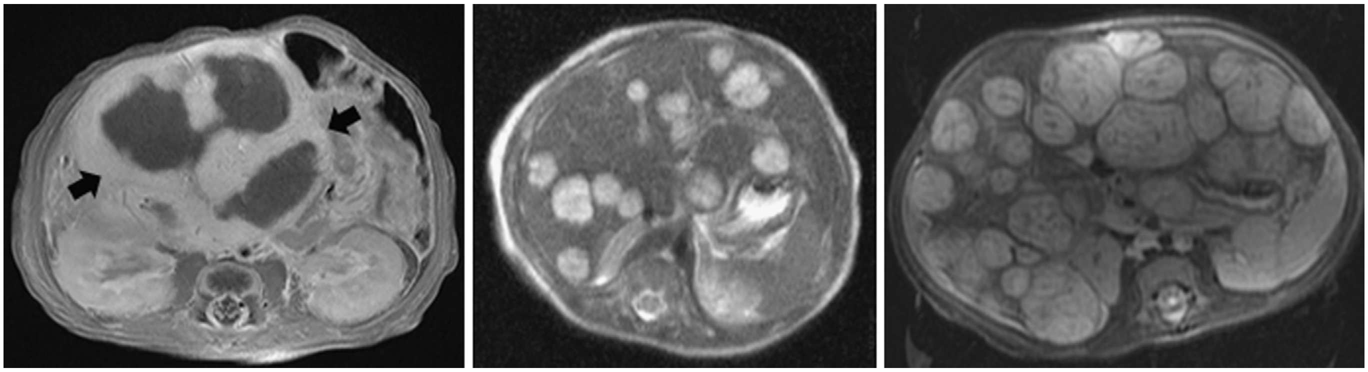

**FIGURE 125-5** Axial magnetic resonance images of hepatic hemangioma. T1 postcontrast appearance of a focal hepatic hemangioma *(left)*, which demonstrates peripheral enhancement *(arrows)* with sparing centrally due to thrombosis or scar. T2 images of multifocal hepatic hemangioma *(middle)*. Lesions are hyperintense relative to liver. T2 sequences of diffuse hepatic hemangioma show near-total hepatic parenchymal replacement *(right)*.

## KAPOSIFORM HEMANGIOENDOTHELIOMA AND KASABACH-MERRITT PHENOMENON

Sixty years after the initial report by Kasabach and Merritt, we have learned that the findings of an enlarging vascular lesion and thrombocytopenia are never associated with infantile or congenital hemangioma.[70] Additional features of Kasabach-Merritt phenomenon include microangiopathic hemolytic anemia and a mild consumptive coagulopathy.[71] Kasabach-Merritt phenomenon occurs with more aggressive and invasive vascular tumors such as kaposiform hemangioendothelioma (KHE), kaposiform lymphatic anomaly (KLA), and tufted angioma (TA).[72–74] These tumors are biologically distinct from infantile hemangioma.[75] The term "Kasabach-Merritt phenomenon" is often used mistakenly to describe transient moderate neonatal thrombocytopenia seen with focal hepatic hemangioma (RICH), as well as a localized intravascular coagulopathy seen with some extensive venous and lymphatic malformations.

KHE and TA are typically present at birth, although they may also appear postnatally. There is an equal gender distribution. The tumors are unifocal and mostly located on the trunk and extremities. KHE can occur in the retroperitoneum. TA appears as erythematous macules; Kasabach-Merritt phenomenon may also be evident. KHE is more extensive than tufted angioma and can rapidly expand. KHE continues to proliferate into early childhood followed by incomplete regression in midchildhood. The superficial component of KHE appears in the skin and causes a red-purple discoloration with surrounding ecchymosis (Fig. 125-7). Generalized petechiae may be apparent due to profound thrombocytopenia (<10,000 platelets/μL). Infants with Kasabach-Merritt phenomenon are at risk for intracranial, pleural, pulmonary, peritoneal, and GI hemorrhage. Thrombocytopenia is unresponsive to platelet transfusion due to intralesional trapping. The prothrombin time and activated partial thromboplastin time are usually normal to mildly elevated. D-dimer is increased while fibrinogen is low. KHEs less than 8 cm in size are less likely to have Kasabach-Merritt phenomenon.[76]

Histopathology of KHE reveals aggressive infiltration of normal tissues by sheets or lobules of oval or spindled endothelial cells, dilated lymphatic channels, and slitlike vascular spaces filled with hemosiderin and compacted erythrocytes suggesting stasis.[74] When lymphatic channels predominate, the condition is called KLA. The microscopic appearance of TA shows tufts of capillaries in the middle to deep dermis.[77]

On MRI, KHE demonstrates enhanced signal on T2. Tumor margins are not well defined. The tumor does not respect tissue planes as it passes through skin down to muscle. There is stranding in the subcutaneous fat due to lymphatic obstruction or invasion. Feeding and draining vessels are small relative to tumor size. Osteolysis may be evident when KHE is adjacent to bone.[74] Imaging patterns are similar for TAs.

The treatment for KHE and TA with Kasabach-Merritt phenomenon is primarily medical. Due to its size and permeation of multiple tissue planes, KHE can rarely be resected safely. Drug options include corticosteroid, vincristine, or interferon. No treatment is uniformly effective. Vincristine has been associated with improved platelet counts.[71] Platelet transfusions should not be given unless there is active bleeding. Heparin should be avoided because it can stimulate tumor growth, exacerbating platelet trapping and thrombocytopenia. For KHE not associated with Kasabach-Merritt phenomenon, the decision to treat should be based on size, location, treatment side effects, and long-term complications (such as joint

**FIGURE 125-7** Kaposiform hemangioendothelioma (KHE) with Kasabach-Merritt phenomenon (KMP). KHE of the chest at 2 years of age *(left)*. Appearance at 6 years of age after treatment with vincristine and resolution of KMP *(middle)*. Tumor regression has resulted in joint contracture. Further involution at 8 years of age *(right)*.

contracture or myofascial pain syndromes).[76,78] All infants should be followed closely because mortality is high (20% to 30%). Previously quiescent tumors can be associated with recurrent Kasabach-Merritt phenomenon.

### OTHER RARE AND MALIGNANT VASCULAR TUMORS

Infants with cutaneovisceral angiomatosis with thrombocytopenia present with multiple red to brown cutaneous lesions in one or multiple sites. The skin lesions are present at birth and may be mistaken for infantile hemangioma. Infants may present with GI bleeding or hemoptysis. GI endoscopy demonstrates multiple, flat, red lesions. The lung parenchyma may also be involved. The lesions proliferate throughout early infancy. Histology shows variable endothelial hyperplasia. Due to the rarity of cutaneovisceral angiomatosis, optimal treatment has not been delineated. It is postulated that angiogenic inhibitors may be of benefit.[79]

Angiosarcoma is a rarely encountered aggressive malignancy in children. It is characterized by rapidly proliferating, infiltrating anaplastic cells derived from blood vessels. Angiosarcomas occur in soft tissue, bones, and viscera (liver, spleen, and heart). More common locations in the pediatric age group include the head, neck, and mediastinum.[80] Environmental exposure to arsenic and vinyl chloride can increase the risk of angiosarcoma. The most efficacious treatment is resection. Curative resections are rare given that many angiosarcomas are not limited to one anatomic area. They have a high rate of local recurrence and metastasis.

Kaposi sarcoma is a low-grade vascular neoplasm mediated by the human herpesvirus-8. The endemic/African clinical subtype is seen in the pediatric population. Unlike adults, children rarely present with cutaneous findings. Generalized lymphadenopathy may be their only presenting symptom. Definitive diagnosis requires histologic examination.[81]

## Vascular Malformations

Vascular malformations are localized or diffuse errors of development that may affect any segment of the vascular tree including arterial, venous, capillary, and lymphatic vessels. They are named on the basis of the predominant channel type and flow characteristics (Table 125-1). Slow-flow anomalies include capillary, lymphatic, and venous malformations; fast-flow lesions include arteriovenous malformations and arteriovenous fistulae. Vascular malformations, unlike vascular tumors, which expand postnatally, exhibit growth commensurate with that of the child. The prevalence of congenital vascular malformations is 1.2% to 1.5%.[21] Most vascular malformations are sporadic. Some inherited forms have been observed, usually in autosomal-dominant pattern. Multiple lesions are frequently observed in the familial forms.[82,83] Unfortunately, vascular malformations tend to enlarge during puberty and recur after treatment.

### EMBRYOLOGY AND DEVELOPMENT OF THE VASCULAR AND LYMPHATIC SYSTEMS

The development of the embryonic vascular system involves two separate but intimately connected processes: vasculogenesis and angiogenesis. Vasculogenesis is the formation of new vascular channels. Angiogenesis is the formation of new blood vessels from preexisting vessels by budding or branching. Around the third week of development, embryonic blood vessels begin developing when mesodermally derived hemangioblasts aggregate to form blood islands. The inner cells of the blood islands become hematopoietic stem cells. The outer layer differentiates into angioblasts, endothelial cell precursors. Proliferating angioblasts form a capillary-like network, which constitutes the primary vascular plexus. Angiogenesis occurs as this plexus is reorganized into a functional vascular system and new capillaries begin sprouting.[21,84]

The predisposition of endothelial precursors to differentiate into distinct channel types is imprinted early in embryogenesis by the detection of unique cell-surface markers.[85] Arterial endothelial cells express ephrin-B2, and venous endothelial cells express Eph-B4.[86] The recruitment of periendothelial cells stabilizes the vessel wall and allows for deposition of the extracellular matrix and basement membrane. Vascular endothelial growth factor, platelet-derived growth factor-$\beta$, angiopoietins and their receptors, and transforming growth factor-$\beta_1$ all play roles in vessel assembly and maturation.[87]

The lymphatic system begins its formation near the end of the sixth week, only after the establishment of functional blood vessels.[88,89] Lymphatics most likely arise from veins.[88–91] The earliest indication of the future lymphatic system is the appearance of lymphatic vessel endothelial hyaluronan receptor (LYVE-1) in a number of the endothelial cells lining the anterior cardinal vein.[88,92] A subpopulation of these LYVE-1 venous endothelial cells begin to express the transcription factor prospero-related homeobox 1 (PROX-1) on one side of the anterior cardinal vein.[91] As development continues, the number of PROX-1 cells increases and they ultimately migrate from the veins to establish primitive lymph sacs.[91] PROX-1 acts as a master regulator of lymphatic endothelial differentiation.[93] Lymph sacs are formed close to major veins throughout the embryo. Lymphatic endothelial cells sprout from the sacs to form the peripheral lymphatic network.[88,89] Lymphatic endothelial cells express vascular endothelial growth factor receptor-3, which via interaction with its ligand, vascular endothelial growth factor-C, promotes and guides the budding of lymphatic endothelial cells.[91,94]

### CAPILLARY MALFORMATIONS

Capillary malformation (CM) is the proper name for "port-wine stain." *Nevus flammeus neonatorum,* also known as "angel kiss" (on the forehead) and "stork bite" (on the nuchal area), are faint macular stains seen in 50% of Caucasian neonates. They are due to transient dilation of dermal vessels. These lesions predictably fade, whereas a CM does not. CMs affect 0.3% of infants with an equal sex distribution.[95] Most CMs are sporadic, but some are inherited in an autosomal dominant pattern.[96] They are present at birth and appear as flat, pink-red, cutaneous patches. They can be localized or extensive and can be found anywhere on the body (Fig. 125-8). CMs are composed of dilated, ectatic capillary-to-venule-sized vessels in the superficial dermis. Histopathology demonstrates a paucity of nerves surrounding these vessels.[97] With age, the vessels gradually dilate due to lack of innervation, explaining the observed darkening and nodular expansion.[98] Associated hypertrophy of the subcutaneous tissue, muscle, and

**FIGURE 125-8** Diffuse capillary malformation with overgrowth. Posterior view shows the capillary malformation involving the right arm, trunk, and left leg. Soft tissue overgrowth of the left leg is apparent.

bone underlying a CM is common, and when located on an extremity a limb length discrepancy may be apparent.

Occasionally, the presence of a CM signals an underlying structural abnormality. A CM overlying the cervical or lumbar spine may be associated with an occult spinal dysraphism or tethered cord. Encephalocele or ectopic meninges may be found beneath an occipital CM. Children with CMs in the distribution of the ophthalmic and maxillary branches of the trigeminal dermatomes should be evaluated for Sturge-Weber syndrome. This syndrome consists of a facial CM with ipsilateral ocular and leptomeningeal vascular anomalies. Extensive leptomeningeal involvement can manifest as seizures, contralateral hemiplegia, and variable motor and cognitive delays. CMs are also seen in complex-combined vascular malformations.

Treatment for CM is indicated primarily for cosmetic purposes. Vascular-selective pulsed dye lasers cause photothermolysis of the CM and will improve the appearance by lightening the color of the lesion in 70% of patients.[99] Early, thin CMs such as in the neonate respond well especially when located on the lateral aspect of the face. Complete eradication of the CM is difficult, and despite multiple laser sessions some lesions continue to darken.[100] The timing of therapy remains controversial. Initiating treatment before 6 months of age is an option and short-term follow-up appears promising.[101] Surgical intervention may be required for associated soft tissue hypertrophy and limb length discrepancy.

### Cutis Marmorata Telangiectatica Congenita

Cutis marmorata telangiectatica congenita (CMTC) is a rare vascular anomaly.[102] The involved skin is bluish to deep purple in color with a characteristic reticular vascular pattern. Cutaneous marbling is apparent at room temperature and becomes more pronounced with lower temperatures and crying. The affected skin is depressed and can ulcerate and bleed. CMTC occurs in a localized, segmental, or generalized distribution. It is more frequent on the trunk and lower extremities.[103,104] Histopathology reveals dilated capillaries in the papillary dermis and proliferation of blood vessels in the reticular dermis with occasional dilated veins and venous lakes.[105] It is sporadic and has no gender bias. The etiology of CMTC is unknown.

The clinical course of CMTC is benign with partial regression of the capillary stains in the first year of life, which continues into adolescence. Atrophy, pigmentation, and prominent veins often persist into adulthood. CMTC has been “associated” with abnormalities of many kinds including neurologic, skeletal, and cardiovascular.[106] Stenosis of the common iliac and femoral arteries with resultant claudication has been observed in children with CMTC of the lower extremity.[106,107]

### Telangiectasia

Tiny acquired capillary vascular marks, commonly referred to as *spider nevi* or *spider telangiectasias,* can appear on children in the preschool and school-aged years. There is no gender bias, and epidemiologic studies suggest that they may be present in nearly half of all children.[21] Spontaneous resolution is possible, but pulsed-dye laser can eradicate the lesion.

Hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu syndrome) is an autosomal dominant disorder that commonly results from mutations in endoglin, activin receptor-like kinase 1, or rarely Smad4. These genes encode proteins that modulate transforming growth factor-β signaling in vascular endothelial cells.[108] Mutations lead to the development of fragile telangiectatic vessels and arteriovenous malformations (AVMs). There is marked intrafamilial phenotypic variation. A definite diagnosis of hereditary hemorrhagic telangiectasia is made in the presence of at least three separate manifestations: spontaneous recurrent nosebleeds; mucocutaneous telangiectasia (frequently located on the fingertip pulps, lips, oral mucosa, or tongue); visceral involvement (GI tract, pulmonary, hepatic, cerebral, or spinal AVMs); and family history.[109] Presentation with spontaneous recurrent nosebleeds before school age is most common. Approximately one third of patients have chronic anemia due to lower GI bleeding, which usually becomes apparent in adulthood.[108] In infancy and early childhood, hepatic AVMs of hereditary hemorrhagic telangiectasia can be mistaken for hepatic hemangiomas.

## LYMPHATIC MALFORMATION

Lymphatic malformations (LMs) are frequently called “lymphangiomas,” erroneously suggesting a proliferative tendency. LMs are not tumors. Their pathogenesis is unknown. LMs of the neck and axilla may be due to failure of lymphatic sacs to communicate with the central venous system. Sequestration of lymphatic buds may account for peripheral lesions. Typical LMs seem to be sporadic. Heritable forms of lymphedema, also a type of LM, have been identified.[82]

LMs are classified as microcystic, macrocystic, or combined macrocystic and microcystic lesions (Table 125-1). The difference is clinically and therapeutically useful. Size is

distinguished by whether or not the cystic cavity can be successfully aspirated, resulting in visible decompression. LMs may be focal, discrete masses or infiltrate multiple anatomic locations.

LMs are usually apparent at birth and tend to occur in areas of major lymphatic channels, especially the cervical and axillary locations (Fig. 125-9). They can be found in all tissues or organ systems with the exception of the central nervous system. LMs most commonly appear as ballottable masses with normal overlying skin, although a blue hue may result if large underlying cysts are present. Dermal involvement can appear as puckering or deep cutaneous dimpling. LMs in the subcutis or submucosa appear as tiny clear to white vesicles. Intravesicular bleeding is evidenced by dark red, dome-shaped nodules. Histologically, LMs appear as thin-walled vascular channels lined by lymphatic endothelial cells, which are immunopositive for podoplanin (D2-40) and LYVE-1.[110] The lumens may be empty or filled with a proteinaceous fluid containing macrophages and lymphocytes.[111]

Increasingly, mass lesions and vascular anomalies are detected on antenatal ultrasound.[57,112] The term *cystic hygroma* is used in perinatology to describe a lymphatic anomaly distinct from LMs seen in postnatal pediatrics. A fetal cystic hygroma consists of collections of lymphatic fluid due to a maldevelopment of the cervical lymphatic sacs. Nuchal thickness greater than or equal to 2.5 mm, measured between 10 and 14 weeks gestation, is considered abnormal. Some authors reserve the term cystic hygroma for only those with visible septations and refer to the rest as *simple increased nuchal translucency.*[112] A fetal cystic hygroma ranges from 6.5 to 7.9 mm.[112,113] The finding of a first-trimester septated cystic hygroma has definitively been shown to be associated with a higher risk of aneuploidy, cardiac malformation, and perinatal death over simple increased nuchal translucency.[112] Chromosomal abnormalities such as Down syndrome or Turner syndrome are observed in 50% of fetuses with cystic hygroma; however, 17% to 25% of these pregnancies will result in the birth of a healthy newborn.[112,113] Resolution of a fetal cystic hygroma improves the chance of a normal outcome to as high as 95%.[112]

Fetal cystic hygroma and simple increased nuchal translucencies are always situated in the posterior neck and can extend down the entire dorsum of the fetus.[112] This posterior location is distinct from cervical LMs located in the submandibular, supraclavicular, and anterior/lateral neck regions (see Fig. 125-9). LMs are usually not detected until the second or third trimesters, unlike the more concerning fetal cystic hygroma, which is seen by 14 weeks.[57] Unfortunately, because of continued use of the imprecise term cystic hygroma, some families receive misinformation regarding their true diagnosis and conclude incorrectly that their fetus cannot survive or will have chromosomal abnormalities. Antenatal consultation with pediatric specialists knowledgeable about vascular malformations can benefit families. Reassurance can be given that a lateral or anterior LM is not associated with chromosomal or developmental disorders. It also provides an educational opportunity to discuss the concerns facing a child with a cervicofacial LM.

Large cervicofacial LMs detected in utero should raise concern about potential airway obstruction leading to asphyxia in postnatal life. Results from prenatal ultrasound and fetal MRI allow for assessment of potential airway difficulties at birth. When the risk of airway obstruction is high, consideration should be given to delivery of the fetus via an ex-utero intrapartum treatment (EXIT) procedure.[114] Although the EXIT procedure had early popular appeal, experience has shown that most LMs are compressible, allowing for intubation after delivery in the face of airway compromise. Differentiating LM from teratoma, which is usually firm and noncompressible, is an important distinction in delivery planning.

Fetal pleural, pulmonary, and peritoneal lymphangiectasia may also present in utero as pleural effusions or ascites. These may be isolated or may be a manifestation of Turner, Noonan, or other syndromes. Secondary hydrops fetalis may develop secondary to large pleural effusions. Diagnosis is confirmed when a tap shows more than 80% lymphocytes on the

**FIGURE 125-9** Cervical lymphatic malformation (LM). Prenatal magnetic resonance image shows a fetus with a right cervical macrocystic LM *(left, arrowhead).* Postnatal appearance of the same infant at 1 week of age *(right).*

differential cell count. After chromosomal studies, fetal intervention, when indicated, consists of repeated taps or shunting into the amniotic fluid.[115–117]

The morbidity of LMs is anticipated by anatomic location and extent. Proptosis can result from periorbital and orbital lesions. Facial LMs can be associated with skeletal overgrowth, macroglossia, and macrocheilia.[10] Tongue and oral floor lesions can cause chronic airway problems, recurrent infection, and functional issues related to speech, oral hygiene, and malocclusion.[118] Cervical or axillary LMs can signal an associated mediastinal LM. Chylous pericardial and pleural effusions can be associated with diffuse thoracic lymphatic anomalies or rare abnormalities of the thoracic duct or cisterna chyli. GI LMs can cause chronic protein-losing enteropathy resulting in profound hypoalbuminemia. Pelvic lesions can cause recurrent infections, constipation, and bladder outlet obstruction. LMs in the extremity may result in overgrowth and limb length discrepancy. Gorham-Stout syndrome is a rare, potentially fatal form of skeletal and soft tissue LM. It is characterized by the gradual and often complete resorption of one or multiple skeletal elements (hence the synonym “vanishing bone disease”), which may result in pathologic fractures.[111]

Lymphedema, also a type of LM, is characterized by localized accumulation of protein-rich fluid in the superficial, interstitial space causing enlargement of the subcutaneous tissue; over time, deposition of adipose and fibrous tissue further increases limb volume.[119] It may be primary (idiopathic) or secondary (acquired). The vast majority of patients with primary lymphedema have no family history, but a genetic basis has been found in some families.[120] Milroy disease, a congenital form of lymphedema, is an autosomal dominant condition linked to chromosome 5q35.3, which codes for a mutation in the vascular endothelial growth factor receptor 3 gene.[121,122] Sporadic forms also occur. Greater than 90% of patients with Milroy disease present with lymphedema below the knees.[83] Intrauterine pleural effusion and hydrops fetalis have been observed.[123,124] Skin biopsy from the swollen feet of patients with Milroy disease shows abundant skin lymphatics suggesting malfunction.[125] Meige disease typically presents in puberty. It is an autosomal dominant disorder with variable penetrance and phenotype. Families with lymphedema distichiasis (double row of eyelashes) have been found to have a mutation in transcription factor FOXC2, which plays a role in somite development.[126–128] Systemic involvement such as intestinal lymphangiectasia, ascites, pleural or pericardial effusions, and pulmonary lymphangiectasia have been observed in patients with primary extremity lymphedema.[125]

Ultrasonography is useful to characterize superficial and well-localized LMs. MRI allows for determination of extent and type (microcystic versus macrocystic) (Fig. 125-10). LMs are hyperintense on T2-weighted and turbo-STIR images.[129] Fluid-fluid levels are often seen in macrocystic LMs as a result of layering of blood, protein, or both. Cyst walls and septae enhance with contrast.[36] Microcystic LMs show an intermediate signal on T1 and intermediate to high signal on T2 spin echo sequences.[129] Conventional contrast lymphangiography can be useful for characterization of lymphatic anomalies of the thoracic duct and chylous effusions, allowing for localization of abnormal channels or sites of leakage.[130] It has largely been abandoned in small children due to technical difficulties and morbidity.[131] Lymphoscintigraphy is minimally invasive and safe in infants and children.[132]

The indications for treatment of LMs vary with extent and location. The most common complications requiring treatment include bleeding and infection. Intralesional bleeding, either spontaneous or due to local trauma, can cause expansion. Previously imperceptible lesions may suddenly appear. On physical examination, the LM may be firm and ecchymotic. Treatment is focused on pain control. Intralesional bleeding may transform macrocystic lesions into microcysts.

LMs, unlike other vascular anomalies, may swell in response to systemic viral or bacterial infection. Usually, there are no consequences of this passive engorgement. If accompanied by the rapid onset of localized swelling, tenseness, erythema, and systemic signs of infection, antibiotics (oral or intravenous depending on severity) should be initiated. Frank septic shock may be the presenting symptom in patients with occult retroperitoneal and mesenteric LMs. Bacterial cellulitis is a serious complication of cervicofacial LM due to the risk of airway obstruction, possibly requiring emergent intubation.

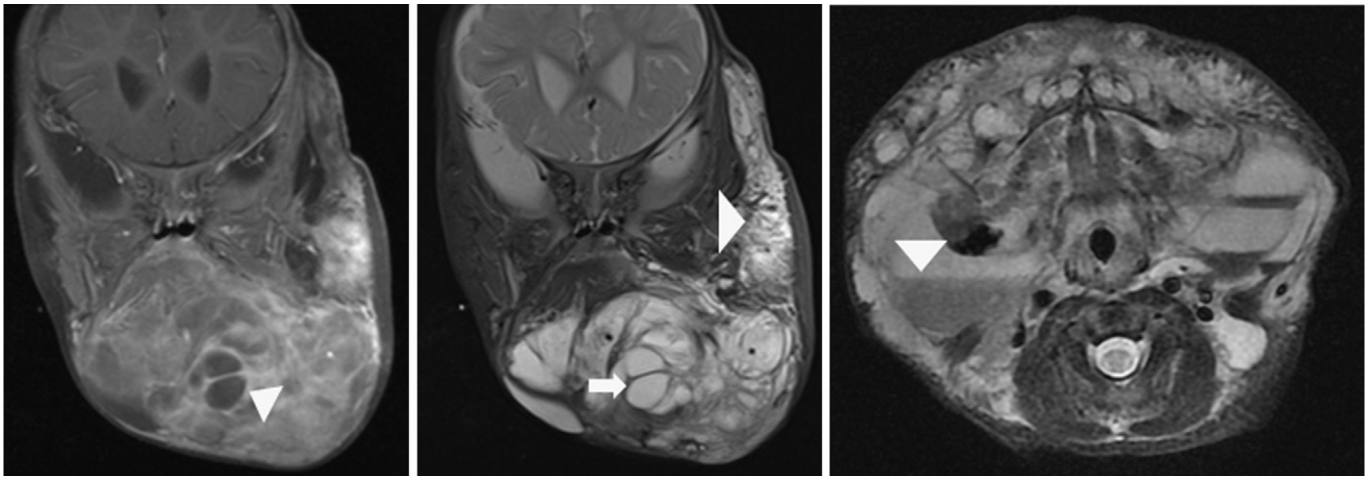

**FIGURE 125-10** Magnetic resonance image of cervicofacial lymphatic malformation (LM). Coronal T1 image of an extensive cervicofacial LM *(left)*, which shows contrast enhancement of septations and rims of cysts *(arrowhead)*. Coronal T2 image *(middle)*, which demonstrates macrocysts *(arrow)* and microcysts *(arrowhead)*. Macrocystic component with a fluid-fluid level *(right, arrowheads)*.

LMs may be treated with sclerotherapy, surgical resection, or both. Sclerotherapy works well for macrocystic LMs and in many cases may render lesions undetectable. Common sclerosants include pure ethanol, sodium tetradecyl sulfate, and doxycycline. Technically, sclerotherapy is usually straightforward. The cystic cavity is entered by direct puncture, and the fluid is aspirated. The needle is maintained in situ, and the sclerosant is injected. Multiple punctures, aspirations, and injections are often performed. Ultrasound guidance is useful. Staged sessions may be necessary for larger lesions. Sclerotherapy preceding resection can shrink LMs, allowing for less morbid surgical procedures. LMs may reexpand after treatment, requiring additional procedures. Microcystic LM is less responsive to sclerotherapy. Superficial lymphatic vesicles can be treated with local intravesicular injection to improve leakage. Complications of sclerotherapy to be avoided include injury to adjacent nerves, necrosis of overlying skin, and cardiotoxicity related to overdose.

The only potential for a definitive cure of LM is surgical resection. Operations near vital structures can be long and tedious. Serial, staged excisions are often necessary, while ensuring complete resection in a given anatomic area as much as possible, because repeat excision of the same area is technically difficult and increases morbidity.[2] Dissection in previously sclerosed areas can be challenging because of fibrosis and scarring, although some authors have found excision after sclerotherapy to be easier.[133] General principles regarding surgical procedures include (1) limiting resection to a defined anatomic region; (2) minimizing blood loss and planning for replacement; (3) performing closed suction drainage of the resection cavity. The "recurrence" rate after macroscopically complete resection ranges from 17% to 40%.[134] The perceived recurrence is thought to be due to growth and expansion of affected lymphatics in the remaining, seemingly normal, yet involved tissue. Sometimes cutaneous "warty" lymphatic vesicles develop in the scar. These can be treated easily with intravesicular sclerotherapy, cauterization, laser coagulation, or excision.

## VENOUS MALFORMATION

Venous malformations (VMs), often incorrectly referred to as *cavernous hemangiomas,* are slow-flow lesions. They may be seen at birth or become apparent later depending on location. VMs are most common in the skin and soft tissues but can be located anywhere in the body (Fig. 125-11). They present in a heterogeneous fashion including simple varicosities and ectasias, discrete spongy masses, or a diffuse network of complex channels that permeate an organ or tissue. VMs grow proportionately with the child and tend to expand slowly with time. Some VMs will dilate when placed in a dependent position or during a Valsalva maneuver. Phlebothrombosis is common and may be painful. Phleboliths can also be easily palpated in many VMs. Histologically, a VM is composed of thin-walled, dilated abnormal channels with clumping of vascular smooth muscle cells. There is often evidence of clot formation and fibrovascular ingrowth.

Most VMs are sporadic (90%). Somatic mutations in the tyrosine kinase receptor TIE2 have been discovered in approximately 50% of sporadic VMs.[135] An autosomal dominant inheritance pattern occurs in cutaneomucosal venous malformation, which accounts for only 1% to 2% of lesions. Mutations in the *TEK* gene, which encodes TIE2, have been identified.[136,137] Cutaneomucosal VMs are dome shaped and range in size from tiny to several centimeters. Glomuvenous malformations account for 5% of lesions and are also inherited in an autosomal dominant fashion.[83] The lesions are mostly superficial and occur as multiple blue to deep-purple nodules or confluent, cobblestone-appearing plaques frequently on the trunk or extremities.[45] They are caused by loss-of-function mutations in glomulin, which derails vascular smooth muscle cell differentiation.[138]

Complications of VMs are related to their location. Cervicofacial VMs are often unilateral. They may distort facial features and cause exophthalmia, dental malalignment, and obstructive sleep apnea. Limb length discrepancy can be seen in an affected limb. VMs involving the synovial lining of the

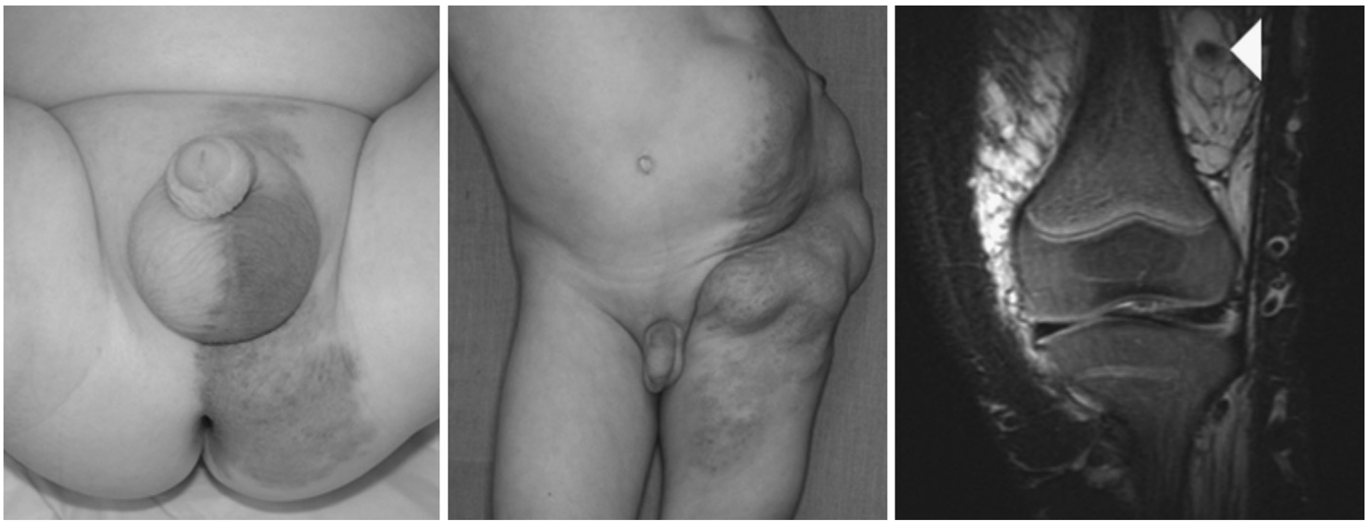

**FIGURE 125-11** Venous malformation (VM). VM of the perineum *(left)*. Truncal VM *(middle)*. Coronal fast spin-echo inversion recovery magnetic resonance image of a VM of the knee *(right)*. There is diffuse involvement of the quadriceps muscle. A phlebolith is present *(arrowhead)*.

knee can cause episodic pain due to repeated bloody effusions. Hemarthrosis may lead to degenerative arthritis.[2]

VMs of the GI tract can be solitary or multifocal. They can involve any or all layers of the bowel wall and can be small or massive. The majority of GI VMs occur as transmural lesions of the left colon and rectum with variable local extension into pelvic structures.[2,53,139] GI bleeding may be the initial symptom. Discoloration in the perineum may indicate an underlying rectal VM. Mesenteric and portal venous anomalies may be associated with GI VMs. A rectal VM associated with ectasia of mesenteric veins is a risk factor for portomesenteric venous thrombosis.[140]

Blue-rubber bleb nevus syndrome (BRBNS) represents a rare disorder consisting of multifocal VMs that affect the skin and GI tract primarily. This should not be confused with benign or malignant blue nevi. The cutaneous lesions of BRBNS are VMs, not true nevi; they are often quite numerous (Fig. 125-12). They range in color from blue to purple and are commonly found on the palms and soles of the feet.[141] There is often a large dominant VM. Diagnosis of GI VMs is generally based on endoscopic findings. As with other GI VMs, chronic bleeding and anemia can result. Intussusception may also occur.[142]

VMs with phleboliths and those that are large ($\geq$10 cm$^2$) and/or deep are more likely to cause a localized intravascular coagulopathy.[143] Constant activation of coagulation caused by stasis and stagnation of blood within the malformation leads to the consumption of coagulation factors. Thrombin is produced and converts fibrinogen into fibrin. Fibrinolysis elevates fibrin degradation products and can be measured by obtaining D-dimer levels.[144] Occasionally, fibrinogen levels are also low.[143,145] Coagulation studies (prothrombin time, activated partial thromboplastin time, and D-dimer and fibrinogen levels) should be reviewed before invasive procedures in patients with extensive VMs. Low-molecular-weight heparin can be given during the perioperative period to improve the hematologic status for patients with elevated D-dimer levels. Platelet counts can be slightly decreased in the 100,000 to 150,000/mm$^3$ range (unlike the marked thrombocytopenia seen with Kasabach-Merritt phenomenon).[144]

Imaging modalities useful for the diagnosis of VM include ultrasonography, MRI, and venography. MRI is the most informative. Lesions are hyperintense with T2 sequences (see Fig. 125-11). Identifiable spaces separated by septations can be seen. The vascular spaces of VM enhance with contrast, whereas LM does not; the exception to this rule is an LM with intralesional bleeding. Phleboliths are often seen as signal voids on all sequences. High-flow vessels are not seen within or around the lesions. Magnetic resonance venography helps delineate deep venous anatomy, especially of the extremity.[36] Doppler ultrasonography reveals soft, compressible masses with monophasic low velocity.[45]

The indications for treatment of VMs include pain, functional loss, bleeding, and appearance. No known systemic pharmacologic agents induce involution of vascular malformations, and therefore they are not used for VMs. Compression therapy aims to reduce swelling and pain in diffuse VMs of the extremities. Sclerotherapy can be effective for symptomatic VMs. Sclerosing agents cause direct endothelial damage, thrombosis, and scarring. Large VMs are accessed by direct puncture under fluoroscopy. Compression and tourniquets can be used to limit venous drainage and minimize systemic delivery of the sclerosant. Staged sessions and occasional embolization of large draining channels are sometimes necessary. Possible local complications are blistering, full-thickness cutaneous necrosis, and nerve injury.[146] Systemic complications include hemolysis, sudden pulmonary hypertension, and cardiac and renal toxicities. Unfortunately, many VMs recanalize and expand after treatment, thus requiring additional procedures.[147] Focal VMs can often be successfully excised. Sclerotherapy before resection may allow removal of larger lesions.[146] Staged subtotal resections may be necessary. Transfusion dependent anemia due to GI VMs should be evaluated for surgical resection. Multifocal VMs of BRBNS can be removed via wedge excision and polypectomy by intussusception of successive lengths of intestine. Intraoperative enteroscopy aids to identify location of all lesions. This technique provides the only chance for cure.[141] Diffuse colorectal VMs causing significant bleeding may be treated with colectomy, anorectal mucosectomy, and coloanal pull-through.[148]

## ARTERIOVENOUS MALFORMATION

Arteriovenous malformations (AVMs) are fast-flow malformations characterized by abnormal collections of arteries and veins that directly communicate (shunts), thus bypassing

**FIGURE 125-12** Blue rubber bleb nevus syndrome. Characteristic dome-shaped plantar lesions *(left)*. Serosal view of venous malformations (VMs) in the small intestine *(middle)*. Endoluminal appearance of a VM in the colon *(right)*.

the high-resistance capillary bed. The shunts comprise the epicenter of the AVM, called the *nidus*. Intracranial AVMs are more common than extracranial AVMs. Areas affected by extracranial AVMs in decreasing frequency are the head and neck, limbs, trunk, and viscera. AVMs may be apparent at birth but are often misdiagnosed initially as a capillary malformation or infantile hemangioma due to pink staining in the overlying skin (Fig. 125-13). The diagnosis becomes more obvious later, particularly during adolescence, when they are more likely to expand.[149] On palpation, the area may be warm with an underlying palpable thrill. Manual compression of feeding arteries and draining veins results in a slowing of the heart rate known as *Nicoladoni sign*.[150] The natural history of AVMs can be documented by a clinical staging system (Table 125-2).[151] As an AVM grows, it can become more mass-like, causing ulceration of the overlying soft tissue, bleeding, pain, or heart failure. Lower-extremity AVMs often develop curious, dry, brown-violaceous-colored plaques.[2]

The majority of AVMs are sporadic. Some forms are heritable (e.g., the autosomal dominant disorder capillary malformation-arteriovenous malformation [CM-AVM], which is caused by mutations in *RASA*).[152] The hallmark of CM-AVM is the randomly distributed, pink to red, multifocal CMs accompanied by a fast-flow vascular lesion such as an intracranial or extracranial AVM, Parkes Weber syndrome (PWS), or a vein of Galen aneurysmal malformation in one third of patients.[153]

Ultrasonography and Doppler imaging can quickly detect the fast flow of an AVM. Dilated feeding arteries and draining veins can be seen as areas of contrast enhancement on CT, signal flow voids (black tubular structures) on spin echo MR images, and signal enhancement (white tubular structures) on gradient sequences including MR angiography. Ability to discern the nidus is variable. Unlike infantile hemangioma, there is no obvious parenchymal mass.[36] Muscle enlargement, bony changes, and increased fat may be seen.

**TABLE 125-2**
**Clinical Staging System for Arteriovenous Malformation**

| *Stage* | *Clinical Findings* |
|---|---|
| I (Quiescence) | Pink-blue warm stain, shunting on Doppler examination |
| II (Expansion) | Enlargement, pulsation, thrill, bruit, tense veins |
| III (Destruction) | Dystrophic skin changes, ulceration, bleeding, pain, or tissue necrosis |
| IV (Decompensation) | Cardiac failure |

Superselective angiography has its role at the time when treatment is planned and often more clearly delineates the nidus (see Fig. 125-13).[2]

Many AVMs require treatment as a result of continued lifelong expansion. Angiographic embolization alone or in combination with surgical excision is the mainstay of treatment. Controversy exists about when to intervene. In the early stages, the full extent of the lesion may not be appreciated at the time of resection, which could result in local recurrence and complicate future procedures. Meanwhile, a well-localized stage I AVM is often more amenable to resection and complete removal. During infancy, treatment is rarely indicated except in rare cases of postnatal heart failure. After a complete diagnostic evaluation, infants and children should be followed annually. Extremity AVMs can result in limb length discrepancy. Stage I and II AVMs are generally observed. Treatment is usually delayed until symptoms indicative of stage III develop: tissue destruction, pain, bleeding, or ulceration. For treatment initiated at any age or stage, proximal feeding arteries must never be ligated or embolized. The nidus of the AVM tends to recruit nearby arteries leading to ongoing growth and continued progression when feeders are ligated.[25] Furthermore, despite temporary improvement

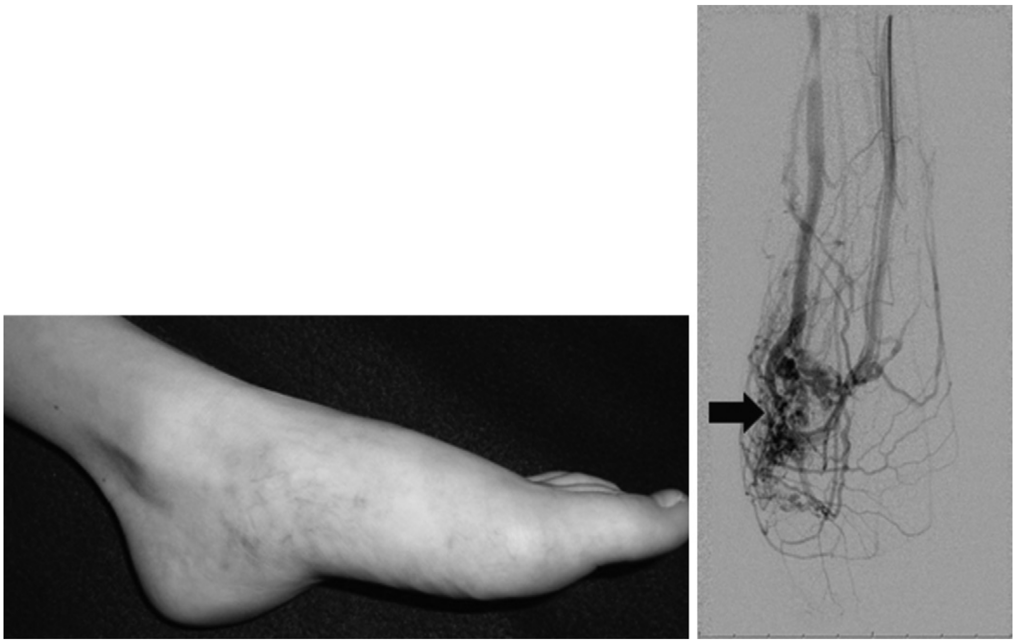

**FIGURE 125-13** Arteriovenous malformation of the foot. AVM of the foot shows faint pink staining of the overlying skin *(left)*. Angiographic appearance of the AVM *(right),* which delineates the nidus *(arrow).*

in bleeding and heart failure, occlusion of feeding arteries precludes future embolization.

All efforts to treat an AVM should be directed toward the nidus. Superselective arterial or retrograde venous embolization can decrease pain and bleeding. Embolic agents include destructive liquids such as ethanol, glue, onyx, particles, or coils. Repeated and staged embolizations are usually necessary. Symptomatic improvement is only temporary because it is nearly impossible to occlude all microscopic arteriovenous shunts. The preferred strategy consists of arterial embolization of the nidus followed by surgical resection 2 to 3 days later. Preoperative embolization decreases intraoperative blood loss but does not decrease the extent of resection. Complete removal of the nidus and overlying soft tissue and skin is the goal; this will decrease recurrence. Resection extent is determined by reviewing the earliest radiologic imaging, preferably before any treatment. Primary closure is sometimes possible. More frequently, though, skin grafting or tissue transfer is necessary. The best results are seen with well-localized AVMs. These patients must be followed closely with physical examination and MRI or ultrasonography because the recurrence rate is high. In some cases, AVMs are unresectable. Amputation is a last resort for debilitating AVMs of the extremities.[2,25,45] Drugs that inhibit angiogenesis and extracellular matrix remodeling are being explored given poor outcomes with other modalities.[154]

**FIGURE 125-14** Capillary-lymphatico-venous malformation of the lower extremity. Note the soft tissue hypertrophy and lateral position of the capillary malformation. Acral anomalies are also present.

# Complex-Combined Vascular Malformations

Like single-channel-type vascular malformations, combined lesions are also categorized as slow-flow and fast-flow (See Table 125-1). These disorders are usually associated with hypertrophy and skeletal overgrowth.

## CAPILLARY-LYMPHATICOVENOUS MALFORMATION

Klippel-Trenaunay syndrome is a well-known eponym for capillary-lymphatico-venous malformation (CLVM).[2] It is often incorrectly called "Klippel-Trenaunay-Weber syndrome," suggesting a relation to PWS, a fast-flow malformation consisting of a capillary-arteriovenous malformation in association with limb hypertrophy. CLVM is usually diagnosed at birth by the presence of an enlarged lower extremity with lateral capillary malformations (CMs), lymphatic vesicles, and visible varicosities. CLVM can be suspected on antenatal imaging but often cannot be confirmed until delivery because congenital lymphedema, PWS, and CLOVES syndrome (*C*ongenital, *L*ipomatous, *O*vergrowth, *V*ascular malformations, *E*pidermal nevi and *S*pinal/skeletal anomalies/scoliosis) are included in the differential diagnosis.

CLVM most frequently involves the lower extremity (88%) but can involve the upper extremity (29%) and trunk (23%).[155] The deformity can range from barely perceptible capillary staining with mild soft tissue overgrowth to a grotesquely deformed limb (Fig. 125-14). Soft tissue and skeletal hypertrophy of the involved limb predominate. CLVM of the torso and upper extremities may involve the mediastinum or retropleural space. The affected extremity may be short or hypotrophic in 10% of patients. Lymphatic anomalies include lymphedema or lymphatic cysts (macrocysts or microcysts). Lymphatic vesicles often erupt through the CM. LMs are common in the buttock, perineum, and pelvis. Persistent embryonic veins are found in patients with lower extremity CLVM; the most common is the marginal vein of Servelle. Branches of the marginal vein become prominent due to incompetent valves. The deep venous system may be absent.

Pelvic, perineal, and genital involvement is common in CLVM. The vascular malformations may cause bladder outlet obstruction. In some infants and children, extension of an LM through the inguinal canal is mistaken for an inguinal hernia. LMs in the perineum can serve as an infectious source. The rectum is variably involved. Portomesenteric venous thrombosis and portal hypertension have been observed in some patients.[156] Venous abnormalities of the lower limbs often extend into the pelvis, connecting anomalously with the femoral and iliac veins and inferior vena cava. This aberrant connection can result in pulmonary embolism in 4% to 25% of cases.

MRI and MR venography (MRV) provide the foundation for describing the type, location, and extent of the vascular malformation components of CLVM. Hypertrophic fatty tissue in areas of overgrowth can be evaluated (Fig. 125-15). MRV delineates the normal state of the veins and reliably demonstrates the anomalous venous channels present in CLVM of the extremity. The lateral marginal vein of Servelle can be seen coursing along the lateral calf and thigh (see Fig. 125-15). Microcystic LMs can be seen in the abdominal wall, buttock, and extremity, whereas macrocysts are seen in the pelvis and perineum. Plain radiographs are used to evaluate and follow limb-length discrepancies. Venography may be used to map

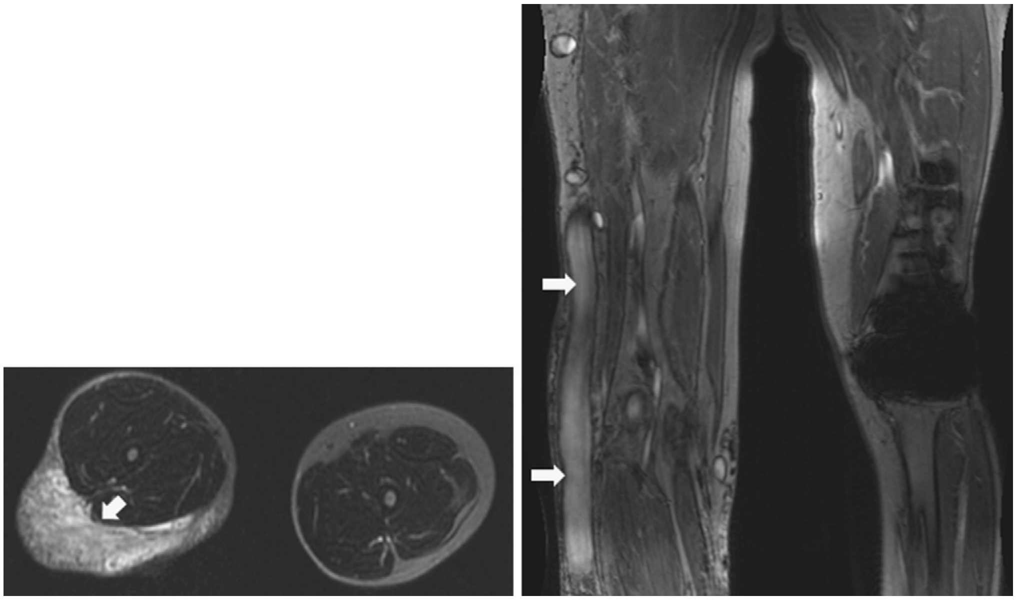

**FIGURE 125-15** Imaging of lower extremity capillary-lymphatico-venous malformation (CLVM). Axial T2 view of CLVM of the right leg *(left)* shows predominantly extrafascial soft tissue overgrowth and microcystic lymphatic malformation *(arrow)*. Magnetic resonance venogram *(right)* depicts the lateral marginal vein of Servelle *(arrows)*.

the venous drainage of the extremity when resection or sclerotherapy is being considered.

In general, treatment for CLVM is conservative and focused on symptoms. Compression therapy is the mainstay of conservative treatment. It can be delayed until the child is walking. Lymphatic oozing may improve with compression therapy. Sclerotherapy can be used to treat macrocystic LMs and venous components. Intradermal lymphatic vesicles can also be sclerosed. Persistent embryonic and other anomalous veins may be amenable to endovenous laser ablation or resection. Veins with direct connections to the femoral or iliac veins or inferior vena cava should be considered for pre-emptive ablation or resection to prevent pulmonary embolism.

Surgical debulking procedures can be of tremendous physical and psychological benefit (Fig. 125-16). The location of the soft tissue overgrowth, either extrafascial or intrafascial, is critical in determining which patients will benefit from staged contour resection. In general, intrafascial overgrowth should not be debulked due to risk of injury to major neurovascular structures and immobility. Truncal and thoracic wall CLVM are also amenable to staged resections. Excision of mediastinal and intrathoracic components is performed only when symptomatic. Postoperative healing can be problematic regardless of location since flaps are made of abnormal tissue with poor lymphatic drainage and altered circulation. Prolonged closed-suction drainage is used. Perioperative

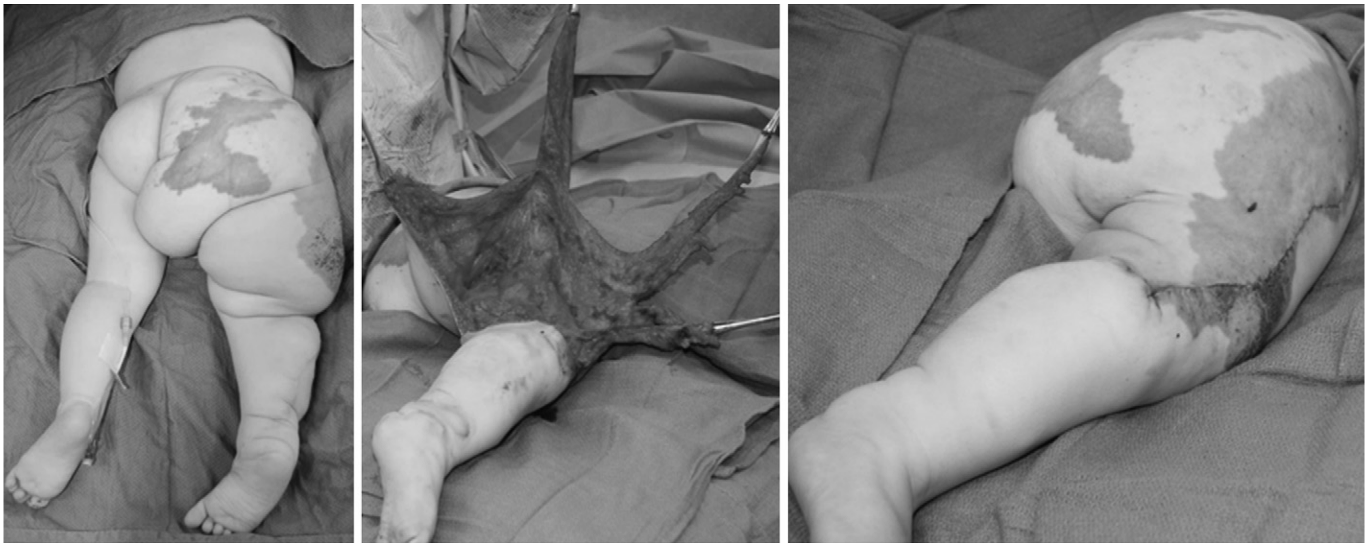

**FIGURE 125-16** Debulking of capillary-lymphatico-venous malformation. Overgrowth of right buttock and extremity *(left)*. Intraoperative appearance of buttock flaps and excision of soft tissue overgrowth *(middle)*. Postoperative appearance of leg *(right)*.

anticoagulation and placement of a temporary inferior vena cava filter to decrease deep venous thrombosis and prevent pulmonary embolism should be considered for extensive surgical procedures.[25]

Gross foot enlargement that impairs ambulation and the ability to wear shoes requires orthopedic corrective procedures and partial amputations to permit the use of custom footwear.[25] Limb length discrepancy should be monitored annually by an orthopedic surgeon. Differences less than 0.5 cm require no therapy. Those between 0.5 and 2 cm are managed non-operatively with internal or external heel lifts. Discrepancies in the legs greater than 2 cm are often treated with epiphysiodesis at the distal femoral growth plate around 12 years of age. Correction of upper extremity discrepancies is not necessary.

## PARKES WEBER SYNDROME

Capillary-arteriovenous malformation (CAVM) and capillary-arteriovenous fistulas (CAVFs) correspond to the eponym Parkes Weber syndrome. Lymphatic anomalies are often present (capillary-arteriovenous-lymphatico-venous malformation). The syndrome is characterized by the presence of a confluent or patchy capillary malformation with multiple underlying micro-AVFs (Fig. 125-17). There is soft tissue and skeletal hypertrophy of the affected limb, usually a lower extremity.[153] The bony overgrowth can result in a limb length discrepancy. The stained areas are usually warm; a thrill may be palpable. Hand-held Doppler examination often reveals increased flow and low-resistance run-off when placed over the stained areas.

De novo or inherited mutations in RASA1 have been identified in those patients with multifocal CMs.[153] The genetic mutation in those without multifocal CMs is yet to be elucidated (see Fig. 125-17). The distinction between the two presentations is clinically relevant. Some patients with RASA1 mutations have been found to have vein of Galen aneurysmal malformations and tumors similar to those observed in neurofibromatosis.[153]

On imaging, the involved extremity usually has fusiform subcutaneous, muscular, and bony overgrowth with diffuse microfistulas. Angiography and venography can reveal generalized arterial and venous dilation and a soft tissue blush involving muscles and subcutaneous fat.

Some patients with PWS are incorrectly diagnosed as having CLVM or diffuse capillary malformation with overgrowth. An accurate diagnosis is critical. Up to 30% of patients with PWS exhibit signs of cardiac volume overload, which is generally well tolerated.[153] In rare instances, cardiac failure can develop secondary to shunting through the arteriovenous fistulas. Infants and children are seen yearly and monitored for axial overgrowth, signs of cardiac failure, and cutaneous problems related to ischemia. Treatment is reserved for symptomatic patients. Flow reduction may be accomplished with repetitive superselective embolization to improve heart failure.[2] Limb amputation may be required for recalcitrant disease.

## CLOVES SYNDROME

Congenital lipomatous overgrowth, vascular malformations, epidermal nevi, and skeletal anomalies are recognized as features in a new syndrome.[157,158] CLOVES syndrome's main features are truncal lipomatous masses, vascular malformations, and acral/musculoskeletal anomalies (Fig. 125-18). The key feature is the presence of a truncal lipomatous mass,

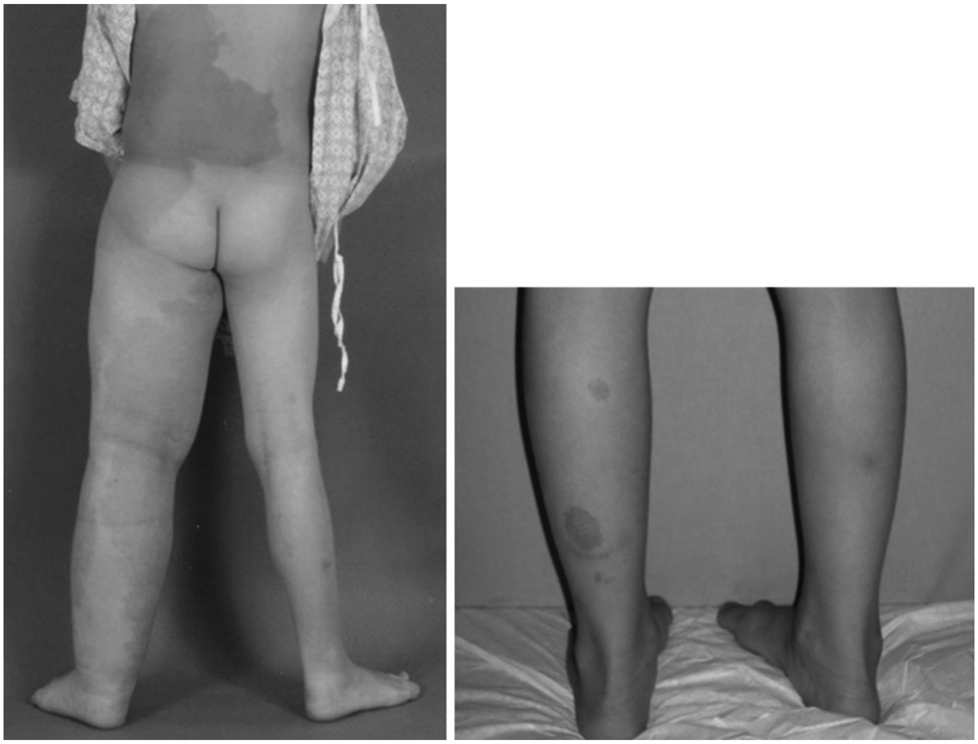

**FIGURE 125-17** Parkes Weber syndrome and capillary malformation-arteriovenous malformation (CM-AVM). Parkes Weber syndrome of the left lower extremity *(left)*. Notice geographic CM with fusiform, symmetric hypertrophy of the entire leg and foot. Characteristic appearance of CMs seen in CM-AVM *(right)*.

FIGURE 125-18 CLOVES syndrome. Truncal lipomatous mass in an infant *(left)*. A common acral skeletal anomaly is depicted showing widened triangular feet and polydactyly *(middle)*. Coronal fast spin-echo inversion recovery magnetic resonance image of a truncal lipomatous mass *(right, arrowheads)*. Scoliosis is also apparent.

which is usually evident at birth. The lesions may be mistaken for an LM; however, the truncal masses are hypervascular and exhibit rapid postresection recurrence. On imaging, the lesions are also infiltrative and can extend into adjacent areas such as the retroperitoneum, mediastinum, and pleural cavity. The lipomatous growths may involve the spinal column and epidural space. Compression of the cord, thecal sac, and nerve roots can occur.

Vascular malformations are also present with slow-flow lesions having been identified in all documented cases.[157,158] CMs can be seen on the trunk. LMs are often located adjacent to or within the truncal lipomatous masses. VMs, in the form of phlebectasia, can course over or around the truncal lesions and can be a source of pulmonary embolus. Paraspinal AVMs can result in paresis and spasticity. MRI with venous and arterial sequences to determine the presence, location, and extent of these lesions should be obtained early in life. Acral deformities include large, wide feet and hands; macrodactyly; and a wide sandal gap. Scoliosis has been documented in 50% of patients.[157]

### PTEN HAMARTOMA-TUMOR SYNDROME

Mutations in the PTEN (phosphatase tensin homolog on chromosome 10) gene cause two autosomal dominant disorders that have predisposition for cancer, Bannayan-Riley-Ruvalcaba and Cowden syndromes. These two entities comprise the PTEN hamartoma-tumor syndrome. Bannayan-Riley-Ruvalcaba syndrome is characterized by macrosomia at birth, macrocephaly, lipomas, hamartomatous intestinal polyposis, and variable degrees of developmental delay. Genital lentiginosis, seen best in males as freckling on the glans penis, can be present at birth or develop in early childhood or puberty. Cowden syndrome is characterized by multiple hamartomas and neoplasias of ectodermal, mesodermal, and endodermal origin. Vascular anomalies are present in about 50% of patients with PTEN mutations and are typically multifocal intramuscular combinations of fast-flow channels and ectopic fat.[159] The presence of a fast-flow lesion in a macrocephalic patient should raise suspicion of PTEN hamartoma-tumor syndrome.

## Conclusions

The past 30 years have witnessed remarkable gains in understanding the pathogenesis of vascular anomalies. Confusing nomenclature has been supplanted by precise terminology based on a genetic-anatomic-histologic classification system. Multidisciplinary vascular anomaly centers combine medical, surgical, radiologic, and pathologic expertise, assisting proper diagnosis and treatment of what were previously hopeless situations.

CHAPTER 126

# Pediatric Arterial Diseases

James C. Stanley and Jonathan L. Eliason

Arterial occlusive and aneurysmal diseases in infancy, childhood, and adolescence are uncommon. An understanding of their etiology, manifestations, and treatment is often based on anecdotal case reports. Nevertheless, the more frequent use of contemporary imaging and advances in vascular surgery have defined the management of most arterial diseases affecting pediatric patients. This chapter addresses common arterial problems affecting the aortic, renal, splanchnic, extremity, and cerebrovascular circulations.

## Aortic Disease

### ABDOMINAL AORTIC COARCTATION AND HYPOPLASIA

Coarctation and hypoplasia of the abdominal aorta are uncommon and are often associated with coexisting splanchnic and renal artery occlusive disease.[1–6] The anatomic location of the aortic narrowing is important, with 69% being suprarenal, 23% intrarenal, and 8% infrarenal (Figs. 126-1, 126-2 and 126-3).[5] The contemporary classification of aortic coarctation is based on the most superior level of the narrowing. It is the most cephalad extent of the disease that defines the complexity of the aortic reconstruction, with considerable differences if the celiac artery (CA) and superior mesenteric artery (SMA) are involved, compared with the renal arteries alone. Most aortic coarctations are diminutive vessels, having an hourglass appearance.

The cause of most abdominal aortic coarctations appears related to events occurring around day 25 day of fetal development when the two embryonic dorsal aortas fuse and lose their intervening wall to form a single vessel. Overfusion of the two embryonic dorsal aortas or their failure to fuse with subsequent obliteration of one of these vessels would predictably result in an aortic narrowing.

Developmental overfusion of the two primitive dorsal aortas receives support in patients with decreased aortic diameters who have single origins of the lumbar arteries. In addition, the presence of multiple renal arteries to one or both kidneys in these patients is nearly twice that observed in the general population, lending further support to a developmental etiology.[5,7,8] Normal aortic development occurs at approximately the same embryonic time that the multiple metanephric arteries involute, leaving a single renal artery. It is likely that if aortic narrowings exist, flow disturbances will occur in the vicinity of what would usually be the principal renal artery and diminish its hemodynamic advantage, allowing persistence of adjacent metanephric channels.

Certain well-known genetic diseases appear to be associated with these arterial anomalies. The most common is neurofibromatosis-1 (NF-1), in which patients exhibit an unusually high frequency of developmental abdominal aortic coarctations and renal artery stenoses.[5] Because of the protean nature of NF-1 and infrequent genetic analyses of patients with abdominal aortic coarctation, the exact frequency of this disease is likely to exceed the 29% reported in a recent University of Michigan series. The primary vascular pathology in neurofibromatosis appears to be related to an inhibition of vessel growth, not entrapment or invasion of the arterial wall by neural elements. Williams' syndrome is a second genetic disease associated with atypical abdominal aortic narrowings.

Viral-mediated events may impede transition of fetal mesenchymal tissue to vascular smooth muscle or alter its organization and growth in utero. They may also result in developmental aortic narrowings. Certain viruses including rubella are cytocidal and inhibitory to cell replication, with intimal fibroplasia and aortic hypoplasia occurring as a consequence. In this regard, fibroproliferative intimal disorders have been documented in the aorta and large elastic arteries of 16.5% of patients exhibiting the congenital rubella syndrome.[9]

Panaortitis with adventitial or periadventitial fibrosis and associated inflammatory cell infiltrates, suggesting an active or chronic aortitis, is another well-recognized cause of abdominal aortic coarctations. The proposition that most abdominal aortic coarctations are a variant of an inflammatory aortitis like Takayasu disease is quite controversial yet such may be the most common cause of these aortic narrowings in the subcontinent populations of Asia and South America.

Associated narrowings of the abdominal aortic branches are common in these patients. Nearly 90% of those with abdominal aortic coarctation have renal artery stenoses.[5] Splanchnic arterial occlusive disease occurs in 62% of these patients, with both CA and SMA stenoses and occlusions involved in 82% of the affected patients.[5]

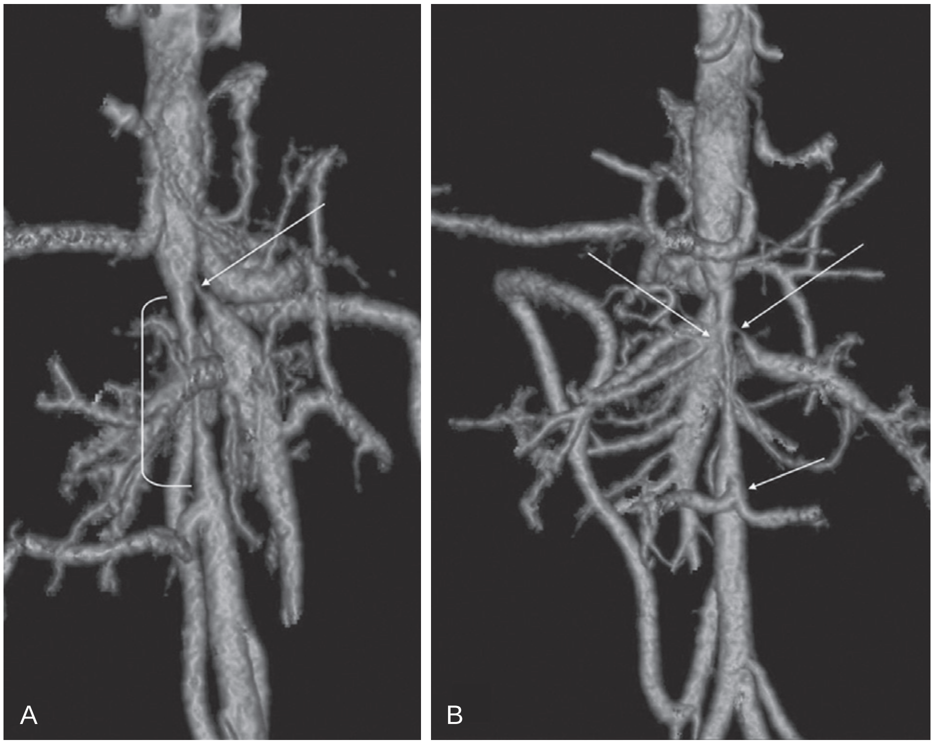

**FIGURE 126-1** **A,** Suprarenal abdominal aortic coarctation (*bracket*) with superior mesenteric artery stenosis (*arrow*) and **B,** bilateral renal artery stenoses (*arrows*). Note common trunk of lower lumbar artery (*arrow*) on posterior projection. (From Stanley JC, Criado E, Eliason JL, et al: Abdominal aortic coarctation: Surgical treatment of 53 patients with a thoracoabdominal bypass, patch aortoplasty, or interposition aortoaortic graft. J Vasc Surg 2008;48:1073-1082.)

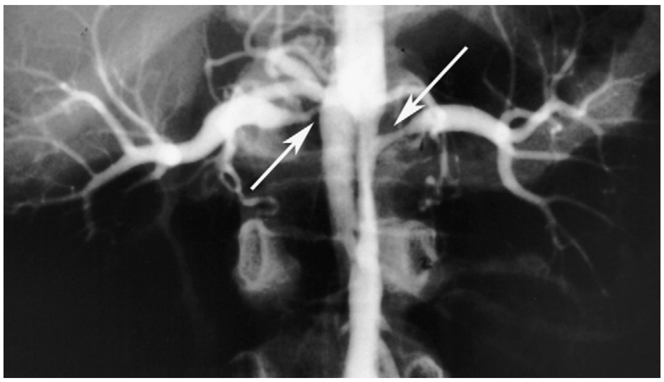

**FIGURE 126-2** Intrarenal abdominal aortic coarctation with bilateral artery stenosis (*arrows*). (From Stanley JC, Criado E, Eliason JL, et al: Abdominal aortic coarctation: Surgical treatment of 53 patients with a thoracoabdominal bypass, patch aortoplasty, or interposition aortoaortic graft. J Vasc Surg 2008;48:1073-1082).

Clinical manifestations of this disease usually reflect uncontrolled hypertension due to suprarenal or intrarenal aortic narrowings. Two thirds of developmental coarctations and a quarter of those having inflammatory-related aortic narrowings have associated renal artery stenoses. The secondary hypertension in these instances is usually resistant to simple pharmacologic control. Occasionally, a patient reports exercise-related lower extremity fatigue, but true claudication is rare.[5] Symptomatic intestinal ischemia is uncommon, affecting only 6% of those having known CA and SMA disease accompanying their aortic narrowings.[10]

**FIGURE 126-3** Infrarenal abdominal aortic coarctation manifest by tubular stenosis extending from dilated inferior mesenteric artery to the aortic bifurcation.

Abdominal aortic coarctations usually cause signs or symptoms during the first or second decade of life in contemporary times. An earlier review noted that patients had reached a mean age of 22 years before the diagnosis was actually confirmed.[3] Untreated, this entity has been associated with

stroke, progressive left ventricular hypertrophy, congestive heart failure, flash pulmonary edema, and less often with renal insufficiency.[11,12] In one review, 55% of untreated patients died at a mean age of 34 years.[3]

Treatment of abdominal aortic narrowings in children has most often entailed open surgery.[5] Historically, thoracoabdominal bypass was the conventional means of treating these patients (Figs. 126-4 and 126-5). In more recent years patch aortoplasty has become preferred when it can be performed safely (Figs. 126-6 and 126-7). Both procedures can be technically challenging, especially in the face of coexisting splanchnic or renal disease requiring simultaneous treatment.

Thoracoabdominal bypass grafts originate from the distal thoracic aorta above the diaphragm or from the supraceliac aorta at the diaphragmatic hiatus and are passed behind the left kidney to the distal aorta. Expanded Teflon grafts are favored because of their greater stability regarding postimplantation dilatation. Graft diameter should be chosen to be as big as possible, short of being so large that excessive luminal thrombus would accumulate. The intent is to oversize grafts compared with the aorta, with anticipated growth otherwise resulting in a graft too small to maintain normal distal pressures and flow. In the ideal circumstance, one should use a graft whose size would not represent an energy-consuming constriction as the child grows into maturity. This means having a conduit at least 60% or 70% the size of the adult aorta. In early childhood the use of large conduits may not be possible. Graft length is a nonissue in older children and

adolescents, with axial growth from the diaphragm to pelvis being minimal after reaching an age of 9 or 10 years.

Patch aortoplasty is usually undertaken when the coarctation segment has a large enough diameter to allow completion of an anastomosis without an overlap of sutures from the opposing sides of the patch. Whenever possible, patches in children should be large enough, similar to thoracoabdominal graft sizing, so as to not be constrictive with growth into adulthood, yet not so generous as to risk development of an extensive lining of unstable thrombus. Teflon graft material is again favored over Dacron graft because of the latter's propensity for dilatation years after implantation.

Reoperations are infrequent but may be required for anastomotic narrowings or if a patient outgrows the adequacy of the primary aortic reconstructive procedure. The fact that nearly 10% of the cases in a recent report from the University of Michigan required late secondary operations supports the importance of long-term follow-up of these patients.[5]

Simultaneous visceral artery reconstructions depend on the clinical relevance of the nonaortic disease, as well as the proximity of the aortic reconstruction to the affected aortic branches. Renal artery stenoses causing secondary renovascular hypertension justify their reconstruction. A mandate to reconstruct the CA or SMA applies only to symptomatic cases. Nevertheless, a relative indication to prophylactically reconstruct these vessels exists when performance of an aortoplasty or renal revascularization would make a subsequent CA or SMA revascularization exceedingly difficult. When the aortic reconstruction is distant from the CA or SMA, such as with thoracoabdominal bypass, a concomitant splanchnic revascularization is less likely to be warranted.

Treatment of select focal abdominal aortic coarctations distant from the renal and splanchnic branches may involve endoluminal interventions. When such is undertaken, stent placement is necessary to overcome the significant recoil of these hypoplastic and highly fibrotic aortic narrowings.[13–15] However, one should remain cautious about accepting the long-term benefits of endoluminal treatment of abdominal aortic coarctation in children. Given the high frequency with which the visceral arteries are involved in abdominal aortic narrowings, the number of lesions amenable to endovascular repair is likely to be limited.

More than 90% of patients with abdominal aortic coarctation benefit when treated with a patch aortoplasty or a thoracoabdominal bypass.[5] Accompanying postoperative morbidity is low, and mortality should approach zero. Nevertheless, long-term follow-up of these young patients with annual noninvasive assessments of lower extremity blood flow is recommended. Imaging with magnetic resonance angiogram (MRA) studies or computed tomography angiogram (CTA) should be obtained if any evidence of diminished blood flow exists.

## ABDOMINAL AORTIC ANEURYSMS

Abdominal aortic aneurysms (AAAs) are rare in children. All are considered life threatening. The etiology is often difficult to ascertain, but in general these AAAs have been categorized as (1) infectious, (2) related to known vascular disease entities, or (3) due to unknown congenital developmental misadventures. The clinical manifestations vary widely among these different categories. The diagnosis typically follows imaging with ultrasonography, MRA, or CTA.

Infectious AAAs associated with umbilical artery catheterizations (UACs) account for approximately one third of aortic aneurysms reported in children. These aneurysms may present anytime during the first 2 years of life, but most are encountered in the newborn period. Repeated UAC insertion and prolonged UAC use have been implicated as risk factors for this type of AAA. Whether these aneurysms are the result

of a bacteremic invasion of a catheter-injured aorta or due to an infected thrombus is problematic, but the outcome is destruction of the involved vessel and aneurysm formation. More than 75% of these aneurysms are associated with a *Staphylococcus aureus* or *Staphylococcus albus* infection.[16] The resulting AAAs are usually saccular, and more than 50% involve the abdominal aorta (Fig. 126-8). Aortic infection related to UAC represents a life-threatening illness,[16,17] with AAA rupture being the most serious complication. These infected AAAs, with rare exception, require early operation. Interventions range from simple aortic ligation to aneurysmectomy with an autologous or synthetic graft aortic reconstruction. Long-term antibiotic administration must accompany these procedures.

**FIGURE 126-8** Aortic and iliac artery aneurysms due to infection secondary to umbilical artery catheterization.

Aortic aneurysms in childhood may also be related to known vascular diseases, the more common of which deserve mention. Tuberous sclerosis (TS) is an autosomal dominant disease with hamartomas in multiple organ systems, with central nervous system involvement manifest by learning difficulties and seizures, as well as vascular lesions.[18,19] Most TS-related aortic aneurysms are abdominal in location, with less frequent thoracic aortic involvement. Fatal rupture of these AAAs is well recognized.[19,20] Treatment strategies are often complex and tailored to anatomic involvement, with a frequent need to reconstruct the splanchnic and renal vessels (Fig. 126-9).

Ehlers Danlos syndrome (EDS) includes a spectrum of disorders with vascular involvement. This is especially the case in type IV EDS, an autosomal dominant disease resulting in defective type III collagen production. It is often manifest by spontaneous rupture of a hollow viscus or large arteries. Among 132 vascular complications in 24 patients with EDS, 17 had thoracic or abdominal aortic involvement including dissections, aneurysms, and ruptures.[21] Unfortunately, the true prevalence of this disease is unknown, in that catastrophic complications of EDS resulting in death may occur before a definitive diagnosis is established. Vascular surgery in these patients is often required, but because of vessel fragility and bleeding, operative treatment must be approached with extreme care.[22]

Marfan syndrome is an autosomal dominant disorder, affecting collagen cross-linking due to mutations in the fibrillin-1 gene. Infantile arterial involvement in Marfan syndrome is rare. The vast majority of these children have cardiac problems including dilation of the aortic root, mitral valve prolapse, and valvular regurgitation.[23] Nevertheless, 20% of these children develop aortic aneurysmal changes as they grow older.[24]

Takayasu aortoarteritis is also a recognized cause of pediatric aortic aneurysm formation, pseudoaneurysm formation, aortic stenoses, and aortic dissections.[25,26] The clinical presentation may be marked by systemic symptoms of inflammation or may be related to aortic involvement. Aortic

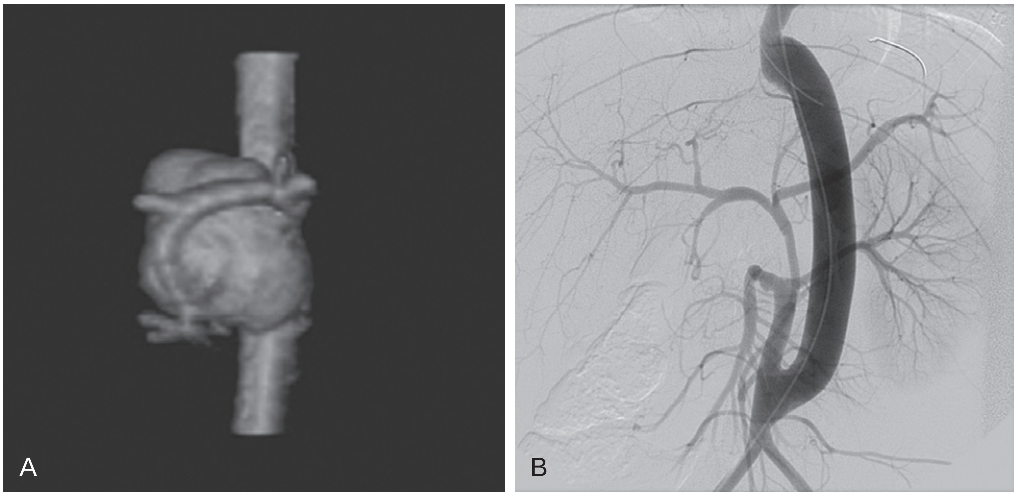

**FIGURE 126-9** **A,** Preoperative tuberous sclerosis-related abdominal aortic aneurysm with renal and splanchnic arterial involvement. **B,** Postoperative appearance following aneurysmectomy, aortic reconstruction, and revascularization of the celiac and superior mesenteric arteries.

reconstructions are less urgent in this group of children and are best undertaken when the aortoarteritis is quiescent.

Certain pediatric AAAs are not infectious or related to an underlying connective tissue disease. Their etiology is related to developmental events evolving during fetal growth (Fig. 126-10). Aneurysms in this group are commonly associated with stenotic lesions and multiple aneurysms in other locations. Concomitant renal, upper extremity, or iliac artery aneurysms occur most often in these children, with cerebrovascular, mesenteric, and lower extremity arterial involvement being less common.[27]

Seven children, ranging in age from 2 weeks to 8 years, have undergone surgical repair of their AAAs at University of Michigan from 2002 to 2010, with six survivors. The AAAs involved 10 renal arteries in five patients, all of whom were hypertensive. No two aneurysms were of the same clear etiology, and aortic reconstructions varied in each case including concomitant renal or splanchnic arterial reconstructions in four children.

### ABDOMINAL AORTIC THROMBOSIS

Acute thrombotic occlusions of the aorta and its branches have multiple causes including prothrombotic coagulation disorders, sepsis, and certain cardiopulmonary diseases. However, iatrogenic injury is the most common inciting event, usually a complication of a neonatal UAC.[17,28,29] Some degree of aortic thrombosis accompanies 20% to 30% of UACs,[30] and 89% of neonates experiencing aortic thrombosis had indwelling arterial catheters.[31]

Clinical presentations vary widely from silent thromboses to profound tissue ischemia manifest by lower extremity discoloration and multiple systemic organ failure. Overall mortality with neonatal aortic occlusion approaches 15% to 20%.[31,32] Diagnoses are most often made with Doppler evidence of absent extremity blood flow in the face of no palpable peripheral pulses and CTA or MRA imaging confirming the aortic involvement. Intravenous digital subtraction arteriography has a role in select patients. Conventional catheter-based diagnostic arteriography in the neonate is ill-advised but may provide a means for delivering lytic agents in select cases. In that setting, access may be best through an umbilical artery catheter.[29]

Treatment of acute aortic thromboses in neonates is initiated with heparin anticoagulation. Fibrinolytic therapy, a challenge because of low plasminogen levels in the newborn, is an important therapy.[33–35] Heparin administration should accompany tissue plasminogen activator (tPA) infusions in these cases. Hemorrhagic complications may accompany tPA therapy and such risks must be weighed when considering the benefits of lytic treatment. Mechanical thrombectomy using small balloon catheters or polyethylene tubing advanced through an aortotomy allows disobliteration of the aorta and extraction of branch thrombus.[17]

Aortic thromboses in older children and adolescents are frequently associated with intimal flaps and dissections caused by blunt trauma.[36,37] Abdominal and chest injuries occurring in motor vehicle accidents and falls from great heights are common contributors to this trauma. Other life-threatening injuries often accompany the aortic thrombosis in these cases. Obvious pulse deficits and tissue ischemia are manifestations of aortic occlusion in these older children with the diagnosis being confirmed by CTA, MRA, or conventional arteriography.[38] Aortic interposition or bypass grafts are usually undertaken in these instances with nonanatomic axillofemoral or thoracoabdominal bypasses required if intestinal perforation has contaminated the immediate area of aortic injury. Endovascular repairs offer certain benefits in the adolescents having severe coexisting injuries in addition to the aortic injury.[39,40]

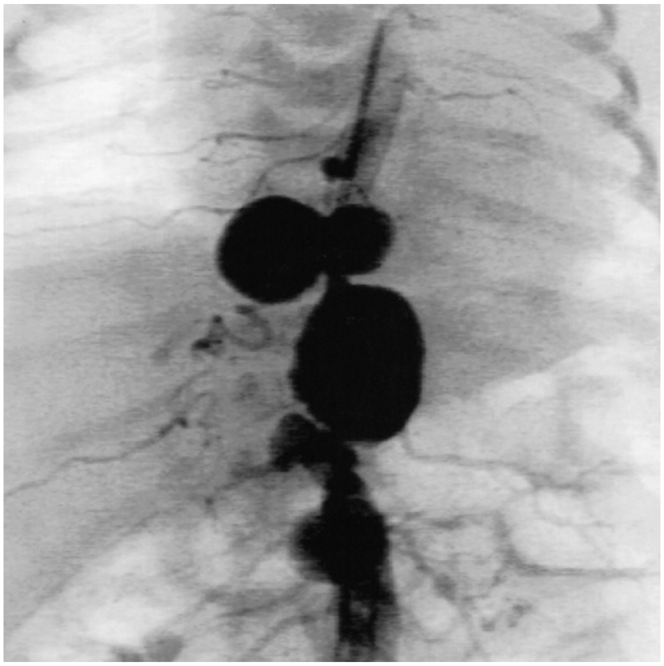

FIGURE 126-10 Idiopathic multiple aortic aneurysms in a newborn.

# Renal Artery Disease

### RENAL ARTERY STENOSIS

Occlusive disease affecting the renal arteries is the third most common cause of hypertension in children following coarctation of the thoracic aorta and parenchymal renal disease. The precise incidence of this type of secondary hypertension in children is unknown but is likely to account for 5% to 10% of those exhibiting marked blood pressure elevations. Pediatric renovascular hypertension, when unrecognized and untreated, has been associated with hemorrhagic stroke, hypertensive encephalopathy with impaired mental development, and failure to thrive. Poorly controlled hypertension may result in left ventricular hypertrophy and severe diastolic dysfunction. When the entire renal mass is involved, flash pulmonary edema associated with renal insufficiency may occur.

Pediatric renal artery stenoses represent a spectrum of diseases. Most developmental renal artery stenoses encountered in North American Caucasian children[11,12] are different from the inflammatory aortoarteritis related stenoses that dominate reports from the Asian subcontinent.[41–43] The cause of most developmental renal occlusive lesions are the same as those causing abdominal aortic coarctations.[5,11] Many of these patients have NF-1.[7,11,44,45] The vast majority of renal artery

narrowings are ostial in location, representing true hypoplastic stenoses (Fig. 126-11).

Recognition of renal artery stenotic disease in children requires detailed vascular imaging.[11,46] Conventional catheter-based digital-subtraction arteriography has been a standard, but at many institutions it is being replaced with newer CTA technology.[5] Nevertheless, digital-subtraction arteriography should be pursued when a strong suspicion of renovascular disease exists.[5] Screening modalities including MRA, nuclear renal scans with ACE inhibitors, and deep abdominal ultrasonography all have value but are currently too inconsistent to be used as confirmatory diagnostic or prognostic tests.

Optimal surgical therapy depends on the specific character of the renal artery disease being treated. The most common surgical procedure has been renal artery implantation into the aorta, as well as into the main or adjacent segmental renal arteries (Figs. 126-12 and 126-13).[11] Aortorenal bypasses with vein grafts were frequently used in the past but are not favored because in follow-up more than half of these conduits undergo aneurysmal deterioration.[47] The internal iliac artery has become the preferred conduit for aortorenal bypasses (Fig. 126-14). Splenorenal reconstructions with a direct anastomosis of the splenic and renal vessels are not favored because of coexistent or later development of a celiac artery stenosis that would perpetuate the hypertensive state. Resections of the stenotic renal artery with primary reanastomosis, focal arterioplasty, or open operative dilation are less common reconstructive procedures. Nephrectomy may be appropriate for irreparable renal disease including multiple intrarenal stenoses not amenable to open in situ or ex vivo repairs, as well as diminutive kidneys 2 to 3 cm in size. In these cases it is assumed that the contralateral kidney will suffice in keeping the child from going into renal failure. There is a certain logic in undertaking single-stage vascular reconstructive procedures given that a later operation in the same anatomic area entails significant hazards of reoperations.

**FIGURE 126-11** Ostial main renal artery stenoses.

**FIGURE 126-12** Bilateral renal artery-aortic implantations. Note the residual origins of the native renal arteries. (From Stanley JC, Zelenock GB, Messina LM, Wakefield TW: Pediatric renovascular hypertension: A thirty-year experience of operative treatment. J Vasc Surg 1995; 21:212-227.)

Undertaking surgical therapy in small infants is controversial. Technical challenges exist in reconstructing renal arteries less than 2 mm in diameter and renal revascularization in these circumstances should be pursued only when uncontrolled severe hypertension or renal failure threaten the patient. Renal revascularizations are most likely to be successful after age 3 years, and deferring reconstructive procedures in younger children when possible is reasonable. Drug treatment of hypertension in the young child may be difficult and requires frequent and fastidious monitoring.

Large clinical experiences with pediatric-aged renovascular hypertension are uncommon.[11,48–51] The University of Michigan series included 39 girls and 58 boys, aged from 3 months to 17 years, who underwent operation from 1963 to 2006.[11] All but one patient had refractory hypertension not responsive to contemporary medical therapy. Developmental renal artery stenoses accounted for 80% of the renal artery disease. Splanchnic arterial occlusive lesions affected 24%, and abdominal coarctations affected 33%. Primary renal artery operations were undertaken 132 times. Procedures included resection beyond the stenosis and implantation into the aorta in 49, renal artery in 7, or SMA in 3; aortorenal and iliorenal bypasses with vein or iliac artery grafts in 40; focal arterioplasty in 10; resection with reanastomosis in 4; operative dilation in 4; splenorenal bypass in 2; and primary nephrectomy in 13 when arterial reconstructions proved impossible. Bilateral renal artery operations were done in 32 children. The fact that 17 underwent CA or SMA reconstruction, 19 underwent patch aortoplasty, and 11 underwent thoracoabdominal bypass underscored the complexity of disease being treated. Thirty secondary renal artery procedures were done in 19 patients including nine nephrectomies. Hypertension was cured in 68 children (70%), improved in 26 (27%), and unchanged in 3 (3%). Follow-up averaged 4.2 years. No patients required dialysis, and there were no operative deaths.

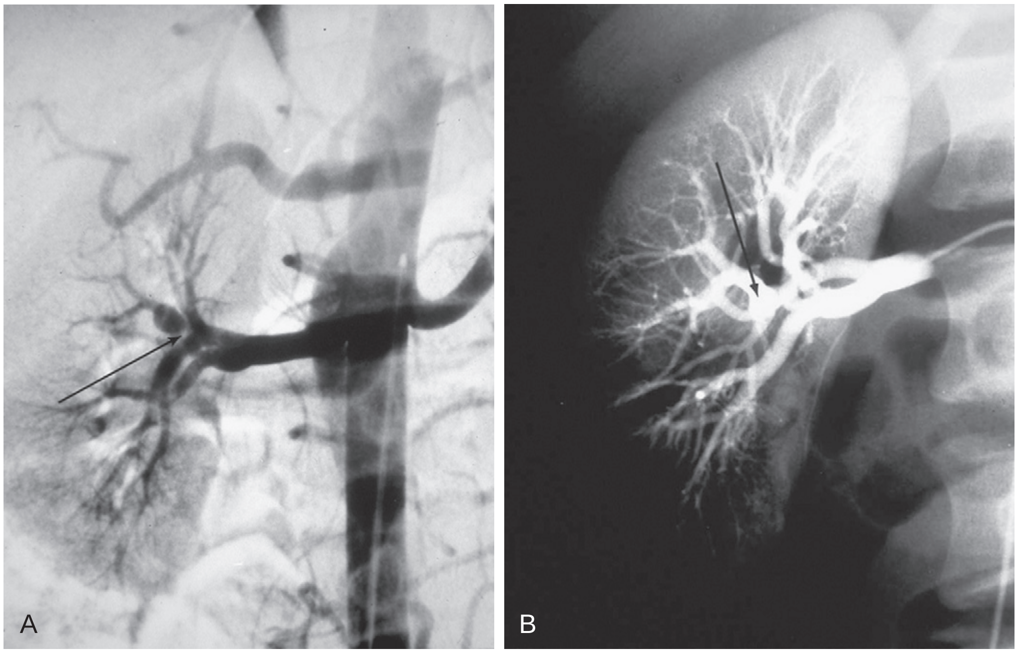

FIGURE 126-13 **A,** Focal stenosis of intraparenchymal segmental renal artery with poststenotic dilation (*arrow*). **B,** Segmental renal artery implantation into the distal main renal artery (*arrow*). (From Stanley JC, Zelenock GB, Messina LM, Wakefield TW: Pediatric renovascular hypertension: A thirty-year experience of operative treatment. J Vasc Surg 1995;21:212-227.)

A second large series was reported from the Hospital Beaujon in France.[48] That series encompassed 78 children, 35 boys and 43 girls, ranging in age from 1.4 to 18 years. There were 91 primary revascularization procedures and 15 nephrectomies. These numbers were quite similar to the University of Michigan series. A third series emanated from the Cleveland Clinic involving 56 children including 23 boys and 33 girls ranging in age from 0.7 to 21 years.[49] They reported 46 primary operations and 10 primary nephrectomies. A fourth series was from Vanderbilt University and the Children's Hospital of Philadelphia.[50] This experience included 50 children, 24 boys and 26 girls, ranging in age from 0.4 to 16 years. These children were subjected to 28 primary reconstructive procedures and an additional 12 primary nephrectomies. The latter two series, unlike the University of Michigan experience, did not contain many patients treated for aortic or splanchnic arterial disease.

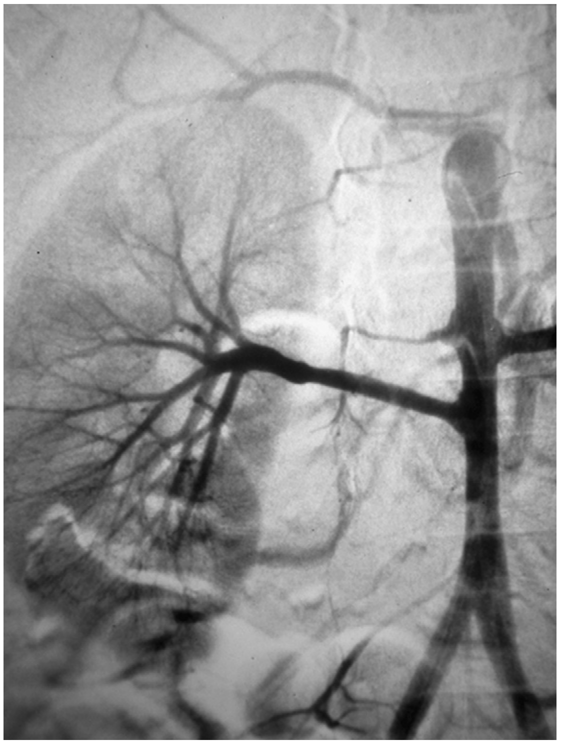

FIGURE 126-14 Aortorenal bypass with an internal iliac artery graft. (From Stanley JC, Zelenock GB, Messina LM, Wakefield TW: Pediatric renovascular hypertension: A thirty-year experience of operative treatment. J Vasc Surg 1995;21:212-227.)

Outcomes regarding blood pressure control were remarkably similar at the University of Michigan, Vanderbilt-University-Children's Hospital of Philadelphia, and Cleveland Clinic, with respective *cure* rates of 70%, 70%, and 66%; reported *improvement* rates of 27%, 26%, and 23%; and *failure* rates of 3%, 4%, and 11%. Surgical therapy in all three of the former experiences consisted of conventional open operative interventions.

The role of percutaneous transluminal angioplasty (PTA) in treating pediatric renovascular hypertension remains controversial.[52,53] Failure following PTA for developmental disease might be anticipated, given the excessive elastic tissue in many stenoses that would predictably contribute to early postdilation recoil, as well as the minute caliber of developmentally narrowed vessels that might lead to their disruption. Nevertheless, a small number of recent reports suggest success with catheter-based interventions.[54,55] It is of note that if the disease being treated is a quiescent inflammatory aortoarteritis, then more salutary outcomes would follow PTA than might be the case if treating developmentally hypoplastic renal arteries. However, even in the former setting recurrent stenoses are frequent.[42,43]

### ACUTE RENAL ARTERY DISSECTIONS AND THROMBOSES

Acute renal artery dissections and thromboses are most often a result of UAC in the neonate or iatrogenic events accompanying diagnostic or therapeutic catheterizations in older children. Among adolescents, blunt or deceleration injury with stretching and dissections of the renal artery is a common cause of an acute occlusion. Flank pain, hematuria, and hypertension are frequent manifestations of acute renal artery occlusions with evolving renal infarction in these children.

Acute thrombosis of an otherwise nondiseased renal artery resulting in interruption of blood flow for more than 90 minutes invariably results in an irreversible loss of renal function. Nevertheless, an attempted operative repair is justified, especially when treating a vascular injury to a solitary kidney or bilateral injuries.[56] Endovascular interventions offer a less invasive means of treating select patients in this setting.[10]

Surgical therapy in the chronic setting and in cases of subtotal occlusions may require an aortorenal bypass. Revascularization attempts in these children are justified if sufficient parenchyma exists and nuclide studies suggest the affected kidney to be functioning at 10% to 20% of the contralateral unaffected kidney. Nephrectomy is undertaken when recovery of renal function is impossible.

### RENAL ARTERY ANEURYSMS

The clinical relevance of renal artery aneurysms in children is poorly understood including an undefined risk of rupture.[11,57] Aneurysms affecting the renal artery are generally of two categories.

The most common aneurysms are those associated with an underlying congenital vasculopathy or a connective tissue disorder. More often than not the congenital nature of this remains unknown, although in some patients genetic diseases like Ehlers-Danlos are obvious. These aneurysms usually occur at branch points as saccular lesions (Fig. 126-15). Their discovery usually occurs as an incidental finding during imaging for other suspected vascular or renal diseases. An occasional aneurysm may have been the source of embolic material responsible for distal arterial occlusion, renal ischemia, and secondary renovascular hypertension.

Treatment is recommended for extraparenchymal aneurysms in hypertensive children or when they exceed 1 cm in diameter regardless of blood pressure levels. Larger aneurysms may be excised with a primary angioplastic closure, and smaller ones plicated with fine cardiovascular suture in the form of a closed aneurysmorrhaphy. Aneurysms arising within the cortical substance may be treated with catheter-delivered occlusive material or carefully delivered absolute alcohol. In that setting there is a predictable loss of kidney substance beyond the aneurysm.

The second group of renal aneurysms are due to poststenotic turbulent blood flow. Renal artery aneurysms in this category were encountered in 8 children among 97 treated for renovascular hypertension at the University of Michigan.[11] These aneurysms tend to be more globular than saccular. Treatment in these cases necessitates eliminating the stenosis with a renal artery reconstruction similar to that in managing renovascular hypertension. Accompanying such a revascularization is aneurysm excision and angioplastic closure of the residual opening at the base of the aneurysm or a closed aneurysmorrhaphy in the case of small aneurysms.

**FIGURE 126-15** Renal artery aneurysm involving second order segmental renal artery. Note the relative hypoperfusion of the upper pole.

# Splanchnic Artery Disease

### SPLANCHNIC ARTERY STENOSES AND ANEURYSMS

Occlusive disease of the splanchnic arteries is rare in pediatric-aged patients and is an even rarer cause of clinically relevant intestinal ischemia.[58] These stenotic narrowings usually affect the origins of the celiac and superior mesenteric arteries (Fig. 126-16). They are recognized most frequently during arteriographic studies for suspected aortic or renal artery pathology.

Developmental lesions appear related to embryonic events similar to those causing aortic and renal artery narrowings. These events likely affect the reorganization of the ventral segmental vessels associated with the cephalic roots of the vitelline arteries that form the CA and SMA. This results in an ostial stenosis or occlusion. Minimal CA and SMA narrowings demonstrated at a young age may not become intrinsically narrower as the child grows, but the vessel origin may simply remain the same size as everything else becomes larger. Thus the artery's origin becomes proportionately narrower until it becomes a critical stenosis.[58] This entire process suggests a major growth arrest of the aortic origins of these arteries.

Symptomatic splanchnic artery disease presents as postprandial intestinal angina with periumbilical discomfort that lasts for the duration of small bowel transit of the ingested

**FIGURE 126-16** Severe celiac artery and superior mesenteric artery ostial stenoses evident on a lateral aortogram.

food. These children develop a food aversion and exhibit a failure to gain weight. In extreme cases they may experience weight loss.

Operative treatment of pediatric splanchnic arterial occlusive disease is complex.[58,59] A mandate to reconstruct these vessels applies only to symptomatic cases. A relative indication to reconstruct the CA or SMA exists when performance of a primary procedure such as patch aortoplasty or renal revascularization would potentially place these splanchnic arteries at risk of occlusion. In these circumstances the proximity of the origins of the CA and SMA to the other reconstruction may justify a prophylactic splanchnic revascularization.

In certain children internal iliac artery grafts are used to treat lengthy CA or SMA stenoses. Anastomoses are fashioned with interrupted sutures when reconstructing small arteries 2 to 3 mm in diameter. In older adolescents, a continuous suture may be used to complete anastomoses of larger splanchnic arteries (see Fig. 126-5). In other children, aortic implantation of the CA or SMA after spatulation of the transected vessel beyond its stenotic origin is favored over an aortosplanchnic bypass (see Figs. 126-7 and 126-17).[58] Children treated by both methods have invariably gained weight and are free of abdominal discomfort.[58] Percutaneous transluminal balloon angioplasty with or without stenting for these developmental ostial lesions is not appropriate and ill-advised.

Splanchnic arterial occlusive disease when encountered in childhood has an uncertain natural history. Long-term follow-up of these children with periodic imaging studies in those operated on seems appropriate, and regular clinical assessment of those not subjected to surgical therapy is recommended. In regard to the latter, it is important to remember that most CA and SMA stenoses are asymptomatic because of the IMA serving effectively as a source of collateral circulation. Unoperated patients should be aware of their splanchnic arterial anatomy and be able to pass this information on to anyone undertaking a later abdominal operation. In these individuals, inadvertently interrupting the collateral circulation might cause catastrophic intestinal ischemia.

The median arcuate ligament syndrome is a poorly defined disorder that has been sporadically described in children.[60,61]

**FIGURE 126-17** *Left,* celiac artery occlusion and severe ostial stenosis of the superior mesenteric artery (SMA). *Right,* Postoperative documentation of widely patent SMA implanted onto anterior aorta. (From Upchurch GR Jr, Henke PK, Eagleton MJ, et al: Pediatric splanchnic arterial occlusive disease: Clinical relevance and operative treatment. J Vasc Surg 2002;35:860-867.)

Compression or entrapment of the celiac artery by unyielding fibers of the diaphragmatic crura the aortic hiatus is a recognized anatomic finding. Intermittent upper abdominal pain has been reported to be the most common clinical manifestation alleged to occur in symptomatic cases. Weight loss in children has not been a constant accompanying finding in these individuals. Treatment usually includes transaction of the compressing tissue and skeletonization of the celiac artery. Celiac artery narrowing may persist if secondary mural fibrosis has occurred, but such is less likely to occur in children compared with adults. Early relief of symptoms is expected, but long-term outcomes remain to be defined.

Splanchnic artery aneurysms in children are uncommon.[57] The etiology that underlies these lesions becomes an important determinant of therapy. Blunt or deceleration injury to the liver and spleen may result in small pseudoaneurysms recognized on a computed tomography (CT) study, but such may often be safely followed without a specific intervention. Most small pseudoaneurysms thrombose without sequelae. Endovascular embolic obliteration of large or unstable aneurysms in these solid organs is usually possible in older children and adolescents.

Splanchnic artery aneurysms associated with childhood Ehlers-Danlos syndrome or Kawasaki disease, as well as some of the necrotizing arteritides such as polyarteritis nodosa, are unlike those traumatic lesions affecting the liver and spleen. The former aneurysms carry a potential risk of rupture or thrombosis. Most are diagnosed by CTA or MRA studies. Treatment includes endoluminal catheter-directed thrombosis, simple ligation, or aneurysmectomy with an arterial repair if necessary. Explicit clinical guidelines have yet to be established in the management of these rare aneurysms.

# Extremity Arterial Disease

## ACUTE LOWER EXTREMITY ARTERIAL OCCLUSION

Catastrophic lower extremity arterial occlusion in pediatric patients is uncommon.[62] It is often a consequence of UAC thromboembolic events in the neonate and femoral artery thromboses following arterial catheterizations or cannulations in the management of congenital heart disease.[63–66] In older children and adolescents, both penetrating and nonpenetrating arterial injuries can cause profound lower extremity ischemia.[67,68] On rare occasions less common etiologies of acute arterial occlusion exist including thrombosed aneurysms, paradoxical emboli, and thromboembolism associated with bacterial endocarditis.[69]

In the very young an isolated femoral artery occlusion without initial evidence of severe ischemia may be managed conservatively with heparin anticoagulation. Some have reported acceptable results of nonoperative therapy even in patients with critical ischemia.[70] The relative effectiveness of the collateral circulation in these circumstances usually preserves limb viability. If impending tissue loss or ischemic nerve dysfunction exists, then an open revascularization is appropriate and preoperative imaging is important by CTA or conventional arteriography by way of umbilical artery catheterization. In instances where further catheterizations should be avoided, an intravenous digital subtraction arteriography often suffices (Fig. 126-18). In cases of arterial injury due to blunt trauma or orthopedic trauma with long-bone fractures or posterior knee dislocations, the exact level of the injury may be difficult to discern and imaging in this setting will be essential to the diagnosis and proper treatment.

In situations of limited lower extremity arterial injury, a local resection and primary repair may be possible. Interrupted sutures in young children with spatulation of the involved vessels, so as to create an ovoid anastomosis, will lessen the risk of later stenosis of the repair. In older patients a patch angioplasty or bypass in the lower extremity with reversed saphenous vein is appropriate (Fig. 126-19).[63,71] Late aneurysmal deterioration of these grafts is unlikely, in contrast to their use in renal artery reconstruction.

## CHRONIC LOWER EXTREMITY ARTERIAL OCCLUSIONS

Chronic lower extremity ischemia in children has the potential to lead to growth retardation and later limb length discrepancies.[63,72] Arterial catheterization-related thromboses are the most common cause of delayed lower extremity ischemia.[63] In this regard, limb length discrepancy rates of 8% have been reported after femoral catheterizations.[73]

Chronic limb ischemia in children is often initially unrecognized because of the child's ability to develop extensive collaterals, with palpable pulses in the affected extremity similar to those in the uninvolved opposite extremity. Thus

**FIGURE 126-18** Intravenous digital subtraction arteriogram documenting occluded right external iliac and common femoral arteries. Iodinated contrast was injected centrally through a catheter advanced through the right brachial vein under fluoroscopic guidance to the junction of the vena cava and right atrium. (From Cardenau JD, Henke PK, Upchurch GR Jr, et al: Efficacy and durability of autogenous saphenous vein conduits for lower extremity arterial reconstructions in preadolescent children. J Vasc Surg 2001;34:34-40.)

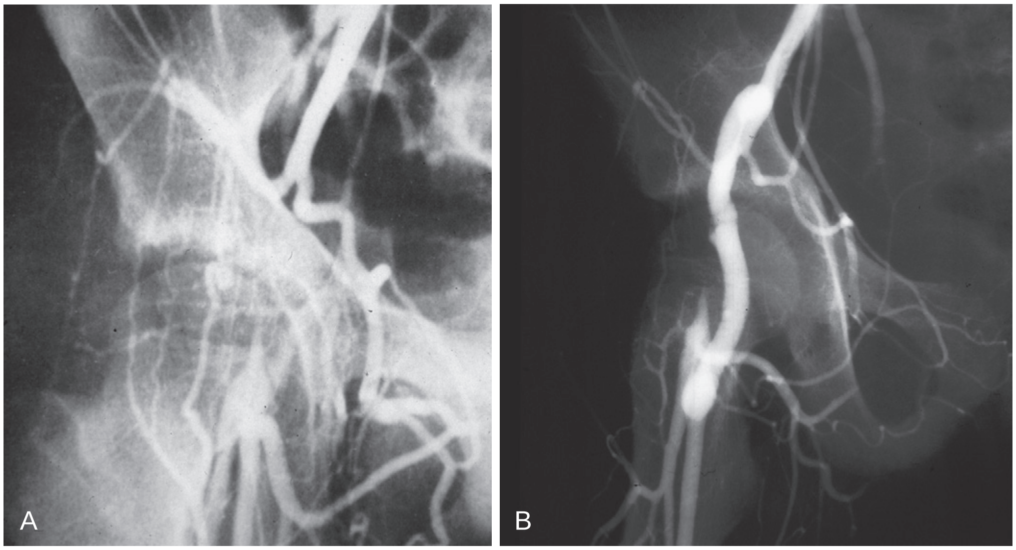

**FIGURE 126-19** **A,** Occlusion of common femoral and external iliac arteries due to thrombosis after cardiopulmonary bypass cannulation of the vessel in a child with a limb length discrepancy. The deep femoral and superficial femoral arteries are reconstituted through abundant collaterals. **B,** Subsequent iliofemoral bypass graft with saphenous vein.

it is often not until a discrepancy in limb length develops with gait abnormalities or the child complains of exercise-related symptoms that the diagnosis is even considered.

Simple Doppler ankle-brachial indices (ABIs) may suggest limb ischemia. However, detection may be evident only if a substantial decline in ABI occurs following treadmill exercise. Conventional arteriographic studies will best define the suspected occlusion in these children. Intravenous digital subtraction arteriography with newer computer-enhanced imaging has proven useful in defining these lesions while avoiding further vascular complications. Both MRA and CTA are evolving as commonly performed imaging techniques, but MRA may not provide small vessel detail and caution is appropriate regarding excessive radiation exposure if serial CTA studies are necessary.

Interestingly, 93% of patients in one study whose acute ischemia was managed without operation had their ABI return to normal after being treated with heparin anticoagulation alone.[74] Thus a normal resting ABI in the presence of an occluded iliac or femoral artery does not necessarily eliminate the risk for later growth problems. It is advised that arterial reconstruction using vein or synthetic grafts is appropriate for occluded iliofemoral or femoral arteries before a child enters rapid growth phases. Revascularization before adolescence when long bone growth is the most active is important to lessen limb length discrepancies. In the past, it had been generally accepted that late operation would not reverse an existing limb length discrepancy, but this has not always proven to be the case.

## UPPER EXTREMITY ARTERY OCCLUSIONS

Upper extremity ischemia is most commonly associated with blunt or penetrating trauma, shoulder or elbow dislocations, or supracondylar humerus fractures. Concomitant nerve injuries accompany many of these vascular injuries. Diagnosis is usually suspected from the clinical findings of pallor, reduced or absent pulses, and weakness with repetitive motions.

Formal imaging is not necessary if the site of injury is obvious by physical examination. In such a setting a standard vascular repair should be pursued if the ischemia is severe with impending tissue loss or pain with minimal activity. Lesser degrees of acute ischemia may abate with development of collateral vessels. In those children, especially the very young, conservative nonoperative therapy may be appropriate. If exercise-related claudication occurs later, a formal revascularization may be undertaken. In many early cases with a focal injury, the involved arterial segment may be excised, the vessel mobilized so as to have no tension on it, and a primary reanastomosis undertaken. In other cases a bypass with autologous saphenous or basilic vein may be required.

Subclavian-axillary artery occlusion is an unusual complication of the birthing process (Fig. 126-20). Mechanisms causing this complication are believed to be similar to those cited for brachial plexus birth injuries. Arterial occlusions may result from intimal fracture secondary to stretching of the vessel or from direct compression due to thoracic outlet closure or shoulder dislocation. Acute ischemia placing the limb at jeopardy in these neonates is rare. Development of more severe symptoms is related to damage of collateral arterial flow around the obstructed vessel. Subclavian artery sacrifice for Blalock-Taussig procedures rarely causes acute ischemia because the collaterals are carefully preserved.[75] Exercise fatigue may accompany later growth abnormalities. Diminutions in longitudinal bone growth and muscle mass are common with subclavian artery occlusion. Growth disturbance alone is not an indication for surgical intervention, inasmuch as upper extremity limb length discrepancies are well tolerated and do not carry the same clinical significance as they do in the lower extremities. Carotid-subclavian or carotid-axillobrachial bypasses in late childhood are often required to relieve symptomatic forearm and hand ischemia.

## EXTREMITY ARTERIAL ANEURYSMS

Upper and lower extremity arterial aneurysms are rare, being associated with penetrating and blunt trauma, iatrogenic pseudoaneurysms following arterial punctures and catheterizations,

FIGURE 126-20 High-grade stenosis of proximal subclavian artery with poststenotic dilation and an axillary artery occlusion associated with birth trauma.

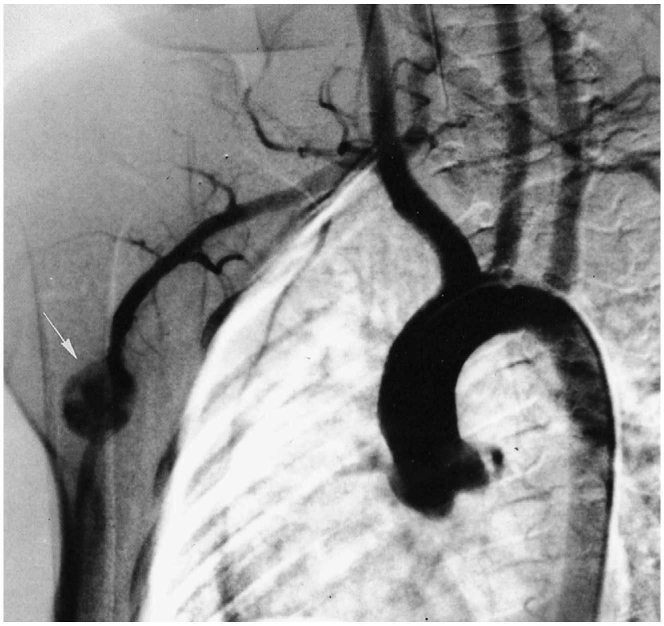

FIGURE 126-21 Brachial artery aneurysm associated with Kawasaki disease.

and nontraumatic aneurysms in cases of Kawasaki disease, Ehlers-Danlos syndrome, and other infrequently encountered vasculopathies. Aneurysms, regardless of etiology, affecting the larger arteries of both upper and lower extremities carry a greater risk of thromboembolism than rupture. Depending on the presence of collateral vessels, most of these aneurysms should be treated operatively with either ligation or vascular reconstruction.[76]

Peripheral aneurysms in Kawasaki disease are of particular note (Fig. 126-21). The syndrome affects children younger than 4 years of age in 80% of cases,[77] and the most lethal aspect of this disease relates to its cardiac complications. Nearly 15% of these children develop coronary aneurysms, which are prone to thrombose, causing myocardial infarction and sudden death. Operative interventions for peripheral aneurysms in children with Ehlers-Danlos syndrome often involve simple ligation with large suture or umbilical tape, with formal arterial reconstructions undertaken when the ligation may cause critical limb ischemia. Ultrasound-guided percutaneous thrombin injection as a means of occluding traumatic and iatrogenic pseudoaneurysms has merit, but such must not result in propagation of thrombus and subsequent severe limb ischemia.[78]

# Cerebrovascular Disease

Ischemic strokes in childhood and adolescence are rare and often multifactorial.[79] Contributing to these strokes are numerous prothrombotic states including protein C and S deficiencies, antithrombin III deficiency, hyperhomocysteinemia, and sickle cell disease; structural cardiac defects accompanying congenital heart disease; a remote history of varicella zoster infection; a recent history of head or neck trauma; and various arteritides such as Takayasu disease (Fig. 126-22). A comprehensive investigation of pediatric patients experiencing a stroke should include characterization of the extracranial and intracranial vessels by

FIGURE 126-22 Magnetic resonance angiography of Takayasu disease evident by stenoses of left carotid and subclavian (*arrowhead*) arterial origins. Irregular narrowing of distal aortic arch (*arrow*).

MRA, CTA, or a conventional digital subtraction arteriogram. Such imaging will lessen the chance of overlooking a lesion amenable to surgical correction.

## CAROTID ARTERY OCCLUSION

Carotid artery stenoses or occlusions were present in approximately 50% of ischemic stroke patients studied at a major children's hospital.[80] Moyamoya disease accounted for nearly a third of these cases. Moyamoya disease is characterized by occlusions of the terminal branches of the internal carotid artery and proximal middle cerebral artery, with a "plume-of-smoke" appearance of the resulting collaterals that typify this entity. Moyamoya disease is a noninflammatory vasculitis of unknown etiology. It is seen most often in children from Southwest Asia, although all racial groups have been reported affected. The use of anticoagulants and calcium channel blockers in the acute setting have a place, although the exact benefits are ill defined. Most relevant to surgeons is recognition of the importance of maintaining normotension, euvolemia, and normocapnia during anesthesia to lessen the risk of further cerebral ischemic injury.[81–83] The operative revascularization procedures including superficial temporal-middle cerebral artery bypass or indirect revascularization procedures are complex and generally lessen the risk of future stroke.[84] The role of thrombolysis in children experiencing a stroke is still undetermined.[85]

Dissections affect the upper cervical region of the internal carotid artery and are known to follow excessive hyperextension or forceful rotation of the head and neck.[86–88] Spontaneous dissections of this type are uncommon in children. Carotid artery dissections are usually accompanied by severe facial and neck pain (hemicrania) and are often associated with syncope, near syncope, a seizure, or stroke. The majority of patients will exhibit Horner syndrome. Treatment is usually conservative, with the use of anticoagulation. The mural hematomas associated with the dissection frequently resolve, leaving a near normal artery. When such does not occur and the child is experiencing cerebral ischemic symptoms, operative therapy is recommended. Resection of the affected carotid artery and reconstruction with an interposition graft is appropriate in that setting.

## CAROTID ARTERY COILING

Developmental coiling and tortuosity of the extracranial internal carotid artery have been reported to affect a quarter to nearly half of young children undergoing arteriographic studies (Fig. 126-23).[65,89] The true incidence of this abnormality is likely less because those being studied may represent a selected group, but nevertheless these findings are not rare in the very young.

Coiling and tortuosity of the internal carotid artery are normal findings in the fetus. As the heart and great vessels migrate caudally, the vessel usually straightens. Occasionally the embryonic tortuosity persists. Frequent demonstration of bilateral abnormalities lends credence to arrested development as the basis of these lesions. The patterns of internal carotid artery coiling and tortuosity range from gentle S-shaped tortuosities to complete coiling.[89] These changes characteristically begin a few centimeters beyond the common carotid artery bifurcation.

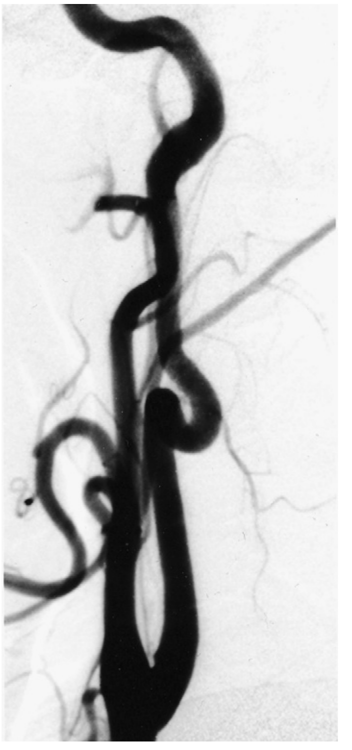

**FIGURE 126-23** Internal carotid artery coiling.

Most children with internal carotid artery coiling are asymptomatic. However, neurologic symptoms including transient ischemic attacks, hemiparesis, and seizures have been alleged to be associated with coiling in certain individuals.[90] Although the subject of considerable controversy, there may be a small number of children having lateralizing neurologic symptoms who may benefit from surgical intervention.[91] Reimplantation of the internal carotid artery more proximally onto the common carotid artery or excision of the redundant artery with reanastomosis is the most frequent reconstruction undertaken in symptomatic children.

## CAROTID ARTERY ANEURYSMS

Aneurysms of the proximal extracranial carotid artery are rare in children.[92] True aneurysms are usually manifestations of a generalized vascular disease like Ehlers-Danlos syndrome. Traumatic pseudoaneurysms are uncommon and are usually the consequence of blunt trauma (Fig. 126-24). Other traumatic aneurysms represent a complication of tonsillectomy or, occasionally, errant placement of central venous catheters. Most carotid artery aneurysms deserve early operative treatment to lessen the risk of cerebral embolization. Simple arterial suture of the entrance into a pseudoaneurysm or an interposition graft, usually with an internal iliac artery segment, in the case of extensive aneurysmal involvement is appropriate. There may be a role for endoluminal therapy, with placement of covered stents in certain children.[93]

Small mural aneurysms affecting the internal carotid artery adjacent to the upper cervical vertebrae are often due to violent head trauma with stretching and fracture of the vessel wall. These may be the source of emboli or thromboses acutely

**FIGURE 126-24** Internal carotid artery aneurysm following blunt trauma.

causing a massive stroke. Anticoagulant and antiplatelet therapy lessen these events. Lining the involved artery with a covered stent or replacement with an interposition graft may be advised if recurrent cerebral ischemic symptoms occur despite medical therapy.

## VERTEBRAL ARTERY DISSECTIONS AND OCCLUSION

Injury of the vertebral artery due to forceful stretching or blunt trauma may result in a dissection causing an acute stroke.[88,94] However, many dissections are initially asymptomatic. CTA imaging in children with severe head and cervical spine trauma may allow earlier recognition and treatment of these lesions. Simple administration of heparin and antiplatelet agents has been successful in many patients.[95] Operative revascularization is usually deferred to symptomatic patients due to chronic occlusions in whom rotational nystagmus and other posterior circulatory phenomena can be demonstrated.

CHAPTER 127

# Congenital Heart Disease and Anomalies of the Great Vessels

Richard G. Ohye and Jennifer C. Hirsch

Congenital cardiac malformations are the most common congenital defects, with an incidence of 0.5% to 1% of live births (excluding trivial lesions and bicuspid aortic valves). Although the technical details of the repair of complex malformations are beyond the scope of this textbook, pediatric surgeons should have a basic understanding of the anomalies and their repair because they are often involved in the management of these patients. All patients undergoing open cardiac surgical procedures receive standard gram-positive antibiotic prophylaxis at the time of surgery. Prophylaxis for future noncardiac surgical procedures is based on the current American Heart Association guidelines recommending prophylaxis for any patients with significant residual defects or significant valvar dysfunction. Prophylaxis is not required for patients who have patch material in place for greater than 6 months. The pediatric surgeons' "encounters" with the pediatric cardiac population may occur in many different contexts: (1) A cardiac malformation may be present or suspected in a fetus for whom the pediatric surgeon is consulted for a general surgical malformation, the prognosis of which may be affected by the cardiac defect (i.e., giant omphalocele); (2) intestinal ischemia is often suspected in premature infants with a patent ductus arteriosus or term babies with cardiac malformations leading to decreased splanchnic blood flow; (3) cardiac defects are common in patients with esophageal atresia, with aortic arch anomalies presenting specific challenges to pediatric surgeons; (4) vascular anomalies such as a persistent left superior vena cava may be associated with cardiac malformations and pose problems during attempts at central venous access; (5) polysplenia/asplenia and intestinal malrotation are frequent in patients with situs inversus; and (6) finally, pediatric surgeons may be involved in postcardiac surgery ECMO or may be called urgently for insertion of a peritoneal drainage catheter after an infant has undergone a cardiac surgical procedure. For all these reasons, pediatric surgeons should understand the anatomy and pathophysiology of common malformations of the heart and great vessels.

## Patent Ductus Arteriosus

The ductus arteriosus is a normal fetal structure that communicates between the pulmonary trunk or proximal left pulmonary artery (PA) and the proximal descending thoracic aorta (Fig. 127-1). During fetal development, this vessel provides a pathway for blood leaving the right ventricle to bypass the high-resistance pulmonary vascular bed and traverse the systemic circulation instead. Histologically, the media of the aorta and PA contain circumferentially arranged elastic fibers, whereas the media of the ductus is composed mostly of smooth muscle cells. Normally after birth, the rise in oxygen tension that accompanies ventilation of the lungs signals closure of the ductus. In a full-term infant, closure of the ductus is usually complete by 12 to 24 hours. Closure of the ductus creates a fibrous cord called the *ligamentum arteriosum.* Failure of closure of the ductus leads to the condition known as *patent ductus arteriosus* (PDA). The incidence of isolated PDA is approximately 1 in 1200 live births and accounts for about 7% of all congenital heart defects.[1] The incidence is higher in preterm infants (>20%).[2] This defect may occur in isolation or in association with a number of other anomalies. In some heart defects in which there is inadequate pulmonary blood flow (such as pulmonary atresia) or inadequate systemic blood flow (e.g., severe coarctation of the aorta), persistent patency of the ductus is desirable. The discovery of prostaglandins to maintain ductal patency has played a significant role in improving the survival of such patients.[3]

### NATURAL HISTORY AND DIAGNOSIS

The pathophysiology of PDA involves shunting of blood across the ductus. The shunt volume is determined by the size of the ductus, as well as the ratio of pulmonary to systemic vascular resistance. Pulmonary vascular resistance drops dramatically at birth and continues to decrease over the first weeks of life. This leads to left-to-right flow across the ductus. Excessive pulmonary blood flow typically leads to congestive heart failure, and in extreme cases, hypotension and systemic malperfusion may also occur. For patients with a large PDA who survive infancy, there is a risk of developing pulmonary

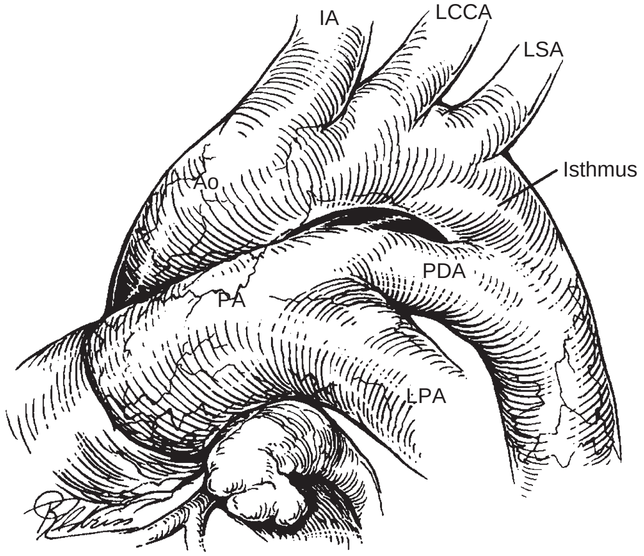

FIGURE 127-1 Anatomy of patent ductus arteriosus (PDA) as seen from a left thoracotomy. The ductus extends from the main pulmonary artery (PA) and enters the proximal descending thoracic aorta distal to the left subclavian artery (LSA). Ao, aorta; IA, innominate artery; LCCA, left common carotid artery. (From Hillman ND, Mavroudis C, Backer CL: Patent ductus arteriosus. In Mavroudis C, Backer CL [eds]: Pediatric Cardiac Surgery, 3rd ed. Philadelphia, Mosby, 2003.)

vascular obstructive disease. In these cases, Eisenmenger's physiology may develop when pulmonary vascular resistance exceeds systemic vascular resistance, leading to a reversal of shunting across the ductus (from left to right to right to left), causing cyanosis and, eventually, right ventricular failure. Some patients with a small PDA may remain asymptomatic until adulthood. Endocarditis and endarteritis have been reported as long-term complications of PDA.[4]

The clinical manifestations of PDA are determined by the shunt volume and the presence of associated cardiac defects. Left-to-right shunt flow leads to volume overload of the left heart. Signs of congestive heart failure in infants commonly include tachypnea, tachycardia, and poor feeding. Older children may present with recurrent respiratory infections, fatigue, and failure to thrive. Physical findings include a widened pulse pressure and an active precordium. Auscultation reveals a continuous "machinery" murmur heard best along the left upper sternal border. Radiographic findings include increased pulmonary vascular markings and left heart enlargement generally in proportion to the degree of shunting. Electrocardiography may demonstrate left ventricular hypertrophy and left atrial enlargement. Echocardiography is currently the diagnostic method of choice and can additionally rule out the presence of associated defects. Cardiac catheterization is reserved for two principal indications. First, in older patients with suspected pulmonary hypertension, it can be used to evaluate for pulmonary vascular obstructive disease. Second, transcatheter techniques have been developed to occlude the ductus in selected cases.[5–7]

## MANAGEMENT

Three management schemes for the closure of a PDA exist: pharmacologic therapy, surgical closure, and endovascular device closure. Indomethacin and ibuprofen, cyclooxygenase inhibitors, are useful for stimulating PDA closure in premature infants.[8] Indomethacin and ibuprofen are known to have a number of possible side effects including hypotension, decreased gastrointestinal blood flow (which may lead to necrotizing enterocolitis or spontaneous intestinal perforation), decreased renal blood flow, and interference with platelet function. Due to an improved side effect profile regarding gastrointestinal bleeding and renal dysfunction, ibuprofen is the current drug of choice.[9] It is rarely effective in full-term babies. The dosing regimen is 10 mg/kg intravenously, followed by 5 mg/kg intravenously at 24-hour intervals for a total of three doses. This approach is successful in nearly 80% of premature infants.[9,10] Contraindications to ibuprofen therapy include sepsis, renal insufficiency, and bleeding disorders. Failure of ibuprofen after two complete courses results in referral for surgical closure.

The surgical approach to the PDA is usually via a left posterolateral thoracotomy through the third or fourth intercostal space (Fig. 127-2). The pleura is divided longitudinally over the proximal descending thoracic aorta. The vagus nerve is thereby lifted medially. Dissection is carried out to demonstrate unequivocally the distal transverse aortic arch and ductus. In some cases the ductus may be the largest vascular structure present, so it is critical that it not be confused with the aorta. Once the anatomy is confirmed, the ductus is gently dissected. Ductal tissue is extremely friable, especially in premature infants, so direct manipulation is not recommended.

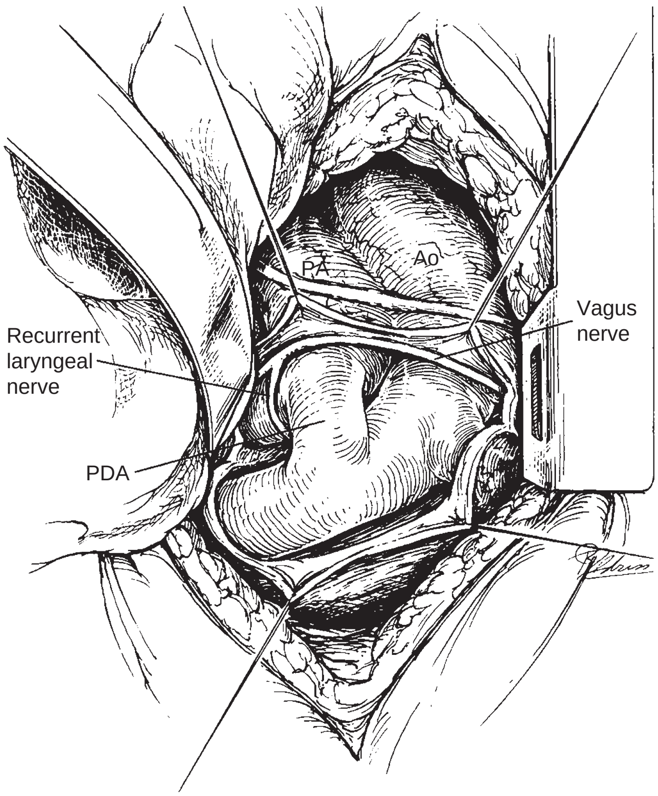

FIGURE 127-2 Exposure of patent ductus arteriosus (PDA) by left thoracotomy. The mediastinal pleura has been divided and reflected with preservation of the vagus and recurrent laryngeal nerves. Ao, aorta; PA, pulmonary artery. (From Hillman ND, Mavroudis C, Backer CL: Patent ductus arteriosus. In Mavroudis C, Backer CL [eds]: Pediatric Cardiac Surgery, 3rd ed. Philadelphia, Mosby, 2003.)

The recurrent laryngeal nerve curves behind the ductus and must be preserved during the dissection. The ductus may be occluded with a surgical clip or silk ligature, or it may be divided between ligatures (Fig. 127-3). The latter is preferred in most cases; however, in premature infants, the safest approach is clip occlusion. The surgical procedure is commonly performed in the neonatal intensive care unit, which avoids problems associated with patient transfer.[11,12]

Recently, PDA ligation has been performed using video-assisted thoracoscopy.[13] This approach has the potential benefits of decreased pain and shorter hospital stay. Disadvantages include a substantial learning curve and increased operating time.

Several endovascular devices have been developed for the purpose of transcatheter occlusion of the PDA.[5–7] These devices have proved to be so successful that at most centers, transcatheter occlusion has become the treatment of choice for older infants and children with small- to moderate-sized PDAs. Surgical therapy is reserved for patients with larger-sized ducts.

## RESULTS

Closure of the PDA by surgical or transcatheter approach can be performed with a mortality close to zero.[11] Potential morbidity from surgical therapy may include pneumothorax, recurrent laryngeal nerve injury, phrenic nerve injury, and chylothorax. Most patients should experience a normal life expectancy following PDA ligation. Long-term survival in premature infants depends primarily on the extent of prematurity and the presence of associated anomalies.

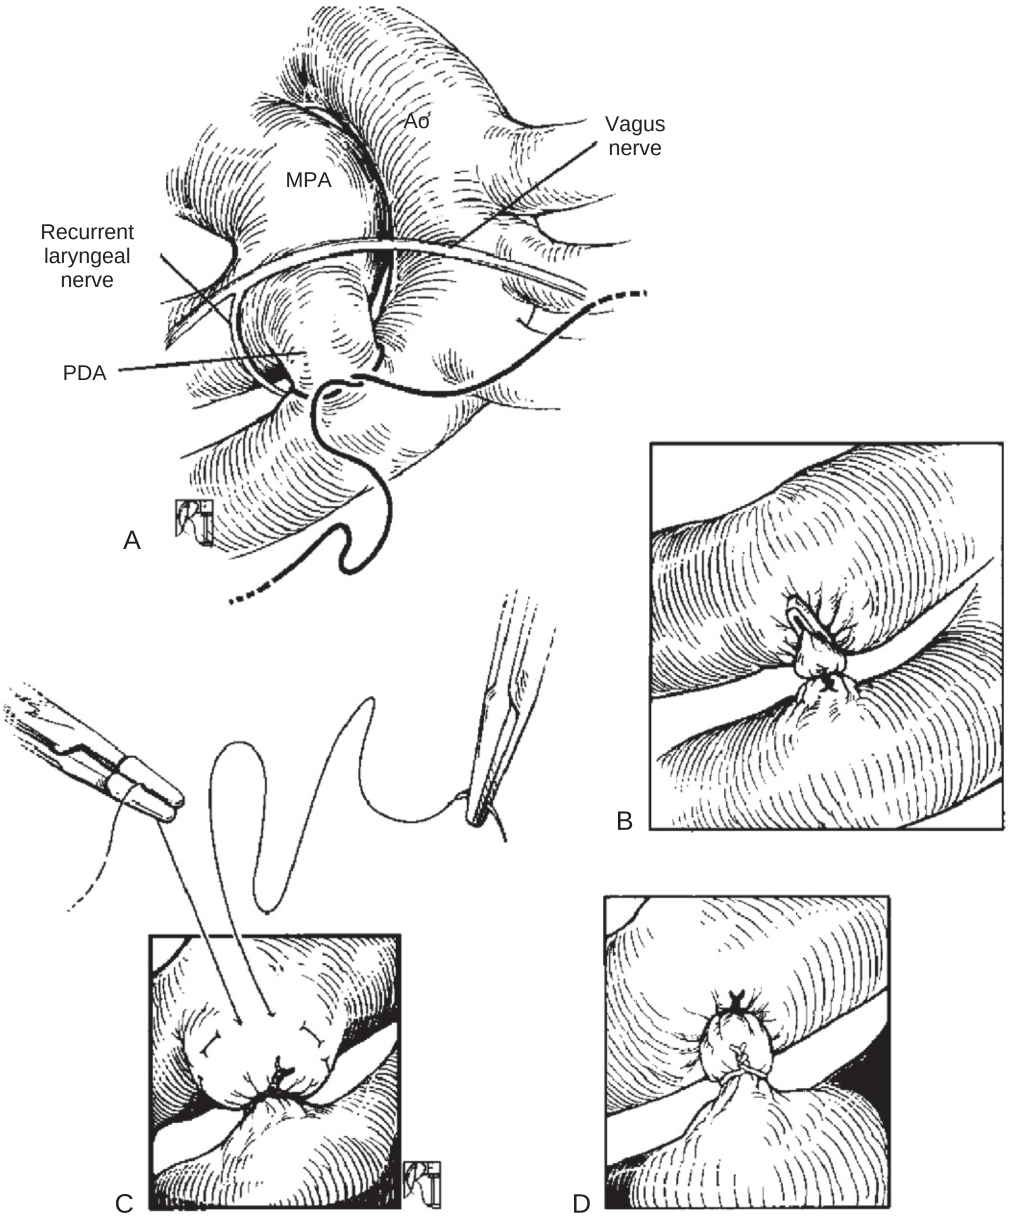

**FIGURE 127-3** Various techniques for control of the patent ductus arteriosus (PDA). **A**, Simple ligation. **B**, Ligation and hemoclip application. **C** and **D,** Ligation and adventitial pursestring. Ao, aorta; MPA, main pulmonary artery. (From Hillman ND, Mavroudis C, Backer CL: Patent ductus arteriosus. In Mavroudis C, Backer CL [eds]: Pediatric Cardiac Surgery, 3rd ed. Philadelphia, Mosby, 2003.)

# Coarctation of the Aorta

Coarctation of the aorta is a congenital narrowing of the proximal descending thoracic aorta near the insertion of the ductus arteriosus (or ligamentum arteriosum). This creates obstruction to blood flow and results in a pressure load on the left ventricle. The incidence of coarctation is about 0.5 per 1000 live births, and its prevalence is 5% of congenital heart defects.[1] Coarctation is commonly associated with other heart defects including bicuspid aortic valve (in > 50% of cases), patent ductus arteriosus, and ventricular septal defect. Other left-sided obstructive lesions may be present including aortic arch hypoplasia, aortic stenosis, mitral stenosis, and left ventricular hypoplasia.

## NATURAL HISTORY AND DIAGNOSIS

Two patterns of presentation are based on anatomy, age, and symptoms (Fig. 127-4). In infantile coarctation, patients develop symptoms in the first week of life. These infants have such severe aortic obstruction that perfusion of the lower body depends on flow from the ductus arteriosus. Spontaneous ductal closure (which also tends to worsen the aortic obstruction) then precipitates ischemia to tissues beyond the coarctation. The resultant pressure load on the left ventricle may lead to congestive heart failure. Patients may exhibit shock with severe acidosis, oliguria, and diminished distal pulses. Survival for these patients is unlikely without intervention.

The second pattern of presentation is sometimes called *adult coarctation*. Patients with adult coarctation are usually asymptomatic during infancy and present later in life with hypertension. These patients generally develop extensive collaterals, which serve to bypass the obstruction. Life expectancy for these patients is limited due to the development of heart failure later in life and the cumulative risk of endocarditis (frequently involving a bicuspid aortic valve) or endarteritis (in the poststenotic aorta at the site of the turbulent jet), aortic rupture, or intracranial hemorrhage (from Berry aneurysms, which are more common in patients with coarctation).[14]

Coarctation can usually be diagnosed clinically. The newborn infant with significant coarctation may appear normal at birth but following ductal closure develops signs of heart failure such as irritability, tachypnea, and poor feeding. Lower-extremity pulses are absent, and upper-extremity pulses may be weak. Chest radiography may show cardiomegaly and pulmonary venous congestion. There is a left ventricular strain pattern on the electrocardiogram. Echocardiography is usually diagnostic, demonstrating anatomic narrowing at the coarctation site with a loss of pulsatility in the descending aorta; additional cardiac defects are also demonstrable.

In older children and adults, there is usually a pressure gradient between the arms and legs, which can be identified by measuring cuff pressures in all four extremities. Radiography may demonstrate rib notching, which is secondary to the development of large intercostal collaterals that erode into the inferior aspects of the ribs. Echocardiography is usually sufficient to confirm the diagnosis in older patients; however, computed tomography (CT) and magnetic resonance imaging (MRI) provide excellent anatomic detail, which may aid in therapeutic planning. Cardiac catheterization is usually not necessary.

## MANAGEMENT

The diagnosis of coarctation usually mandates surgical correction; however, the acute medical management of the sick neonate demands careful attention. Prostaglandin $E_1$ is usually effective for reopening the ductus when administered within 7 to 10 days after birth; its effectiveness wanes when initiated after 2 weeks of life. Intravenous fluids, inotropic agents, and correction of anemia may also be important for the resuscitation of the patient with coarctation.

Surgical exposure of coarctation is performed by left posterolateral thoracotomy through the third or fourth intercostal space. The mediastinal pleura overlying the left subclavian artery and proximal descending thoracic aorta is incised, and the descending aorta, transverse arch, brachiocephalic vessels, and ductus (or ligamentum) are mobilized. Care is taken to avoid injury to the vagus nerve and its

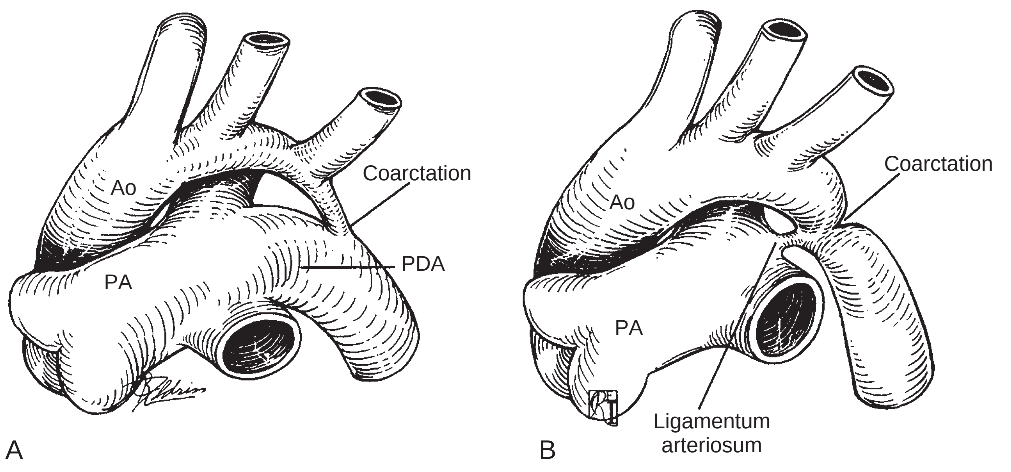

FIGURE 127-4 **A**, Infantile coarctation of the aorta (Ao). The isthmus (segment of the aorta between the left subclavian artery and ductal insertion) is hypoplastic, and the descending aorta receives most of its flow from the ductus. **B**, Adult coarctation with juxtaductal narrowing of the aorta and a prominent posterior shelf. The ductus has contracted to form the ligamentum arteriosum. PA, pulmonary artery; PDA, patent ductus arteriosus. (From Backer CL, Mavroudis C: Coarctation of the aorta. In Mavroudis C, Backer CL [eds]: Pediatric Cardiac Surgery, 3rd ed. Philadelphia, Mosby, 2003.)

recurrent branch. The coarctation is usually evident externally by narrowing or posterior indentation; however, the degree of internal narrowing is usually much more severe. A dose of heparin (100 units/kg) may be given intravenously for patients younger than 2 years. Proximal and distal control of the aorta is achieved using clamps. Usually the proximal clamp is positioned on the transverse arch between the innominate and left carotid vessels with concomitant occlusion of the left carotid and left subclavian. In infants and children, the preferred surgical approach to coarctation is resection with extended end-to-end repair (Fig. 127-5).[15] A generous resection of the coarctation segment is performed. The proximal aorta is then spatulated along the lesser curvature and the distal aorta along the greater curvature. An extended end-to-end anastomosis is then performed.

In older children and adults, it may not be possible to perform a resection with primary repair without creating excessive tension on the anastomosis, which might lead to hemorrhage or scarring with recurrent coarctation. In these cases, an alternative strategy is indicated. In children, in whom further growth is expected, the coarctation may be repaired by patch aortoplasty.[16,17] Less initial dissection is required. After achieving proximal and distal control, a longitudinal aortotomy is made across the area of narrowing. A patch of polytetrafluoroethylene or the left subclavian artery can be used to patch augment the coarctation. By avoiding circumferential prosthetic material, growth potential of the native aortic tissue is preserved. In adults, growth is no longer an issue and resection of the coarctation may be performed with subsequent placement of an interposition graft (either polytetrafluoroethylene or Dacron).

During the operative repair of coarctation, injury to the spinal cord is a major concern. In patients who do not have well-formed collaterals, ischemia of the spinal cord may be precipitated by aortic cross-clamping and paraplegia may result. Standard protective measures include induction of mild hypothermia (35° C), maintenance of a high proximal aortic pressure, and minimization of cross-clamp time. In older children and adults

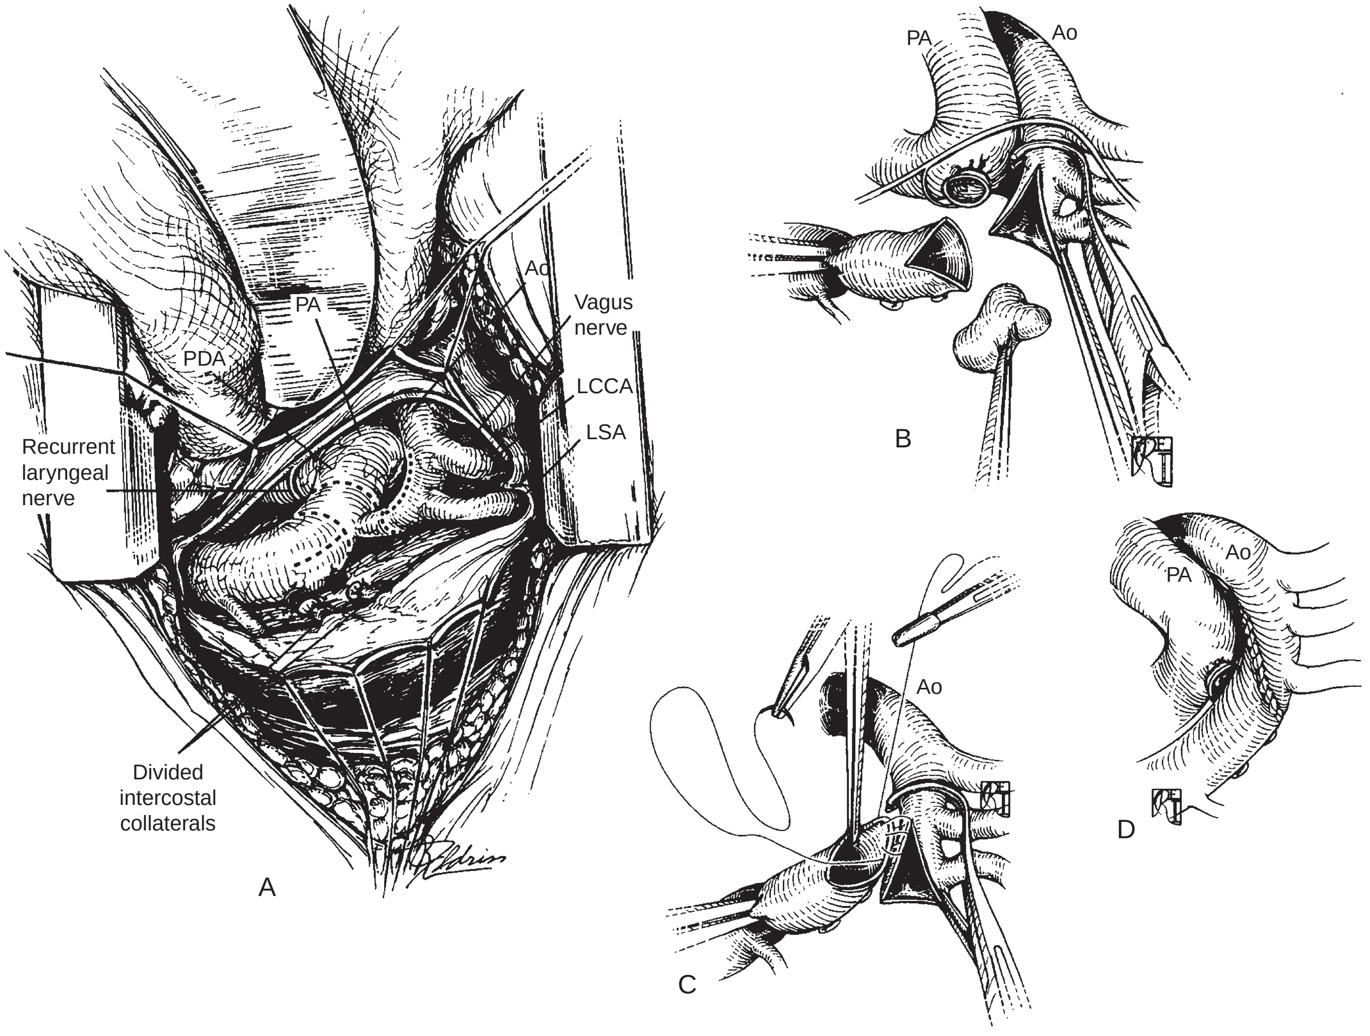

**FIGURE 127-5** Resection with extended end-to-end anastomosis. **A**, Exposure by left posterolateral thoracotomy. Vessels are mobilized and intercostals divided when necessary. **B**, The ductus is ligated and divided. Proximal and distal control is achieved, and the coarctation segment is resected. The proximal and distal aortic segments are spatulated along the lesser and greater curvatures, respectively. **C**, The anastomosis is performed using a running technique. **D**, The completed repair. Ao, aorta; LCCA, left common carotid artery; LSA, left subclavian artery; PA, pulmonary artery; PDA, patent ductus arteriosus. (From Backer CL, Mavroudis C: Coarctation of the aorta. In Mavroudis C, Backer CL [eds]: Pediatric Cardiac Surgery, 3rd ed. Philadelphia, Mosby, 2003.)

with inadequate collateral flow, distal aortic perfusion may be maintained by the technique of left heart bypass (in which the left atrium is cannulated for drainage of oxygenated blood, which is then delivered to the femoral artery or distal aorta using a centrifugal pump).[18] Overall, the incidence of paraplegia following coarctation repair is less than 1%.[19]

Following repair, patients may develop severe hypertension. This can be managed using intravenous beta blockers (such as esmolol). Uncontrolled hypertension may lead to the complication of mesenteric arteritis. Hypertension usually resolves within days to weeks after repair, although older children and adults may require permanent antihypertensive therapy. Repair of coarctation during infancy is thought to minimize the risk of late hypertension.[20]

Transcatheter therapy has been attempted as primary therapy for coarctation, but this approach is controversial.[21–24] Limitations of this approach include the incidence of recurrent coarctation, the potential need for multiple interventions, injury to the femoral vasculature (for access), and incidence of aneurysm formation. Technical success rates range from 80% to 98% with a reintervention rate of 10% to 20%.[25,26] Balloon angioplasty is generally recommended for the treatment of recurrent coarctation following surgery, in which its efficacy is on the order of 90%.[27–29]

### RESULTS

The early mortality following repair of coarctation in neonates is 2% to 10%, while the risk in older children and adults is about 1%.[15,30] The incidence of recurrent coarctation following resection and end-to-end repair is about 4% to 8%.[15,31] The long-term survival following coarctation repair is determined by the presence of associated defects and the persistence of hypertension.

## Atrial Septal Defects

Atrial septal defects (ASDs) are the third most common congenital heart defect, occurring in 1 out of 1000 live births and representing 10% of congenital heart defects.[1] In order to understand the terminology of ASDs, a review of normal atrial septation is useful. During embryologic development, the septum primum initially divides the common atrium. The ostium primum, which exists at the inferior edge of the septum primum, is obliterated as the septum primum fuses with the endocardial cushions. The ostium secundum forms in the midportion of the septum primum and is then covered by the septum secundum, which descends from the roof of the atrium along the right side of the septum primum. This arrangement creates a flap valve whereby blood from the inferior vena cava may preferentially stream beneath the edge of the septum secundum and through the ostium secundum into the left atrium. Following birth, the septum secundum fuses with the septum primum, thereby sealing the interatrial communication (Fig. 127-6).

Atrial septal defects may be classified on the basis of this embryology. The most common defect is the secundum atrial septal defect (80%), which occurs when the ostium secundum is too large for complete coverage by the septum secundum

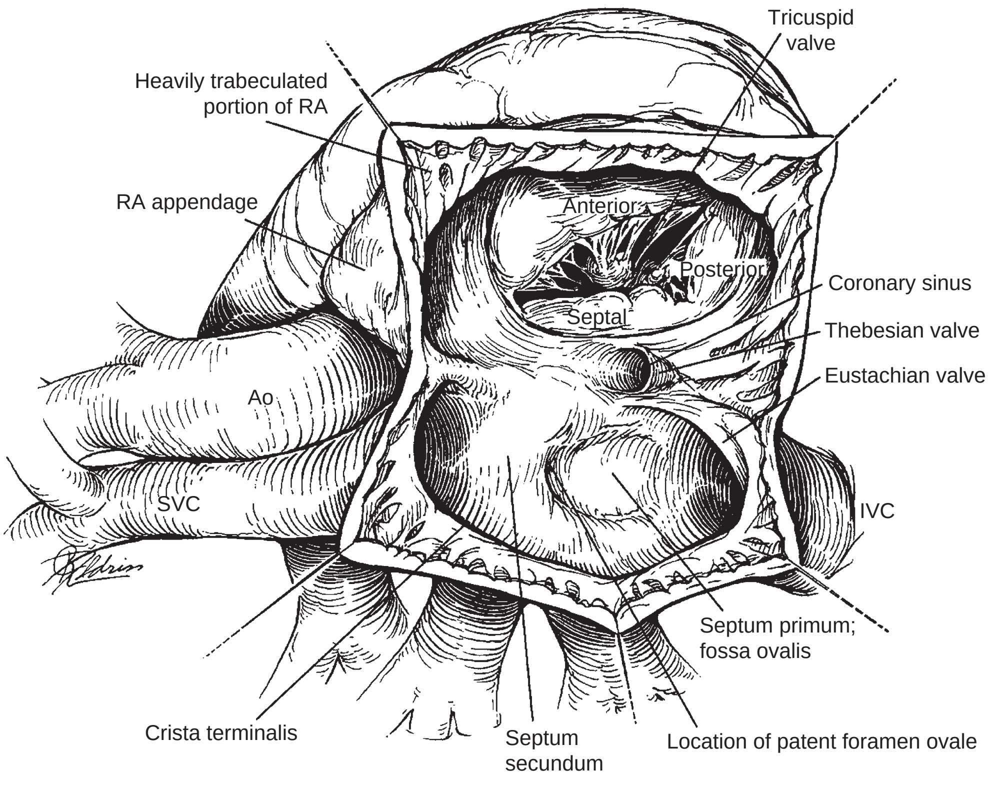

**FIGURE 127-6** Normal intraatrial anatomy as viewed by the surgeon through a right atriotomy. Ao, aorta; IVC, inferior vena cava; SVC, superior vena cava; RA, right atrium. (From Backer CL, Mavroudis C: Atrial septal defect, partial anomalous pulmonary venous connection, and scimitar syndrome. In Mavroudis C, Backer CL [eds]: Pediatric Cardiac Surgery, 3rd ed. Philadelphia, Mosby, 2003.)

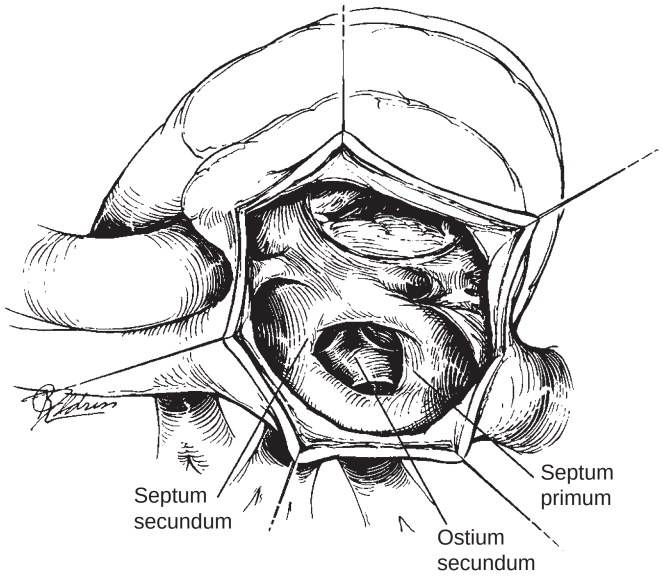

**FIGURE 127-7** Ostium secundum atrial septal defect. Note the deficiency of the septum primum in the region of the normal fossa ovalis. (From Backer CL, Mavroudis C: Atrial septal defect, partial anomalous pulmonary venous connection, and scimitar syndrome. In Mavroudis C, Backer CL [eds]: Pediatric Cardiac Surgery, 3rd ed. Philadelphia, Mosby, 2003.)

(Fig. 127-7). Failure of postnatal fusion of the septum secundum to the septum primum results in a persistent slitlike communication known as a patent foramen ovale (PFO). A primum atrial septal defect (10%) represents persistence of the ostium primum, which occurs as a result of failure of fusion of the septum primum with the endocardial cushions. This defect is discussed in the section on atrioventricular septal defects. Sinus venosus ASDs (10%) are caused by abnormal fusion of the venous pathways with the atrium; these defects can be located high in the atrial septum near the orifice of the superior vena cava, or, less commonly, they may be low in the atrial septum near the orifice of the inferior vena cava (Fig. 127-8). Sinus venosus ASDs occur commonly with partial anomalous pulmonary venous return, usually with the right upper pulmonary vein draining into the superior vena cava near the cavoatrial junction. An uncommon type of ASD is the unroofed coronary sinus septal defect. This occurs when there is loss of the common wall between the coronary sinus and left atrium adjacent to the atrial septum. This unroofing of the coronary sinus results in a communication between the right and left atria at the site of the coronary sinus.

## NATURAL HISTORY AND DIAGNOSIS

Shunting at the atrial level occurs primarily during diastole and is determined in part by the size of the atrial defect and more importantly by the relative ventricular compliance. In other words, blood preferentially fills the more compliant chamber. At birth, both chambers are equally compliant, but as pulmonary vascular resistance falls, the right ventricle remodels and becomes more compliant. As a result, shunting across an ASD in postnatal life is from left to right. This results in a volume load on the right heart. A volume load is a burden created by additional venous return to a chamber during diastole.

The volume overload created by an ASD is usually well tolerated. As a result, patients are frequently asymptomatic. Congestive heart failure is rare in infants. Children may develop symptoms of exertional dyspnea, exercise intolerance, or recurrent respiratory infections. Older patients with untreated ASDs tend to develop atrial dysrhythmias, and adults may develop congestive heart failure and right ventricular dysfunction. Pulmonary vascular obstructive disease may develop as a late complication of untreated ASD; severe pulmonary hypertension has been shown to develop in 14% of adults

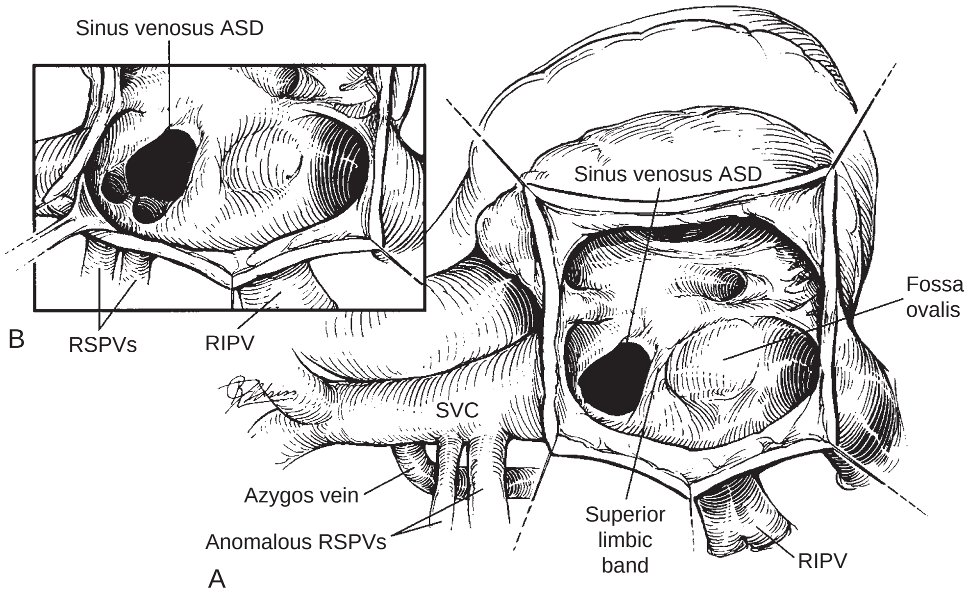

**FIGURE 127-8** Sinus venosus atrial septal defect. **A**, Defect near the superior cavoatrial junction cephalad to the superior limbic band. Note the anomalous drainage of right superior pulmonary veins (RSPVs) to the superior vena cava (SVC) and normal drainage of the right inferior pulmonary veins (RIPVs). **B**, Another type of sinus venosus ASD with anomalous RSPVs draining adjacent to the defect. (From Backer CL, Mavroudis C: Atrial septal defect, partial anomalous pulmonary venous connection, and scimitar syndrome. In Mavroudis C, Backer CL [eds]: Pediatric Cardiac Surgery, 3rd ed. Philadelphia, Mosby, 2003.)

with untreated large ASDs between the ages of 20 and 40 years.[32] Paradoxical embolization (deep venous thrombus passing to the systemic circulation via the ASD) is also an important potential complication of ASD.

On physical examination, a patient with an ASD has fixed splitting of the second heart sound and a systolic ejection murmur at the left upper sternal border due to relative pulmonary stenosis (increased flow across a normal pulmonary valve). A chest radiograph shows cardiomegaly, and electrocardiography frequently demonstrates incomplete right bundle branch block. Echocardiography confirms the clinical diagnosis of ASD and clarifies the anatomy. Cardiac catheterization is rarely necessary for diagnostic purposes but may be necessary to evaluate pulmonary vascular resistance in older patients. Cardiac catheterization is most widely used with therapeutic intent (device closure).

### MANAGEMENT

Due to the long-term complications associated with ASD, repair is recommended for all patients with symptomatic defects and in asymptomatic patients in whom the ratio of pulmonary to systemic blood flow (Qp/Qs) is greater than 1.5. Repair is usually performed in children before school age. Closure of ASDs may be accomplished surgically or using a device deployed in the cardiac catheterization laboratory.

Surgical repair of ASDs is relatively straightforward (Fig. 127-9). Surgical closure is recommended for large secundum defects and most other types of ASDs. The heart is exposed by median sternotomy. Cardiopulmonary bypass is necessary using bicaval cannulation and mild hypothermia. Following aortic clamping and arrest of the heart with cardioplegia, the atrial septum is exposed through a right atriotomy. The defect is then closed using a patch (polytetrafluoroethylene or autologous pericardium) with a running polypropylene suture. If there is anomalous pulmonary venous return, a baffle may be created to redirect the flow across the atrial septal defect into the left atrium. Small defects and PFOs can be closed primarily without a patch. In all cases, care is taken to de-air the left atrium to avoid the complication of air embolization.

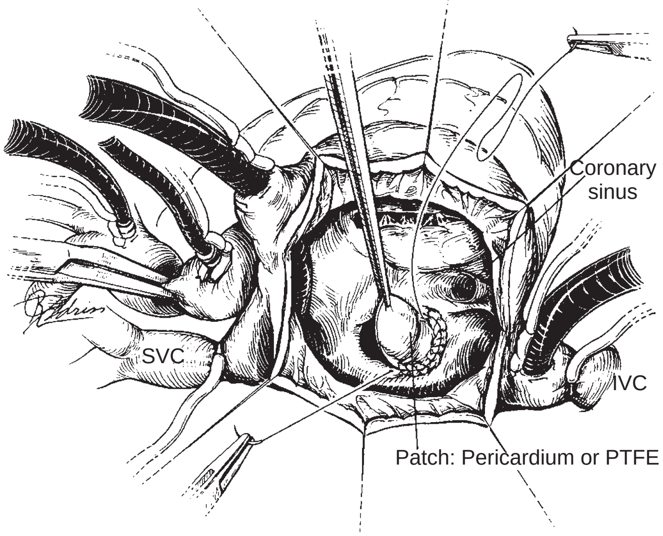

FIGURE 127-9 Patch closure of an ostium secundum atrial septal defect. Bicaval cannulation is used, and cardioplegia is infused through the aortic root to arrest the heart following application of the aortic crossclamp. IVC, inferior vena cava; SVC, superior vena cava. (From Backer CL, Mavroudis C: Atrial septal defect, partial anomalous pulmonary venous connection, and scimitar syndrome. In Mavroudis C, Backer CL [eds]: Pediatric Cardiac Surgery, 3rd ed. Philadelphia, Mosby, 2003.)

Small-to-moderate secundum ASDs and PFOs can now be closed using transcatheter techniques. Device closure of these defects has now become the standard of care at most centers with a device deployment rate of 96% with complete closure at 24 hours of 99% or greater.[33,34]

### RESULTS

ASD closure by either approach is successful.[35] Mortality is less than 1%. Morbidity is infrequent. The long-term survival for patients undergoing ASD repair in childhood is normal.[36,37]

## Ventricular Septal Defects

Ventricular septal defects (VSDs) are the most common congenital heart anomalies (with the exception of bicuspid aortic valve), occurring in 4 of 1000 live births and representing about 40% of congenital heart defects.[1] There is heterogeneity with respect to the location, size, and number of defects present. Associated cardiac defects are common. VSDs occur as a result of failure of ventricular septation. They are most commonly classified on the basis of their location: perimembranous (80%), inlet (5%), outlet (10%), or trabecular (5%) (Fig. 127-10). The most common, perimembranous VSDs, are located in the area of the membranous septum, near the point of contact of the tricuspid, mitral, and aortic valve annuli. Inlet defects are located beneath the septal leaflet of the tricuspid valve. Outlet defects are also known as *supracristal* or *doubly committed subarterial*. These defects are bordered superiorly by both semilunar valves. Outlet defects are more common in the Asian population. Trabecular (or muscular) VSDs are completely bordered by muscle. They are frequently multiple and may be associated with perimembranous or outlet defects. The size of VSDs varies. A VSD is defined as nonrestrictive when its size (or the cumulative size of multiple defects) approximates that of the aortic annulus.

### NATURAL HISTORY AND DIAGNOSIS

The physiology of a VSD involves left-to-right shunting primarily during systole. This creates a volume load on the left heart (the left atrium and ventricle receive the increased venous return during diastole). The right ventricle is not volume loaded (blood is ejected from the left ventricle through the VSD and directly into the pulmonary circulation); however, it does experience a pressure load. Shunt volume across a VSD is determined by the size of the defect and by the ratio of pulmonary-to-systemic vascular resistance. As pulmonary vascular resistance decreases during the first few weeks of life, the shunting across a VSD tends to increase. Therefore a VSD that was asymptomatic at birth may eventually cause severe congestive heart failure.

The natural history of patients with VSD is variable. Most VSDs are restrictive and tend to close spontaneously during

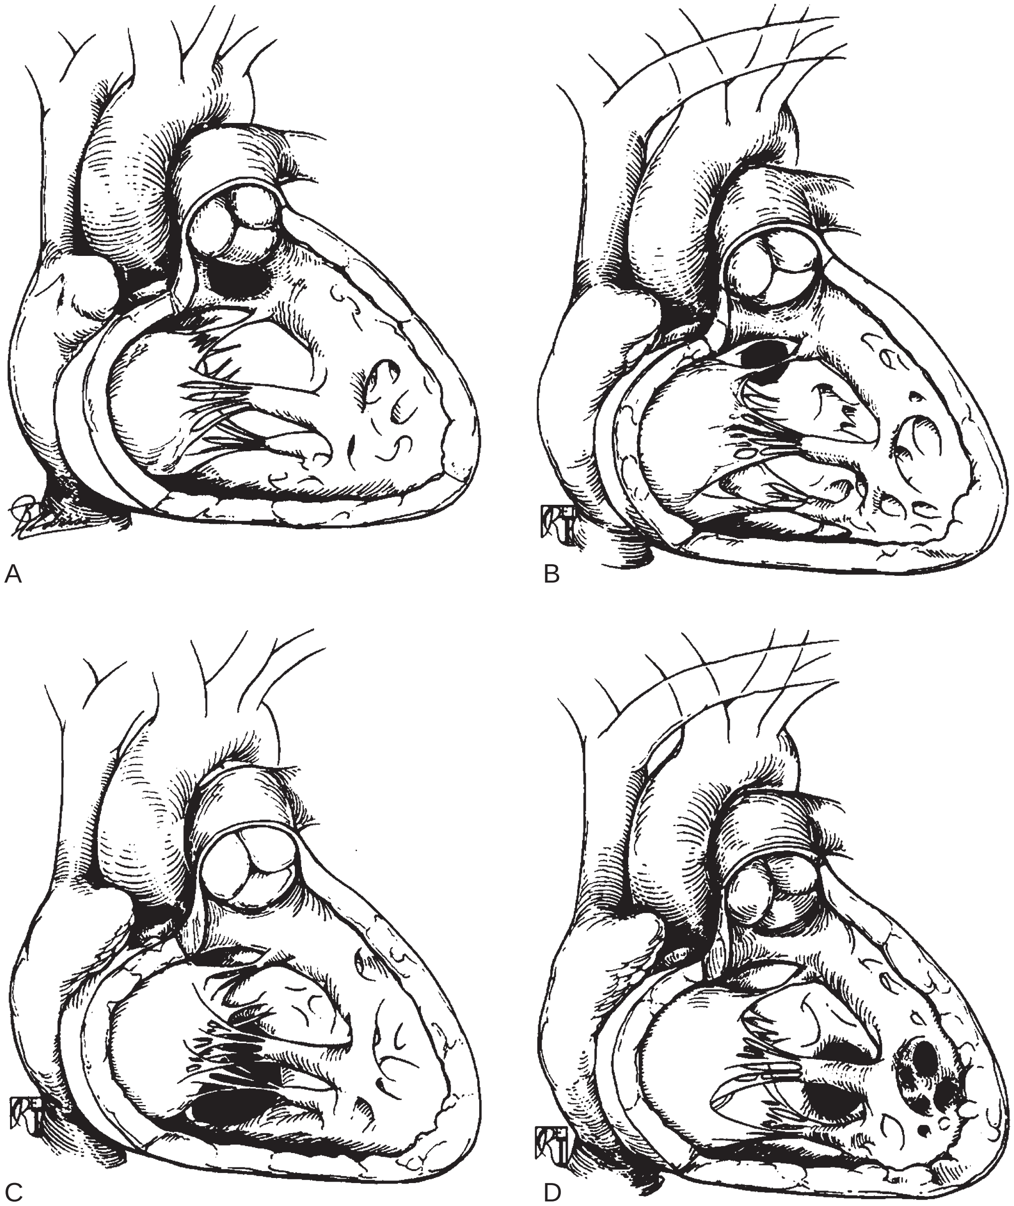

**FIGURE 127-10** Types of ventricular septal defects (VSDs) based on location. **A**, Outlet (supracristal, doubly committed subarterial). **B**, Perimembranous. **C**, Inlet. **D**, Trabecular (muscular). (From Mavroudis C, Backer CL, Jacobs JP: Ventricular septal defect. In Mavroudis C, Backer CL [eds]: Pediatric Cardiac Surgery, 3rd ed. Philadelphia, Mosby, 2003.)

the first year of life.[38] Patients with large VSDs develop symptoms caused by congestive heart failure. Untreated, excessive pulmonary blood flow leads to pulmonary vascular obstructive disease by 1 to 2 years of age. Smaller VSDs may remain asymptomatic. In patients with outlet VSDs, proximity of the aortic valve may lead to prolapse of a valve cusp and aortic insufficiency.[39]

Signs of heart failure in infants with large VSDs include tachypnea, hepatomegaly, poor feeding, and failure to thrive. On examination, there is a holosystolic murmur at the left sternal border. The precordium is active. Usually, the murmur is louder with smaller defects. In patients with pulmonary vascular obstructive disease, there may be no murmur present but the pulmonary component of the second heart sound is prominent. Chest radiography shows increased pulmonary vascular markings and cardiomegaly. Electrocardiography is significant for right ventricular hypertrophy.

Patients with small VSDs have little shunting and are usually asymptomatic, having only a pansystolic murmur. Patients with moderate VSDs manifest symptoms and signs that are proportional to the degree of shunting.

Echocardiography is diagnostic in most cases. The anatomy can be accurately defined, and the presence of associated abnormalities can be excluded. Cardiac catheterization is used selectively in older children and adults with VSDs to determine pulmonary vascular resistance and assess reactivity to pulmonary vasodilators.

## MANAGEMENT

Treatment of a patient with a VSD depends on the size of the defect, type of defect, shunt volume, and pulmonary vascular resistance. In general, patients with large defects who

demonstrate intractable congestive heart failure (CHF) or failure to thrive should undergo early surgical repair. If the congestive symptoms can be moderated by medical therapy, surgery can be delayed to 6 months of age. Patients with moderate defects may be safely followed. If spontaneous closure has not occurred by school age, then surgery may be considered. Small VSDs with Qp/Qs less than 1.5 do not require closure. In these patients there is a small long-term risk of endocarditis, but this is minimized by appropriate antibiotic prophylaxis.[40] As noted previously, patients with outlet VSDs have a significant risk of developing aortic insufficiency secondary to leaflet prolapse; as a result, all outlet defects should be referred for closure.[41] Older children and adults with large VSDs who present late must undergo catheterization to evaluate the pulmonary vasculature. A fixed pulmonary vascular resistance greater than 8 to 10 Woods units/m$^2$ represents a contraindication to surgical closure of the VSD.

Surgical closure is performed through a median sternotomy (Fig. 127-11). Cardiopulmonary bypass is required, using bicaval cannulation. Following delivery of cardioplegia, a right atriotomy is performed. Exposure of the ventricular septum is achieved through the tricuspid valve. This provides access to perimembranous, inlet, and most outlet defects. Most trabecular defects may also be exposed in this fashion. Some outlet VSDs are best exposed via a pulmonary arteriotomy because the defect sits just beneath the valve. Trabecular VSDs located near the ventricular apex are notoriously difficult to expose, and an apical ventriculotomy (left or right) may be necessary. Once the defect is exposed, it is generally closed using a polytetrafluoroethylene patch and a running polypropylene suture, although other centers may prefer other patch material or an interrupted suture technique. Knowledge of the anatomy of the conduction tissue is critical when closing VSDs. The atrioventricular node is an atrial structure that lies in the apex of the triangle of Koch (formed by the coronary sinus, the tendon of Todaro, and the annular attachment of the septal leaflet of the tricuspid valve). The node then gives rise to the bundle of His, which penetrates the atrioventricular junction beneath the membranous septum. The bundle then bifurcates into right and left bundle branches, which descend along either side of the muscular ventricular septum. When a perimembranous VSD is present, the bundle of His traverses the posterior and inferior rim of the defect, generally on the left ventricular side. In this danger area, sutures must be placed superficially on the right ventricular side of the defect and a few millimeters away from the edge of the defect. The His bundle also tends to run along the posterior and inferior margin of inlet VSDs, whereas in outlet and trabecular defects, the conduction tissue is remote.

PA banding is a palliative maneuver that is designed to protect the pulmonary circulation from excessive flow in circumstances when the patient is not a candidate for a surgical closure, either due to associated illness or anatomic complexity (e.g., multiple trabecular VSDs). Placement of a PA band may be accomplished via sternotomy or thoracotomy. The band is tightened, and pressures are measured proximally and distally with a goal of achieving a distal pulmonary pressure of approximately one-half systemic. The band should then be secured to the adventitia of the main PA to prevent its migration. Distal migration may result in narrowing (and poor growth) of one or both branch pulmonary arteries, whereas proximal migration may lead to deformity of the

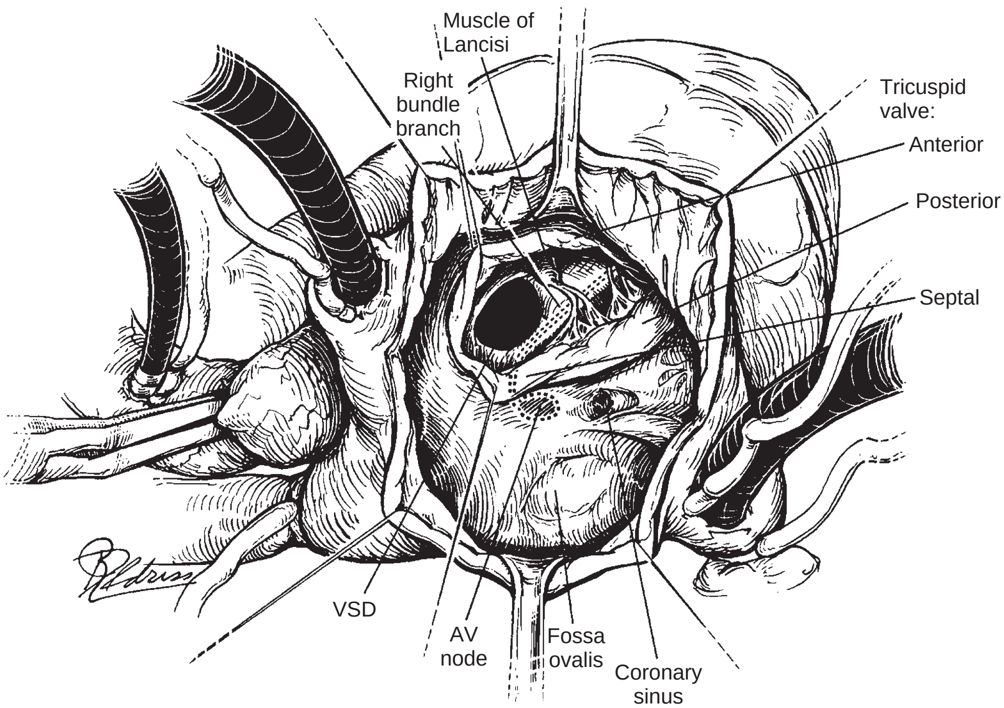

**FIGURE 127-11** Transatrial exposure of a perimembranous ventricular septal defect (VSD) as viewed by the surgeon. The septal and anterior leaflets of the tricuspid valve are retracted to expose the VSD. The conduction tissue is demonstrated by *dashed lines* leading from the atrioventricular (AV) node along the posterior and inferior margin of the VSD. When closing these defects, sutures are placed a few millimeters away from the edge of the defect on the right ventricular side of the septum to avoid conduction injury. (From Mavroudis C, Backer CL, Jacobs JP: Ventricular septal defect. In Mavroudis C, Backer CL [eds]: Pediatric Cardiac Surgery, 3rd ed. Philadelphia, Mosby, 2003.)

pulmonary valve. Ultimately, when the patient is a candidate for VSD closure, the band must be removed. In most cases, a repair (scar resection and primary closure or patch repair) of the main PA will be necessary.

Recently, transcatheter technology has evolved and closure of some VSDs may be accomplished in the cardiac catheterization laboratory or by periventricular deployment without the use of cardiopulmonary bypass.[42,43] Device closure is optimal for large muscular defects with sufficient rims for securing the device. Periventricular closure allows the use of VSD device closure in smaller infants with symptomatic muscular VSDs with excellent results without the challenges of transvenous access in this population.[43] The use of devices for perimembranous VSDs remains limited by the risk of damage to the conduction system or impingement on the function of the tricuspid or aortic valves. A recent series demonstrated a 22% rate of complete heart block, which is prohibitively high in comparison with the surgical rate of complete heart block of less than 1%.[44]

### RESULTS

Repair of a VSD is associated with a mortality of approximately 1%.[45] The main complications include injury to the conduction tissue and injury to the tricuspid or aortic valves. Transient heart block may develop as a result of tissue swelling, but permanent heart block occurs in only 1% to 2% of cases.[45] Patients who develop heart block after surgery are observed for a period of 7 to 10 days. If normal conduction has not returned, then pacemaker implantation is indicated. Tricuspid insufficiency may be precipitated by annular distortion or chordal restriction by the VSD patch or sutures. The aortic valve may also be injured by inaccurate suturing (especially in perimembranous and outlet defects). A residual VSD may be observed in 5% of cases, and reoperation is indicated when significant shunting persists ($Qp/Qs > 1.5$). Intraoperative echocardiography is used routinely to identify valvar dysfunction and residual shunting.

## Atrioventricular Septal Defect

Atrioventricular septal defects (AVSD) represent a group of congenital abnormalities bound by a variable deficiency of the atrioventricular (AV) septum immediately above and below the AV valves. Other terms commonly applied to an AVSD include *atrioventricular canal defects, endocardial cushion defects,* and *atrioventricular communis.* These resulting septal defects are invariably associated with AV valve abnormalities. Atrioventricular septal defects include incomplete AVSDs, also termed *ostium primum atrial septal defects,* which have only a deficiency of the atrial septum immediately superior to the AV valves and two separate valve orifices. The far end of the spectrum encompasses complete AVSDs, with both an ASD and a VSD and a single common AV valve. AVSDs represent approximately 4% of congenital cardiac anomalies and are infrequently associated with other cardiac malformations. AVSDs comprise 30% to 40% of the cardiac abnormalities seen in patients with Down syndrome.[46]

The embryologic abnormality in AVSDs is the failure of the proper development of the endocardial cushions, which results in variable deficiency of the atrial and ventricular septa and malformation of the AV valves. Atrioventricular septal defects are generally categorized into incomplete and complete on the basis of the AV valve morphology. Incomplete, or partial, defects have two separate AV valve orifices (Fig. 127-12). The mitral valve in an incomplete AVSD is invariably associated with a cleft in the anterior leaflet. Although most incomplete AVSDs have no ventricular level shunting, the classification of AVSDs as complete and incomplete depends only on the valve anatomy, not on the presence or absence of a VSD. Incomplete defects without associated ventricular level shunting have also been termed *ostium primum ASDs,* whereas those with a VSD have been described as *intermediate* or *transitional AVSDs.* Complete AVSDs have a single common AV valve orifice resulting in a single five-leaflet valve overlying both the right and left ventricles (Fig. 127-13). Rastelli and colleagues[47] further subclassified complete AVSDs into types A, B, and C on the basis of the morphology of the superior bridging leaflet (SBL) of the common valve.

If both left and right AV valves equally share the common AV valve orifice, the AVSD is termed a *balanced defect.* Occasionally the orifice of the valve may be unbalanced, with one side being dominant. In marked right dominance, the left AV valve and left ventricle are hypoplastic and frequently coexist with other left-sided abnormalities including aortic stenosis, hypoplasia of the aorta, and coarctation. Conversely, marked left dominance is associated hypoplasia of the right ventricle, pulmonary stenosis or atresia, and tetralogy of Fallot.

The location of the conduction tissue is of importance in the surgical treatment of AVSDs because it is at risk during the repair. The AV node is displaced posteriorly and inferiorly toward the coronary sinus. The bundle of His courses anteriorly and superiorly to run along the leftward aspect of the crest of the VSD, giving off the left bundle branch before continuing as the right bundle branch.

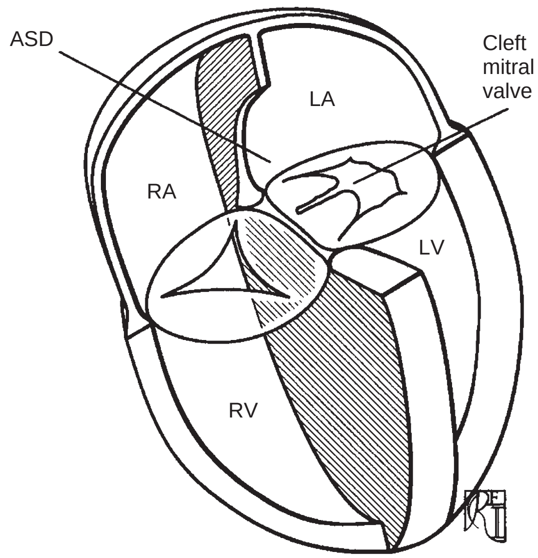

**FIGURE 127-12** Incomplete atrioventricular septal defect. ASD, primum atrial septal defect; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (From Backer CL, Mavroudis C: Atrioventricular canal defects. In Mavroudis C, Backer CL [eds]: Pediatric Cardiac Surgery, Philadelphia, Mosby, 2003.)

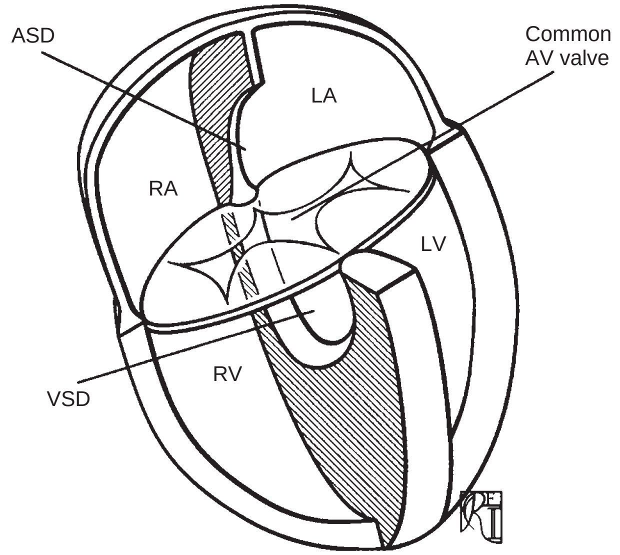

**FIGURE 127-13** Complete atrioventricular septal defect. ASD, primum atrial septal defect; AV, atrioventricular LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; VSD, inlet ventricular septal defect. (From Backer CL, Mavroudis C. Atrioventricular canal defects. In Mavroudis C, Backer CL [eds]: Pediatric Cardiac Surgery, Philadelphia, Mosby, 2003.)

Cardiac anomalies associated with AVSDs include a patent ductus arteriosus (10%) and tetralogy of Fallot (10%).[48] Important abnormalities of the left AV valve include single papillary muscle (parachute mitral valve) (2% to 6%) and double orifice mitral valve (8% to 14%).[49] A persistent left superior vena cava with or without an unroofed coronary sinus is encountered in 3% of patients with an AVSD. A double-outlet right ventricle (2%) significantly complicates or may even preclude complete surgical correction.[48] Left ventricular outflow tract obstruction from subaortic stenosis or redundant AV valve tissue occurs in 4% to 7%.[50,51] Associated transposition of the great arteries and left ventricular inflow obstruction have been reported rarely.[48,50]

## NATURAL HISTORY AND DIAGNOSIS

The predominant hemodynamic features of an AVSD are the result of left-to-right shunting at the atrial and ventricular levels. In the absence of ventricular level shunting, the hemodynamics and clinical presentation resemble that of a typical secundum ASD with right atrial (RA) and right ventricular (RV) volume overload. On physical examination, there is an active precordium, a pulmonary outflow murmur, and a fixed, widely split second heart sound. Electrocardiogram reveals a leftward axis, prominent P waves associated with atrial enlargement, and a prolonged PR interval. Chest radiograph generally shows mild cardiomegaly and increased pulmonary vascular markings. Echocardiography is diagnostic of the atrial septal defect, the absence of ventricular level shunting, and the presence of any AV valve abnormalities. Cardiac catheterization is only indicated in older patients or those manifesting physical or radiologic signs of decreased pulmonary blood flow. The decreased PA blood flow may be a result of pulmonary vascular disease or concurrent right-sided obstructive lesions. A fixed pulmonary vascular resistance of greater than 10 units/m$^2$ is a contraindication to surgical closure.

As with an uncomplicated ASD, the natural history of decades of chronic volume overload results in atrial dilatation and arrhythmias, ventricular dysfunction, and potentially pulmonary vascular disease. Therefore repair is indicated and generally undertaken by age 2 to 4 years.

Patients with a complete AVSD often have both atrial and ventricular level shunting. These patients generally present early in infancy with signs and symptoms of CHF. Moderate or greater left AV valve regurgitation may occur with a complete AVSD, worsening the clinical picture. On physical examination, the precordium is hyperactive, with auscultatory findings of a systolic murmur along the left sternal border, a high-pitched murmur at the apex from left AV valve regurgitation, and a mid-diastolic flow murmur across the common AV valve. Chest radiograph demonstrates significant cardiomegaly and pulmonary overcirculation. Electrocardiogram reveals biventricular hypertrophy, atrial enlargement, prolonged PR interval, leftward axis, and counterclockwise frontal plane loop. Echocardiography is diagnostic, defining the atrial and ventricular level shunting, valvular anatomy, and any associated anomalies. Cardiac catheterization should be performed for patients older than the age of 1 year, patients with signs or symptoms of increased pulmonary vascular resistance, or in select cases to further evaluate other associated major cardiac anomalies.

Up to 90% of untreated individuals with a complete AVSD develop pulmonary vascular disease by 1 year of age due to the large left-to-right shunt, potentially exacerbated by the associated AV valve regurgitation.[52] Patients with trisomy 21 tend to develop pulmonary vascular obstructive disease earlier than chromosomally normal infants due to small airway disease, chronic hypoventilation, and elevated $pCO_2$. Initial aggressive medical management is undertaken to relieve the symptoms of CHF. Elective surgical correction should be performed by age 3 to 6 months. Earlier intervention is indicated for failure of medical management.

## MANAGEMENT

The treatment of choice for an incomplete or complete AVSD is surgical repair. Currently, PA banding for palliation has a limited role in the management of these lesions. Indications for PA banding may include those patients with associated complex cardiac anomalies, functional single ventricle anatomy necessitating ultimate Fontan procedure, and poor clinical condition precluding major cardiac surgery.

A median sternotomy approach is employed, with routine conduct of cardiopulmonary bypass for the majority of patients. Repair of an incomplete AVSD with only atrial level shunting is similar to the approach employed for a secundum-type ASD.

There are two techniques widely employed for the repair of complete AVSDs, a one-patch technique and a two-patch technique. Regardless of which approach is selected, the goals are to close the ASD and VSD and to separate the common AV valve into two nonstenotic, competent valves. The cleft in the anterior leaflet of the mitral valve is generally closed to lessen the risk of long-term mitral regurgitation.[53–55]

For the two-patch technique, separate patches are used for the ASD and VSD (Fig. 127-14, *A*). For the one-patch

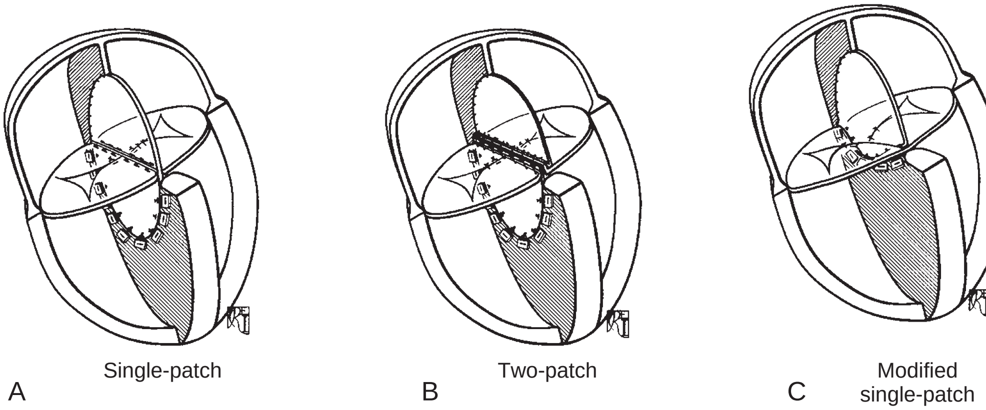

**FIGURE 127-14** Surgical repair of an atrioventricular septal defect using a single-patch **(A),** two-patch **(B),** and modified single-patch **(C)** technique. (From Backer CL, Mavroudis C. Atrioventricular canal defects. In Mavroudis C, Backer CL [eds]: Pediatric Cardiac Surgery, Philadelphia, Mosby, 2003.)

technique, the superior and inferior bridging leaflets are divided along a line separating them into right and left components. A single patch is used to close both the ventricular and atrial septal defects. The cut edges of the leaflets are then resuspended to the patch (see Fig. 127-14, *B*). For defects with a small VSD component, a modified single-patch technique may be employed. For this method, a single patch is sewn directly to the rim of the VSD, sandwiching the bridging leaflets between the patch and the crest of the VSD (see Fig. 127-14, *C*).

### RESULTS

Operative mortality is largely related to any associated cardiac anomalies and left AV valve regurgitation. Mortality for repair of uncomplicated incomplete AVSDs is 0% to 0.6%. The addition of left AV valve regurgitation increases mortality to 4% to 6%.[51,56] For complete AVSDs, the mortality without left AV valve regurgitation is approximately 5%, compared with 13% when significant degrees of regurgitation are present.[51]

The difference in operative mortality between patients with and without regurgitation underscores the importance of careful management of the left AV valve. In addition, the majority of reoperations after repair of AVSD are due to left AV valve regurgitation. Significant postoperative AV valve regurgitation occurs in 10% to 15% of patients, necessitating reoperation for valve repair or replacement in 7% to 12%.[53–55]

The incidence of permanent complete heart block is approximately 1%.[51,57] Heart block encountered in the immediate postoperative period may be transient due to edema or trauma to the AV node or bundle of His. However, right bundle branch block is common (22%).[57]

## Tetralogy of Fallot

Tetralogy of Fallot (TOF) was described by Etienne Fallot in 1888. The pathologic anatomy is frequently described as having four components: a malalignment ventricular septal defect, overriding aorta, pulmonary stenosis, and right ventricular hypertrophy (Fig. 127-15). The anatomy of tetralogy of Fallot has also been related to a single embryologic defect: anterior malalignment of the infundibular septum.[58]

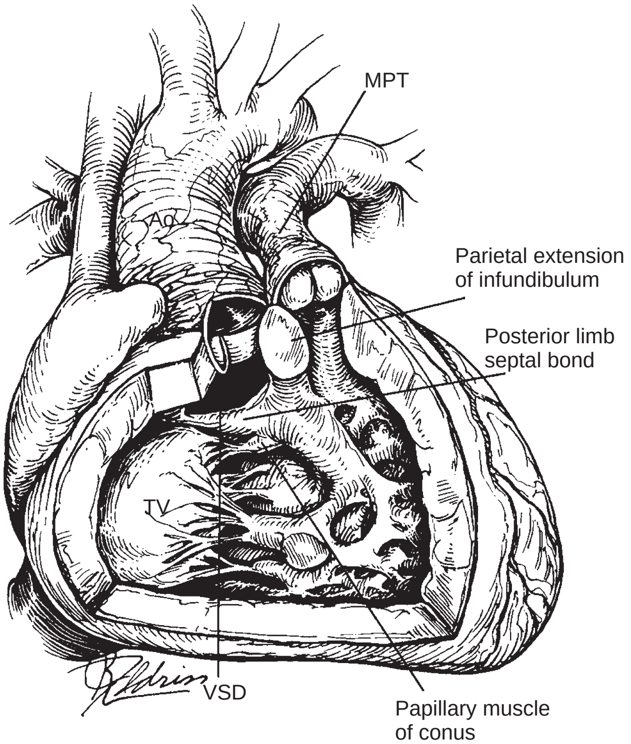

**FIGURE 127-15** Pathologic anatomy of tetralogy of Fallot. The ventricular septal defect (VSD) is nonrestrictive. The infundibular septum is maligned, leading to aortic override and crowding of the right ventricular outflow tract. Note the hypoplastic main pulmonary trunk (MPT). Ao, aorta; TV, tricuspid valve. (From Hirsch JC, Bove EL: Tetralogy of Fallot. In Mavroudis C, Backer CL [eds]: Pediatric Cardiac Surgery, 3rd ed. Philadelphia, Mosby, 2003.)

The infundibular septum normally separates the primitive outflow tracts and fuses with the ventricular septum. Anterior malalignment of the infundibular septum creates a VSD due to failure of fusion with the ventricular septum and also displaces the aorta over the VSD and right ventricle. The malaligned infundibular septum crowds the right ventricular outflow tract, producing pulmonary stenosis and, secondarily, right ventricular hypertrophy. Prominent muscle bands also extend from the septal insertion of the infundibular septum to the right ventricular free wall and contribute to the obstruction

of the right ventricular outflow tract. The pulmonary valve is usually stenotic with thickened leaflets, which are bicuspid in 58% of cases.[59] Abnormalities of coronary artery anatomy may be present, with origin of the left anterior descending from the right coronary artery in 5% of cases. In 25% of cases, there is a right aortic arch. Associated defects may include ASD, complete AVSD, PDA, or multiple VSDs.

Tetralogy of Fallot is the most common cyanotic congenital heart defect. It occurs in 0.6 per 1000 live births and has a prevalence of 5% among all patients with congenital heart disease.[1]

## NATURAL HISTORY AND DIAGNOSIS

Patients with TOF develop cyanosis as a result of shunting from right to left across the ventricular septal defect. The degree of cyanosis is proportional to the degree of obstruction of the right ventricular outflow tract. There is a spectrum of severity, with some patients developing symptoms as neonates and others remaining asymptomatic. The occurrence of intermittent cyanotic spells is a well-known clinical feature of TOF. The etiology of spelling is still controversial but is clearly related to a transient imbalance between pulmonary and systemic blood flow. A spell may be triggered by hypovolemia, peripheral vasodilation (e.g., after a bath), or infundibular spasm. Spells have been reported in neonates but tend to occur most frequently between 3 and 18 months of age. Older children have been observed to spontaneously squat to terminate spells. The squatting position is thought to increase systemic vascular resistance, which thereby favors pulmonary blood flow.

Long-term complications of untreated TOF include clubbing of the fingers and toes, severe dyspnea on exertion, brain abscesses (secondary to right-to-left shunting), paradoxical embolization, and polycythemia (which may lead to cerebral thrombosis). Long-term survival is unlikely for most patients with untreated TOF.

Cyanosis is the most frequent physical examination finding. There is usually a normal first heart sound and a single second heart sound. A systolic pulmonary ejection murmur is present at the left upper sternal border. Older children and adults may exhibit clubbing. Chest radiography characteristically demonstrates a boot-shaped heart because of elevation of the cardiac apex from right ventricular hypertrophy. A right aortic arch may be evident. An echocardiogram shows right ventricular hypertrophy. Echocardiography is definitive, and catheterization is unnecessary in most cases.

## MANAGEMENT

The medical management of TOF is directed at the treatment and prevention of cyanotic spells. The spelling patient should be given oxygen and sedation, and acidosis, if present, should be corrected. Transfusion may be indicated in anemic infants. Alpha-agonists can be administered to increase systemic vascular resistance, which favors pulmonary blood flow. Some centers have used long-term therapy with beta blockers to reduce the incidence of cyanotic spells.

All patients with TOF should undergo surgical repair. In general, asymptomatic patients should be repaired electively between 4 and 6 months of age. Early repair is indicated for neonates with severe cyanosis, as well as for infants who have had a documented spell.[60]

Classically, the repair of TOF was performed in two stages. The first stage involved creation of a systemic-to-pulmonary shunt to relieve cyanosis. The second stage was a complete repair. Currently, one-stage complete repair is preferred by most centers. In some patients (such as those with multiple congenital anomalies, severe concurrent illness, or an anomalous coronary artery crossing a hypoplastic infundibulum), initial palliation with a shunt may still be indicated. The modified Blalock-Taussig shunt is the most common type of shunt used today and consists of an interposition graft (polytetrafluoroethylene) between the innominate or subclavian artery and the ipsilateral pulmonary artery. Creation of a shunt may be performed with or without the use of cardiopulmonary bypass.

Complete repair of TOF is performed using a median sternotomy and cardiopulmonary bypass with bicaval cannulation (Fig. 127-16). Via a transatrial approach, the muscle bundles obstructing the right ventricular outflow tract are divided; resection is rarely necessary. The VSD is closed using a patch. Depending on the status of the pulmonary valve, pulmonary valvotomy may be appropriate. In cases of severe hypoplasia of the pulmonary annulus or infundibulum, a right ventricular outflow tract transannular patch may be required to relieve obstruction (Fig. 127-17). Our philosophy is to minimize right ventricular incisions whenever possible in order to preserve right ventricular function. When an anomalous coronary artery crosses the right ventricular infundibulum, a transannular incision may be contraindicated; in these cases, placement of a conduit (cryopreserved homograft or bioprosthetic heterograft) between the right ventricle (via a separate ventriculotomy) and main PA may be necessary. Patients requiring a transannular patch will develop free pulmonary insufficiency. This is well tolerated in most infants, as long as the tricuspid valve is competent. As adults, these patients will develop right ventricular failure due to chronic pulmonary insufficiency and pulmonary valve implantation will be necessary.[61,62]

## RESULTS

The early mortality following repair of TOF is between 1% and 5%.[59,63] Long-term complications include recurrent obstruction of the right ventricular outflow tract, conduit failure, and development of right ventricular dysfunction due to chronic pulmonary insufficiency. Actuarial survival is 86% at 20 years with excellent functional status.[64]

# Transposition of the Great Arteries

Transposition of the great arteries (TGA) is a common congenital cardiovascular malformation in which there is ventriculoarterial discordance. This discordant anatomy is a result of the aorta arising from the morphologic right ventricle and the PA arising from the morphologic left ventricle (LV). Transposition of the great arteries is divided into *dextro* looped- or d-TGA, and *levo* looped- or l-TGA. The looping refers to the right or left looping of the heart during fetal

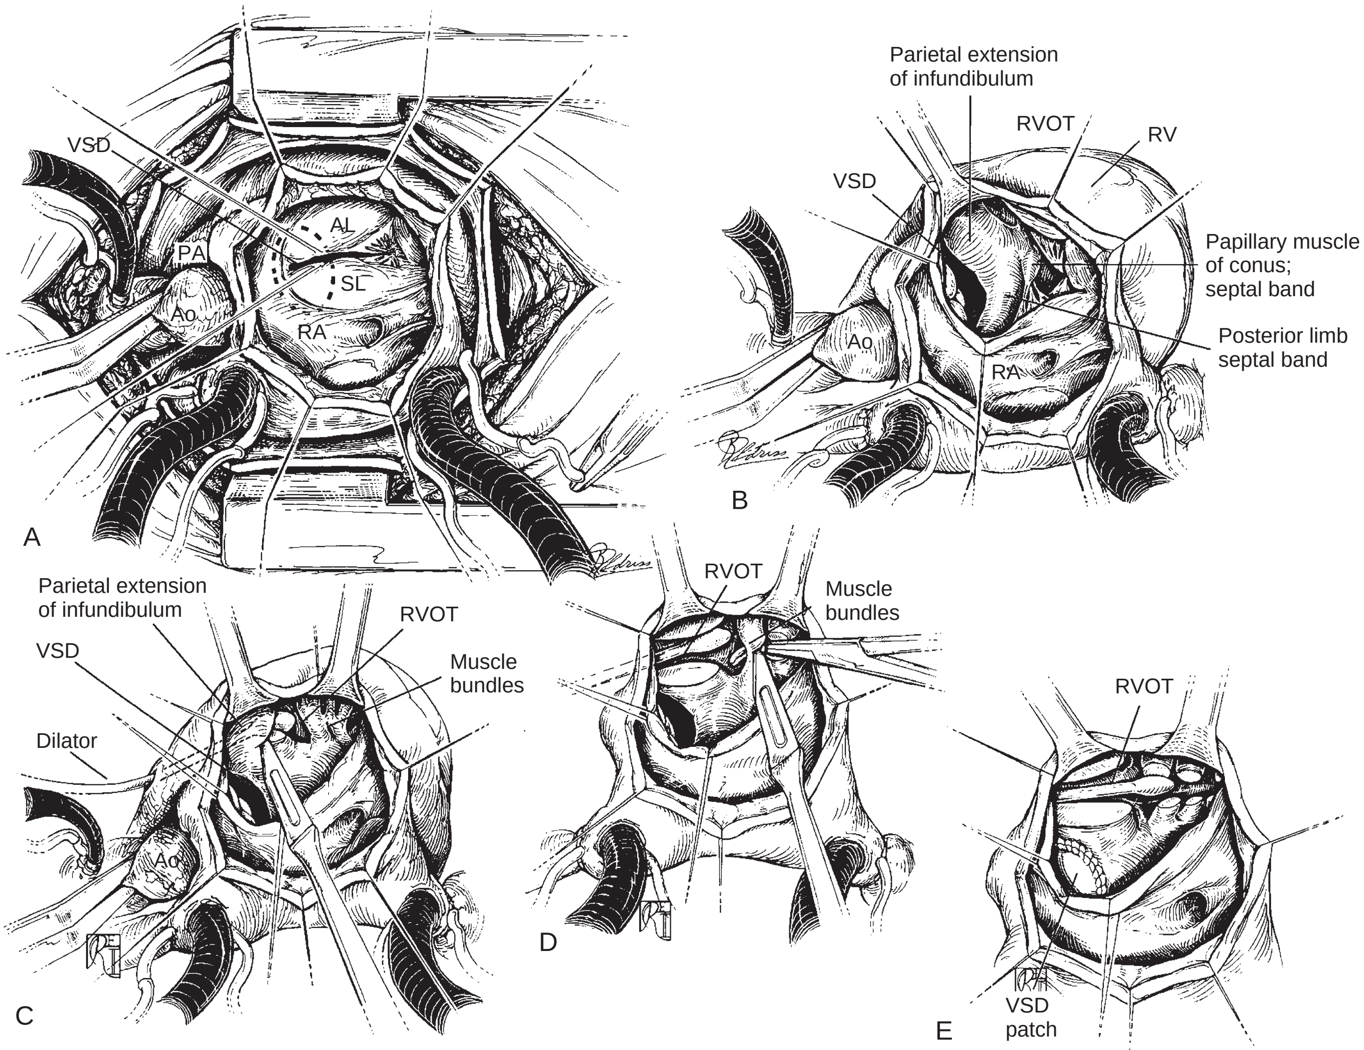

**FIGURE 127-16** Transatrial repair of tetralogy of Fallot. **A,** The location of the ventricular septal defect (VSD) is denoted by the *dashed line*. **B,** Stay sutures on the septal and anterior leaflets of the tricuspid valve allow for exposure of the VSD. **C** and **D,** Using a dilator to demonstrate the course of the right ventricular outflow tract (RVOT), hypertrophied muscle bundles may be divided or resected. **E,** The VSD is closed with a patch. development, which determines whether the atria and ventricles are concordant (right atrium attaches to right ventricle and left atrium attaches to left ventricle) or discordant. L-transposition of the great arteries is associated with both atrioventricular discordance (right atrium attaches to left ventricle and left atrium attaches to right ventricle) and ventriculoarterial discordance and is also termed *congenitally corrected TGA*. L-transposition of the great arteries is a rare variant of TGA and is beyond the scope of this chapter, which focuses on d-TGA.

d-Transposition of the great arteries is the most common cause of cyanosis in the infant and accounts for approximately 10% of all congenital cardiovascular malformations.[65] The defect can be subdivided into d-TGA with intact ventricular septum (IVS) (55% to 60%) and d-TGA with ventricular septal defect (VSD) (40% to 45%), one third of which are hemodynamically insignificant. Pulmonic stenosis (PS), causing significant left ventricular outflow tract obstruction, occurs rarely with an IVS and in approximately 10% of d-TGA/VSD.[66]

## NATURAL HISTORY AND DIAGNOSIS

Without intervention, d-TGA is universally fatal; 30% of neonates will die in the first week of life, 50% by the first month, 70% within 6 months, and 90% by 1 year.[67] Clinical characteristics depend on the degree of mixing and the amount of pulmonary blood flow (PBF). These factors relate to the specific anatomic subtype of d-TGA.

Neonates with d-TGA and IVS (or small VSD) have mixing limited to the atrial level and PDA. The ASD may be restrictive, and the PDA generally will close over the first days to week of life. As the degree of mixing decreases, the patient becomes increasingly cyanotic and will eventually suffer cardiovascular collapse. Fortunately, the majority of these neonates will manifest cyanosis early in life, which is recognized by a nurse or physician within the first hour in 56% and in the first day in 92%.[68]

In d-TGA with a large VSD, there is additional opportunity for mixing and increased PBF. The neonate with d-TGA/VSD

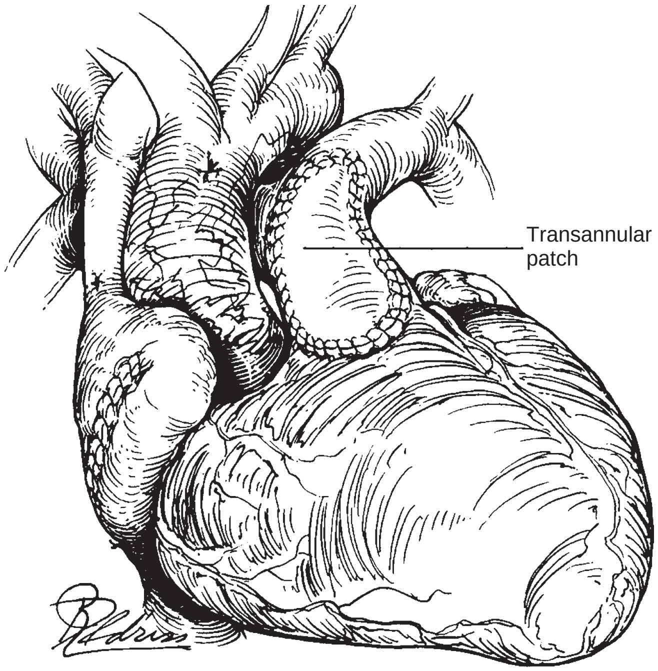

FIGURE 127-17 A transannular patch is used to enlarge a hypoplastic pulmonary annulus and main pulmonary trunk. (From Hirsch JC, Bove EL: Tetralogy of Fallot. In Mavroudis C, Backer CL [eds]: Pediatric Cardiac Surgery, 3rd ed. Philadelphia, Mosby, 2003.)

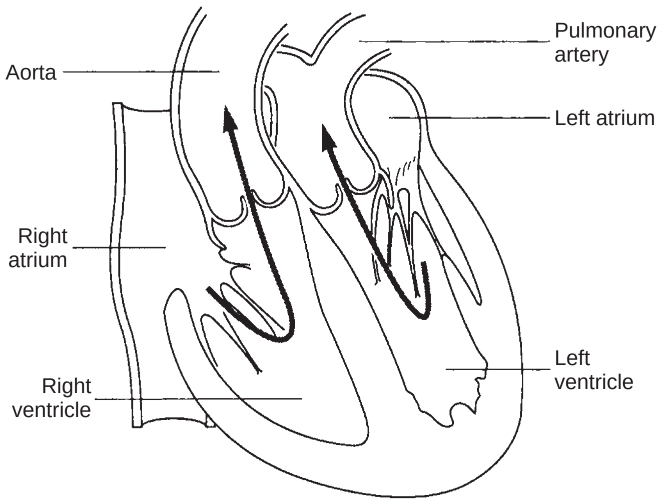

FIGURE 127-18 The anatomy of d-transposition of great arteries with intact ventricular septum. (From Bove EL, Lupinetti FM: Congenital heart disease and cardiac tumors. In Greenfield LJ, Mulholland MW, Oldham KT, Zelenock GB [eds]: Surgery: Scientific Principles and Practice. Philadelphia, JB Lippincott, 1993.)

may only manifest mild cyanosis, which may be initially overlooked. Generally within 2 to 6 weeks, signs and symptoms of congestive heart failure will emerge. Tachypnea and tachycardia become prominent, while cyanosis may remain mild. Auscultatory findings are consistent with congestive heart failure with increased PBF including a pansystolic murmur, third heart sound, mid-diastolic rumble, gallop, and narrowly split second heart sound with increased pulmonary component. Neonates with d-TGA and significant PS present with severe cyanosis at birth. Lesser degrees of PS will result in varying levels of cyanosis.

The diagnosis of d-TGA is generally suspected by the clinical presentation, or it may be seen on prenatal ultrasonography and fetal echocardiography. Chest radiograph reveals an egg-shaped heart with a narrow superior mediastinal shadow, mild cardiomegaly, and increased pulmonary vascular markings. Echocardiography is the diagnostic modality of choice. Diagnostic cardiac catheterization is rarely necessary in the current era.

## MANAGEMENT

With all forms of d-TGA, there is the need to maintain adequate mixing of oxygenated and deoxygenated blood between the right and left sides of the heart. The circulation in d-TGA is of two separate circuits, pulmonary and systemic, in parallel (Fig. 127-18). Without communication between the two sides of the heart, deoxygenated blood does not reach the lungs and oxygenated blood does not reach the systemic circulation. The majority of patients will require two levels of mixing until the time of repair to maintain adequate saturations. In d-TGA/IVS, this is achieved by maintaining a patent ductus arteriosus (PDA) with prostaglandin $E_1$ ($PGE_1$) infusion and ensuring an adequate atrial septal defect (ASD), which may require a balloon atrial septostomy. Occasionally, with d-TGA/VSD with mild or no PS, there will be adequate mixing at the atrial and ventricular levels to allow for discontinuation of $PGE_1$. In the presence of significant PS, $PGE_1$ will be necessary to provide sufficient pulmonary blood flow. These management strategies are used to palliate the patient until definitive surgical correction can be undertaken. In the absence of mitigating factors such as poor clinical condition preventing major open heart surgery, the current treatment of all forms of d-TGA is neonatal complete repair.

### d-Transposition of the Great Arteries Without Pulmonic Stenosis

The current treatment for d-TGA is an arterial switch operation (ASO). The repair is performed via a median sternotomy with standard techniques of cardiopulmonary bypass. The aorta and main PA are divided. The PA is translocated anterior to the aorta using the Lecompte maneuver, and the distal aorta is anastomosed to the proximal PA. The coronary arteries are removed from the aorta with buttons of adjacent artery and transferred to the proximal PA. The proximal aorta is reconstructed using a pantaloon-shaped patch of autologous pericardium and anastomosed to the distal PA. The ASD and, if present, the VSD are closed.

### d-Transposition of the Great Arteries with Ventricular Septal Defect and Pulmonic Stenosis

In the presence of significant PS, a Rastelli procedure is performed because an ASO will result in systemic (LV) outflow tract obstruction. The Rastelli operation uses the VSD to allow the LV to eject via the aorta. The PA is ligated and divided at the level of the pulmonary annulus. The VSD patch is constructed to incorporate both the VSD and the aortic valve, creating a tunnel from the LV to the aorta (Fig. 127-19). Right ventricle-to-PA continuity is established using a conduit from the RV infundibulum to the distal PA.

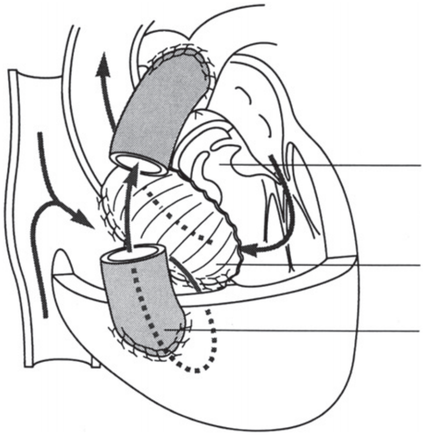

**FIGURE 127-19** The Rastelli procedure. (From Bove EL, Lupinetti FM: Congenital heart disease and cardiac tumors. In Greenfield LJ, Mulholland MW, Oldham KT, Zelenock GB [eds]: Surgery: Scientific Principles and Practice. Philadelphia, JB Lippincott, 1993.)

## RESULTS

Current hospital survival for the ASO ranges from approximately 90% to 98%.[66,69–72] In earlier eras, d-TGA/IVS had a lower mortality than d-TGA/VSD or d-TGA/VSD/PS; however, recent studies have neutralized this difference.[70,72] Long-term survival at 5 to 10 years and 15 years range from 88% to 93% and 86% to 88%, respectively.[69–71] The most common cause for reintervention is supravalvar pulmonic stenosis, occurring in 3.9% to 16%.[69,71] Late follow-up of arterial switch operation patients has led to increased concerns regarding coronary artery patency and neoaortic root dilation.[73]

A study of 101 patients undergoing a Rastelli operation over a 25-year period revealed a hospital mortality of 7%, with no deaths in the past 7 years of the study.[74] Actuarial survival at 5, 10, 15, and 20 years was 82%, 80%, 68%, and 52%.

# Single Ventricle and the Hypoplastic Left Heart Syndrome

A variety of congenital cardiovascular malformations may result in functional single ventricle anatomy, most commonly tricuspid atresia, pulmonary atresia, unbalanced atrioventricular septal defect, and hypoplastic left heart syndrome. The most common lesion is hypoplastic left heart syndrome (HLHS). There are approximately 1000 infants with HLHS born in the United States each year. It is the most common severe congenital heart defect, comprising 7% to 9% of all anomalies diagnosed within the first year of life.[75] All single ventricle lesions share the common physiology of only a single ventricle capable of supporting cardiac output. They also share the need for a two- or three-stage approach to reconstruction, ultimately resulting in a Fontan procedure. The goal of the initial procedure is to maintain adequate cardiac output and oxygen saturation while optimizing the patient for the ultimate Fontan procedure. Characteristics for an optimal Fontan candidate include good ventricular function, low PA vascular resistance, no outflow tract obstruction, and no significant atrioventricular or semilunar valve regurgitation. Another option to staged palliation is cardiac transplantation.

## NATURAL HISTORY AND DIAGNOSIS

The natural history of these lesions depends on the amount of pulmonary blood flow and the degree of systemic outflow tract obstruction. Patients with severely limited pulmonary blood flow or significant systemic outflow tract obstruction will succumb rapidly as the ductus arteriosus closes. Excessive pulmonary blood flow without systemic outflow tract obstruction will result in death due to pulmonary vascular obstructive disease, which develops at months to decades of age, depending on the degree of pulmonary overcirculation. Occasionally, patients may be "balanced" with an appropriate ratio of systemic and pulmonary blood flow, which in rare cases may allow survival into adulthood. The treatment of choice for all of these patients is still staged reconstruction to a Fontan procedure because even a perfectly balanced circulation leaves the heart volume overloaded and subject to ultimate failure. More commonly, this scenario simply allows the patient to avoid the need for an initial stage to control pulmonary blood flow in the neonatal period.

## MANAGEMENT

Due to the limited number of suitable donors, the uncertain effects of long-term immunosuppression, and the limited life span of transplanted hearts, the majority of centers have pursued a policy of staged reconstruction as the primary therapy for single ventricle lesions. Staged reconstruction involves a series of two or three procedures. An initial neonatal operation may or may not be necessary depending on the presence of systemic outflow tract obstruction or the need to limit or augment pulmonary blood flow. This is followed at 4 to 6 months of age by a bidirectional Glenn or hemi-Fontan procedure and the Fontan procedure at 18 to 24 months of age.

Because of the frequent prenatal detection of HLHS, its high morbidity and mortality, and the thought that it may be a consequence of critical aortic stenosis during development, there have been attempts at fetal ultrasound-guided balloon valvuloplasty in a few centers, with limited success thus far.

### Initial Palliation

Patients who do not have balanced systemic and PA flow ratios require an initial operation in the neonatal period. The goal of this first stage of reconstruction is to provide unobstructed blood flow to the systemic and coronary circulations, nonrestrictive pulmonary venous return, and a controlled amount of flow to the lungs. For patients with unobstructed systemic blood flow and excessive pulmonary blood flow, the PA may be banded or disconnected with the placement of a systemic to PA shunt to control the pulmonary overcirculation. For patients with unobstructed systemic blood flow and inadequate pulmonary blood flow, a systemic to PA shunt is placed. The most common single ventricle lesion, HLHS, results in systemic outflow tract obstruction and excessive pulmonary blood flow and requires an initial Norwood operation. During the Norwood procedure, the aorta is reconstructed, incorporating the proximal PA to allow the single right ventricle to eject via the aorta. A systemic to PA shunt or right ventricle

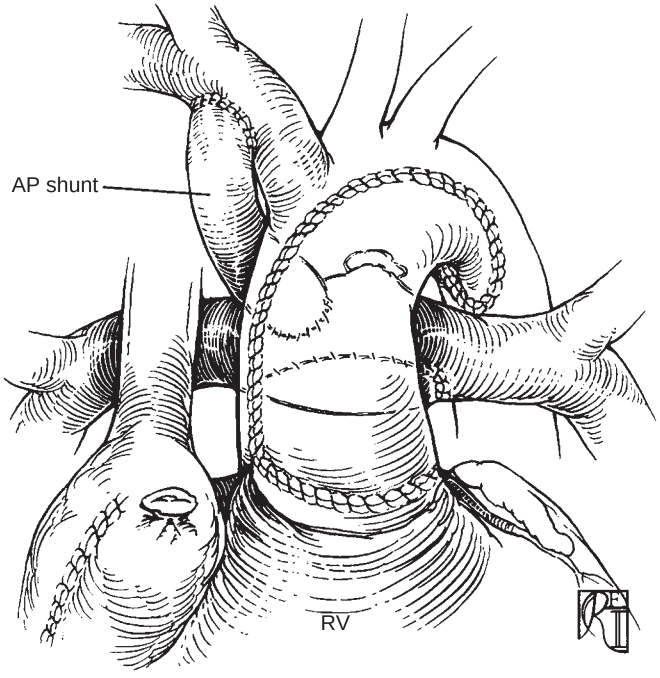

FIGURE 127-20 The completed Norwood procedure. AP, aortopulmonary; RV, right ventricle. (From Ohye RG, Mosca RM, Bove EL, et al: Hypoplastic left heart syndrome. In Mavroudis C, Backer CL [eds]: Pediatric Cardiac Surgery, Philadelphia, Mosby, 2003.)

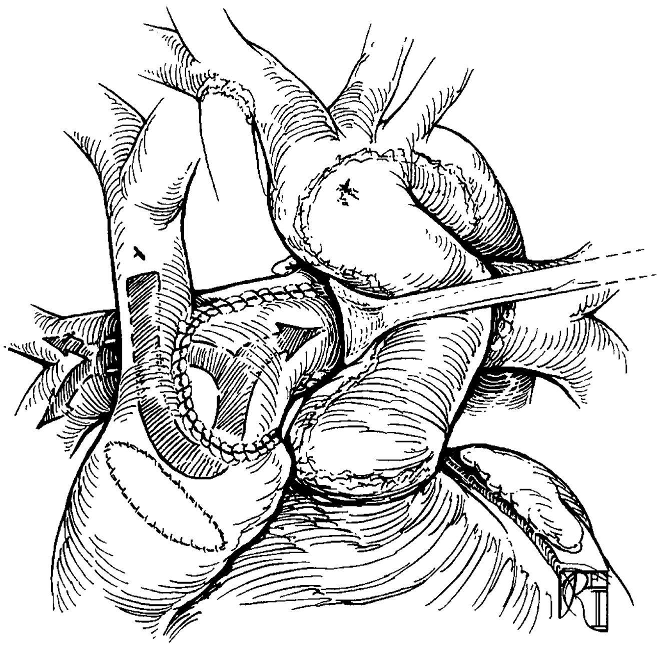

FIGURE 127-21 The completed hemi-Fontan procedure. (From Ohye RG, Mosca RM, Bove EL, et al: Hypoplastic left heart syndrome. In Mavroudis C, Backer CL [eds]: Pediatric Cardiac Surgery, Philadelphia, Mosby, 2003.)

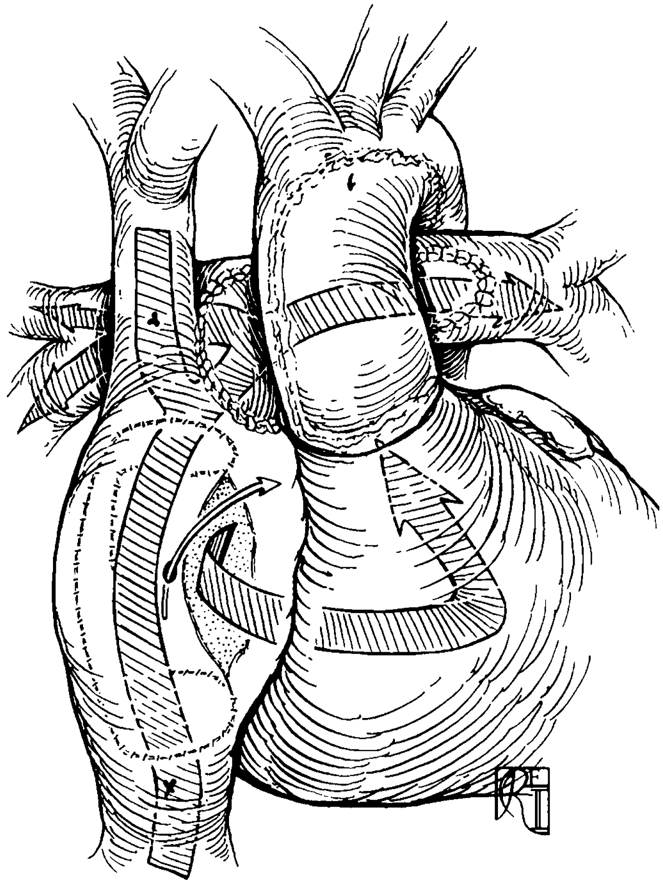

FIGURE 127-22 The completed Fontan procedure. (From Ohye RG, Mosca RM, Bove EL, et al. Hypoplastic left heart syndrome. In Mavroudis C, Backer CL [eds]: Pediatric Cardiac Surgery. Philadelphia, Mosby, 2003.)

to PA conduit is then placed to provide PA blood flow (Fig. 127-20). In response to the high mortality associated with the Norwood procedure at lower volume centers, a hybrid procedure has been introduced. It involves placement of a patent ductus arteriosus stent and bilateral PA bands via a median sternotomy in the catheterization laboratory. This approach has produced improved early results with long-term results still pending.[76] This approach delays the complex aortic arch reconstruction to the second stage.

### Bidirectional Glenn or Hemi-Fontan Procedure

In order to minimize the period of time during which the right ventricle is subject to volume overload, the hemi-Fontan operation or a bidirectional Glenn anastomosis (BDG) is typically performed between 4 to 6 months of age. The BDG entails removing the systemic to PA shunt and connecting the superior vena cava (SVC) directly to the right PA by an end-to-side anastomosis. The pulmonary blood flow after this second stage is provided solely by the SVC. The hemi-Fontan is a modification of the bidirectional Glenn procedure. The hemi-Fontan involves a side-to-side connection between the superior vena cava/right atrial junction and the pulmonary arteries, routine augmentation of the branch pulmonary arteries, and temporary patch closure between the pulmonary arteries and the right atrium (Fig. 127-21).

### Fontan Procedure

The completion of the Fontan procedure is usually performed at 18 to 24 months of age. The Fontan technique that we have employed for HLHS anatomy is the total cavopulmonary connection with a lateral tunnel (Fig. 127-22). During the Fontan procedure, the inferior vena caval venous return is directed to the pulmonary artery. Other centers use an extracardiac

conduit from the IVC to the right pulmonary artery. Of significance to pediatric surgeons, a Fontan procedure may lead to an increased venous pressure in the IVC, which may in turn cause ascites in the early postoperative period, leading to respiratory compromise. Although this has become less frequent with fenestrated Fontans, peritoneal drainage catheters may be required for several days postoperatively in some patients.

### RESULTS

Recently, tremendous strides have been made in the outcomes for patients with single ventricle anatomy. Most notably, survival for patients with HLHS, universally fatal only 2 decades ago, has drastically improved. The highest risk stage of the repair remains the Norwood operation. During the 1990s, the hospital survival for the Norwood procedure across the United States was approximately 40%.[77] Currently, several select centers are reporting hospital survivals of approximately 90% or greater.[78–81] Reported survival for the hemi-Fontan and Fontan procedures has been excellent at 98% for both operations.[82–84]

## Vascular Rings and Slings

Vascular rings comprise a spectrum of vascular anomalies of the aortic arch, pulmonary artery, and brachiocephalic vessels. The clinically significant manifestation of these lesions is a varying degree of tracheoesophageal compression. These vascular anomalies can be divided into complete vascular rings and partial vascular rings. Complete vascular rings can be divided into double aortic arch and right aortic arch with retroesophageal left ligamentum arteriosum. These two categories can be further subdivided on the basis of the specific anatomy (Table 127-1). Incomplete vascular rings include aberrant right subclavian artery, innominate artery compression, and PA sling. Other rare variations, which have been described, include left aortic arch with right descending aorta and right ligamentum and left aortic arch with aberrant right subclavian artery and right ligamentum. The incidence of clinically significant vascular rings is 1% to 2% of all congenital heart defects.

Vascular rings and pulmonary slings have been described in conjunction with other cardiac defects including tetralogy of Fallot, atrial septal defect, branch PA stenosis, coarctation, atrioventricular septal defect, ventricular septal defect, interrupted aortic arch, and aortopulmonary window. Significant associated cardiac anomalies occur in 11% to 20% of patients with a vascular ring.[83,85,86] A right aortic arch is generally associated with a greater incidence of coexisting anomalies. Pediatric surgeons should be aware that arch anomalies and aberrant subclavian arteries are more common in children with esophageal atresia, even in the absence of cardiac malformations.

By the end of the fourth week of embryonic development, the six aortic or branchial arches have formed between the dorsal aortae and ventral roots. Subsequent involution and migration of the arches results in the anatomically normal or abnormal development of the aorta and its branches. The majority of the first, second, and fifth arches regress. The third arch forms the common carotid artery and proximal internal carotid artery. The right fourth arch forms the proximal right subclavian artery. The left fourth arch contributes to the portion of the aortic arch from left carotid to left subclavian arteries. The proximal portion of the right sixth arch becomes the proximal portion of the right pulmonary artery, while the distal segment involutes. Similarly, the proximal left sixth arch contributes to the proximal left pulmonary artery, and the distal sixth arch becomes the ductus arteriosus (Fig. 127-23).

The PA is formed from two vascular precursors, as well as through a combination of angiogenesis, the de novo development of new blood vessels, and vasculogenesis, the budding and migration of existing vessels. As stated earlier, the proximal pulmonary arteries are based on the sixth arches, whereas the primitive lung buds initially derive their blood supply from the splanchnic plexus. Ultimately, these two segments of the PA join to form the vascular network of the lung parenchyma (Fig. 127-24).

**TABLE 127-1**
**Anatomic Classification and Distribution of Vascular Anomalies**

| *Anomaly Prevalence* | % |
|---|---|
| Complete vascular rings | 65-82 |
| Double aortic arch | 38-55 |
| Right dominant | 73-81 |
| Left dominant | 15-20 |
| Co-dominant | 3-11 |
| Right arch, left ligamentum/ductus | 24-55 |
| Aberrant left subclavian | 65-92 |
| Mirror-image branching | 8-35 |
| Right ligamentum | 0-3 |
| Incomplete vascular rings | 14-29 |
| Innominate artery compression | 80-87 |
| Aberrant right subclavian | 13-20 |
| Pulmonary sling | 2-9 |

### NATURAL HISTORY AND DIAGNOSIS

Children with a complete vascular ring generally present within the first weeks to months of life. Typically, children with a double aortic arch present earlier in life than those with a right arch and retroesophageal left ligamentum. In the younger age group, respiratory symptoms predominate, as liquids are generally well tolerated. Respiratory symptoms may include stridor, nonproductive cough, apnea, or frequent respiratory infections. The cough is classically described as "seal bark" or "brassy." These symptoms may mimic asthma, respiratory infection, or reflux, and children with vascular rings are often initially misdiagnosed. With the transition to solid food, dysphagia becomes more apparent.

The presentation of a patient with an incomplete vascular ring is variable. Children with innominate artery compression usually present within the first 1 to 2 years of life with respiratory symptoms. Although aberrant right subclavian artery is the most common arch abnormality, occurring in approximately 0.5% to 1% of the population, it rarely causes symptoms. Classically, when symptoms do occur, they present in the seventh and eighth decade, as the aberrant vessel becomes

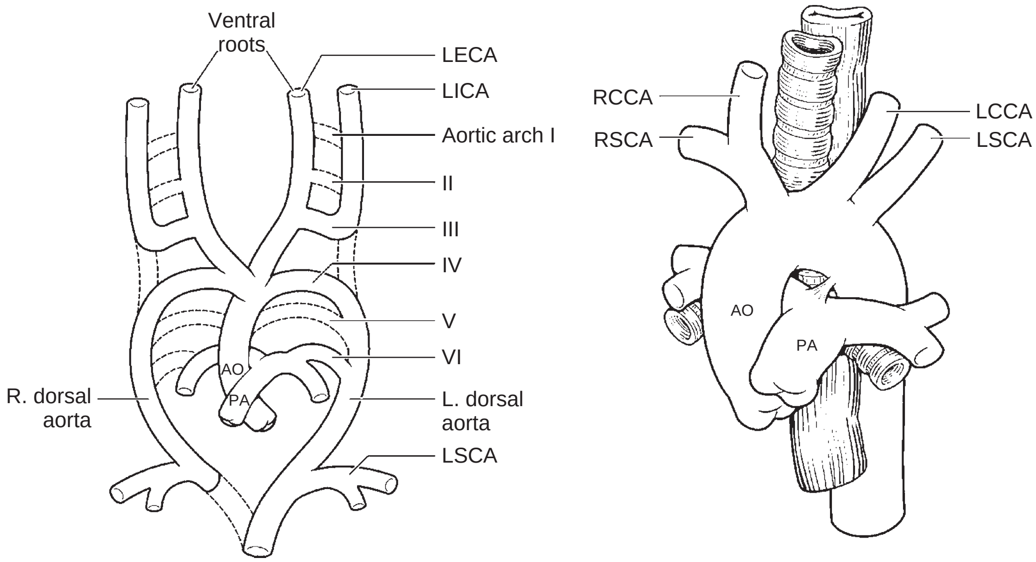

**FIGURE 127-23** Normal aortic arch development. AO, aorta; DA, ductus arteriosum; LCCA, left common carotid artery; LECA, left external carotid artery; LICA, left internal carotid artery; LSCA, left subclavian artery; PA, pulmonary artery; RCCA, right common carotid artery; RSCA, right subclavian artery. (From Ohye RG, Wild LC, Mutabagani K, Bove EL: Vascular rings and slings. In Franco KL, Putman JB [eds]: Advanced Therapy in Thoracic Surgery. Hamilton, Ontario, BC Decker, 2004.)

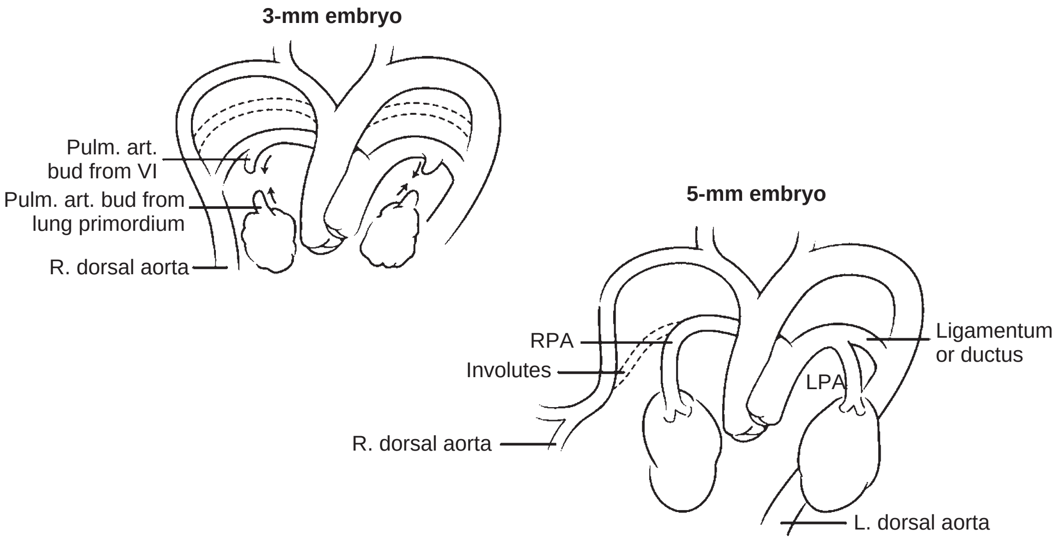

**FIGURE 127-24** Normal pulmonary artery development. LPA, left pulmonary artery; RPA, right pulmonary artery. (From Ohye RG, Wild LC, Mutabagani K, Bove EL: Vascular rings and slings. In Franco KL, Putman JB [eds]: Advanced Therapy in Thoracic Surgery. Hamilton, Ontario, BC Decker, 2004.)

ectatic and calcified, causing *dysphagia lusoria* due to impingement of the artery on the posterior esophagus. An aberrant right subclavian rarely causes symptoms, except when it is of an abnormally large caliber or associated with tracheomalacia.

Children with PA slings generally present with respiratory symptoms within the first few weeks to months of life. As with complete rings, respiratory symptoms may include stridor, nonproductive cough, apnea, or frequent respiratory infections and may mimic other conditions leading to misdiagnosis. PA slings are associated with complete tracheal rings in 30% to 40% of patients, leading to focal or diffuse tracheal stenosis.[87]

The methods for diagnosing a vascular ring are variable due to the variability in presentation and the spectrum of diagnostic tests available. A child with a presumptive diagnosis of asthma or tracheomalacia may be referred to a pulmonologist, and a diagnosis of vascular ring made or suspected initially by chest radiograph and bronchoscopy. In some situations, the diagnosis is made by echocardiography during evaluation for concurrent cardiac defects. Regardless, the diagnosis generally begins with a chest radiograph. Complementary studies may include barium esophagogram, CT, MRI, and bronchoscopy. CT, MRI, and bronchoscopy are important modalities to define the tracheal anatomy in a patient with a PA sling. Echocardiography may be diagnostic and is used to rule out other cardiac anomalies. Tracheograms and cardiac catheterizations, which have been used extensively in the past, are rarely indicated in the current era.

## MANAGEMENT

### Complete Vascular Rings

***Double Aortic Arch*** A double aortic arch occurs when the distal portion of the right dorsal aorta fails to regress (Fig. 127-25). The two arches form a complete ring, encircling the trachea and esophagus. The right arch is dominant in the majority of cases, followed by left dominant, with co-dominant arches being the least common (Table 127-1). The left and right carotid and subclavian arteries generally arise from their respective arches. The ligamentum arteriosum and descending aorta usually remain on the left.

The approach to repair of a double aortic arch is via a left posterolateral thoracotomy. The procedure can easily be accomplished through a limited, muscle-sparing incision through the third or fourth intercostal space. The lung is retracted anteriorly and inferiorly, exposing the posterior mediastinum. The pleura is incised, after identifying the vagus and phrenic nerves. The ligamentum or ductus arteriosum is divided while preserving the recurrent laryngeal nerve. The nondominant arch is then divided between two vascular clamps at the point where brachiocephalic flow is optimally preserved. If there is concern regarding the location for division, the arches can be temporarily occluded at various points while monitoring pulse and blood pressure in each limb. If there is an atretic segment, the division is done at the point of the atresia. Dissection around the esophagus and trachea in the regions of the ligamentum/ductus and nondominant arch allows for retraction of the vascular structures and lysis of any residual obstructing adhesions.

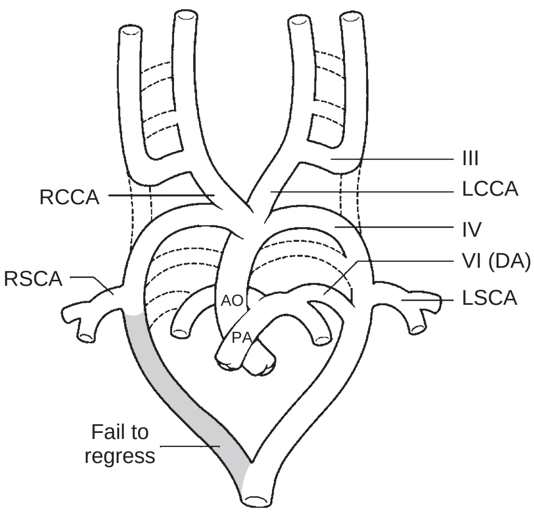
***Right Aortic Arch with Left Ligamentum Arteriosum*** There are three anatomic variations for a right arch with a left ligamentum, which cause a complete vascular ring. If the left fourth arch regresses between the aorta and left subclavian, a right aortic arch with aberrant left subclavian artery results. The ligamentum arteriosum is retroesophageal, bridging the left PA and aberrant left subclavian, forming a complete vascular ring (Fig. 127-26). If the left fourth arch regresses after the origin of the left subclavian artery, but before the arch reaches the dorsal aorta to communicate with the left sixth arch (which becomes the ductus arteriosum), there is mirror-image branching. The retroesophageal ligamentum arteriosum arises directly from the descending aorta, or from a Kommerell diverticulum off of the descending aorta, forming the complete ring (Fig. 127-27). If communication is maintained between the left fourth and sixth arches, there is mirror image branching with the ligamentum arising from the anterior and mirror image left subclavian and a ring is not formed (Fig. 127-28).

The surgical approach for a right aortic arch with retroesophageal left ligamentum arteriosum is the same as for a double arch. The ligamentum is divided, and any adhesions around the esophagus and trachea are lysed. Rarely, the Kommerell diverticulum has been reported to cause compression even after division of the ligamentum. As such, it may be prudent to resect or suspend the diverticulum posteriorly to the prevertebral fascia, if it is particularly prominent.

### Incomplete Vascular Rings

***Innominate Artery Compression*** In innominate artery compression syndrome, the aortic arch and ligamentum are in their normal leftward position; however, the innominate artery arises partially or totally to the left of midline (Fig. 127-29). As the artery courses from left to right anterior to the trachea, it causes tracheal compression. The symptoms of innominate artery compression may be mild to severe. With mild symptoms and minimal tracheal compression on bronchoscopy, children can be observed expectantly because the symptoms may resolve with growth. Indications for surgery include apnea, severe respiratory distress, significant stridor, or recurrent respiratory tract infection.

Several approaches for the correction of innominate artery compression syndrome have been described. These include simple division, division with reimplantation into the right side of the ascending aorta, and suspension to the overlying sternum. Suspension is currently the most widely used



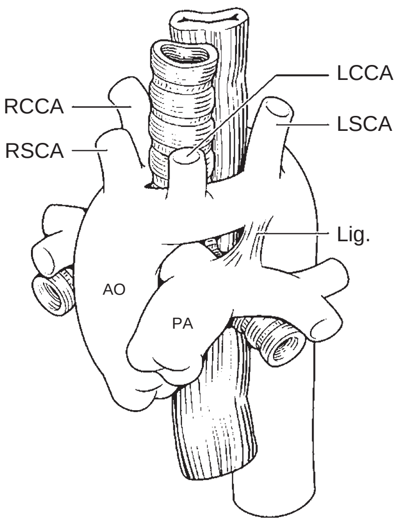


**FIGURE 127-25** Formation of a double aortic arch. technique. Exposure is obtained through a limited left anterior, right anterior, or right inframammary anterolateral thoracotomy. Once the innominate artery is exposed, no dissection of the artery is undertaken. By not performing a circumferential dissection of the innominate artery, the suspension of the vessel will also pull up on the anterior trachea. Pledgeted polypropylene sutures are passed partial thickness through both the innominate artery and the aorta at the origin of the innominate. Temporary distraction on the sutures under bronchoscopic guidance aids in the optimal placement of the sutures in the vessels and overlying sternum. Once satisfactory establishment of tracheal patency is confirmed by bronchoscopy, the sutures are brought through the sternum and secured. The operation is essentially the same as an aortopexy done to relieve severe localized tracheomalacia associated with esophageal atresia (see Chapter 69).

***Left Aortic Arch with Aberrant Right Subclavian Artery*** An aberrant right subclavian artery occurs when there is regression of the right fourth arch between the right common carotid and right subclavian arteries (Fig. 127-30). The right subclavian then arises from the leftward descending aorta, laying posterior to the esophagus as it crosses from left to right. Although the artery can compress the esophagus posteriorly, it is rarely the cause of symptoms in children. Surgical treatment involves simple division via a left posterolateral thoracotomy. Rarely, reimplantation or grafting from the right carotid or aortic arch may be necessary. More significantly, any vascular ring or sling that goes around the esophagus should be a contraindication to long-term nasogastric tubes or any esophageal stent (as may be used in the postoperative management of patients with esophageal atresia), because of the risk of arterio-esophageal fistula.

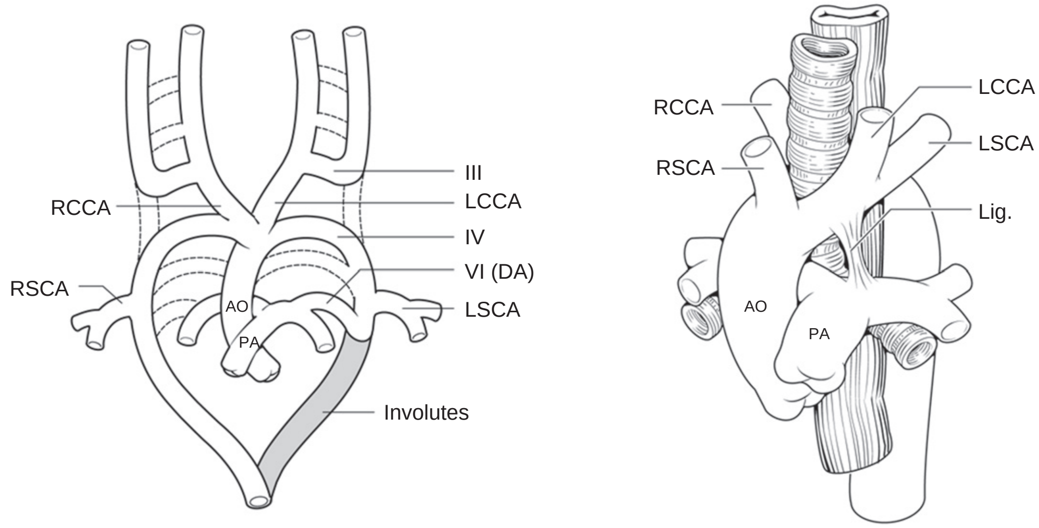

**FIGURE 127-28** Formation of a right aortic arch with mirror imaging branching and left ligamentum arteriosum, which does not form a vascular ring. ### Pulmonary Artery Sling

Normally, the right and left sixth aortic arches contribute to the proximal portions of their respective pulmonary arteries. If the proximal left sixth arch involutes and the bud from the left lung migrates rightward to meet the right pulmonary artery, a PA sling is formed (Fig. 127-31). PA slings are associated with complete tracheal rings and tracheal stenosis in 30% to 40% of patients.[87] Origin of the right upper lobe bronchus from the trachea has been reported in frequent association with PA sling.[88]

Initial attempts at the repair of a PA sling involved reimplantation after division of the left pulmonary artery (LPA) and translocation of the trachea without cardiopulmonary bypass. These early reports had a high incidence of LPA thrombosis. This has led some authors to advocate division of the trachea and translocation of the LPA. This approach would seem sensible if the trachea were being divided in the course of tracheal reconstruction. However, currently most authors advocate the reimplantation of the LPA, which has resulted in excellent results.[89,90] The procedure is done via a median sternotomy on cardiopulmonary bypass to ensure optimal visualization of the repair. Aortic cross clamping is not necessary. The LPA is divided from the RPA, translocated anterior to the trachea, and reimplanted into the main pulmonary artery.

Any necessary reconstruction of the trachea is done concurrently with bronchoscopic assistance. Many techniques for tracheal reconstruction have been described, the most

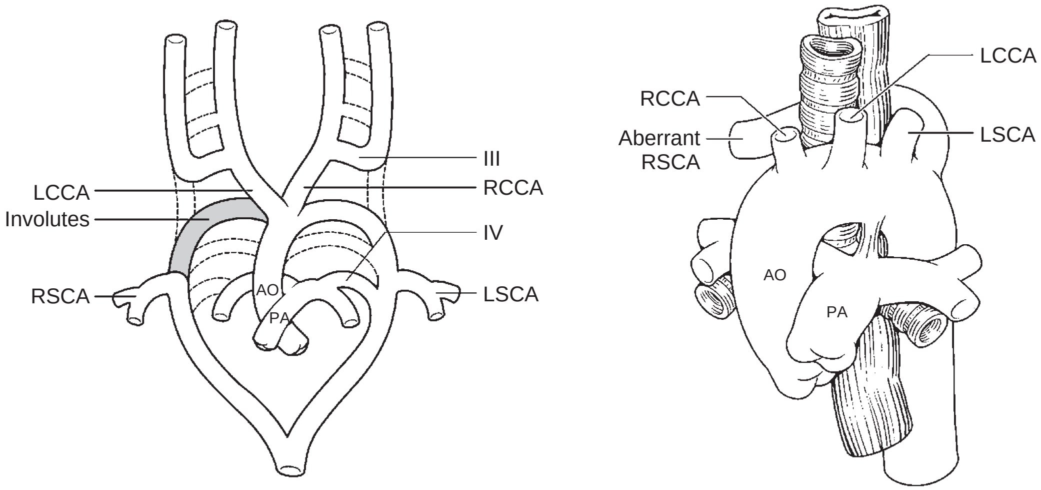

FIGURE 127-30 Formation of a left aortic arch with aberrant right subclavian artery. common of which are resection with primary reanastomosis and sliding tracheoplasty for short segment stenosis and rib cartilage or pericardial patch for long areas of narrowing.

## Vascular Rings Requiring a Right Thoracotomy

More than 95% of vascular rings without concurrent cardiac defects can be performed through a left thoracotomy. A right thoracotomy is indicated for the rare cases where there is a right ligamentum arteriosum. A right ligamentum occurs in the setting of a left aortic arch with right descending aorta, where the ligamentum bridges from the descending aorta to the right PA, forming a complete ring. Right ligamentum arteriosum has also been described with a left aortic arch with aberrant right subclavian artery. In this case, the ligamentum may arise from the aberrant subclavian artery, a diverticulum off of the arch, or directly from the left arch to the right pulmonary artery. In addition, a double aortic arch with an atretic segment proximal to the right carotid artery is more easily divided through a right thoracotomy. The approach to these anomalies is the same as for a left-sided ring division, with the caveat that the right recurrent laryngeal nerve will loop around the right ligamentum.

## Video-Assisted Thoracoscopic Surgery

We and Burke and colleagues have repaired vascular rings using video-assisted thoracoscopic surgery (VATS) both with[91] and without[92] robotic assistance. Candidates for thoracoscopic division in both series were limited to those patients requiring

only the division of nonpatent vascular structures. There were no operative deaths, and all procedures were completed by VATS. In general, VATS is used for patients greater than 15 kg due to current size limitations of the instruments.[93]

## RESULTS

Mortality for the repair of a vascular ring is 0.5% to 7.6%, with improved survival occurring in more recent series.[83,85,88,94] The majority of deaths are related to other cardiac defects or respiratory infection and failure. Backer and colleagues[89] reported a series of 16 patients repaired using LPA division and reimplantation for PA sling, all of whom also required tracheal reconstruction. There were no operative mortalities and one late death due to respiratory complications. The major source of morbidity, as well as mortality, in this and other series is related to the tracheal reconstruction.[89,90]

CHAPTER 128

# Management of Neural Tube Defects, Hydrocephalus, Refractory Epilepsy, and Central Nervous System Infections

Jodi L. Smith

## Neural Tube Defects

Neurulation, one of the earliest and most crucial events in human development, generates the neural tube (NT), the rudiment of the entire adult central nervous system (CNS) (i.e., the brain and spinal cord [SC]). The NT forms during primary and secondary neurulation. Primary neurulation involves the formation of a neural plate (NP) and the subsequent morphogenetic movements that transform it into an NT. Secondary neurulation involves the formation of an epithelial cord (i.e., the medullary cord) and its subsequent cavitation to form an NT. In humans, the brain and SC as far caudally as the S2 level form by primary neurulation, whereas the SC caudal to the S2 level and the filum terminale form by secondary neurulation. For more than a century, investigators have used many different animal models and experimental paradigms to ascertain the mechanisms underlying primary and secondary neurulation. When these processes go awry in humans, neural tube defects (NTDs) result. NTDs are among the most common of all human birth defects, with incidence rates varying from less than 1 to more than 6 per 1000 pregnancies around the world and affecting about 3000 pregnancies per year in the United States.[1,2,2a] These complex congenital malformations occur when the NT, which ultimately forms the brain and SC, fails to close during the first few weeks of embryonic development. NTDs are commonly classified as open or closed on the basis of the presence or absence of exposed neural tissue. In open NTDs, which occur as a consequence of failed primary neurulation, the NT and its membranous coverings are abnormal and are exposed at birth through a defect in the skull or spine. In closed NTDs, which occur because of faulty secondary neurulation, the NT and its membranous coverings are abnormal but the overlying skin is intact. Open NTDs, which occur more frequently than closed NTDs, include anencephaly, spinal rachischisis or spina bifida aperta/cystica (i.e., myeloschisis, myelomeningocele, and meningocele), and encephalocele. Closed NTDs include spina bifida occulta; lipomatous malformations (e.g., lipomas and lipomyelomeningoceles); split cord malformations (diastematomyelia, diplomyelia); neurenteric cysts; dermal sinuses; tethered SC; and sacral agenesis (caudal regression). Anencephaly, or absence of the brain, is invariably fatal and results when the cephalic part of the NT fails to close. Infants born with this condition typically die at birth or within the first few days after birth. Spina bifida cystica (i.e., myeloschisis, myelomeningocele, and meningocele) results from incomplete development of the NT more caudally, with protrusion of the malformed neural tissue, meninges, or both through an opening in the vertebral arches, muscle, and skin (Fig. 128-1). Open NTDs range in severity from craniorachischisis, in which the entire NT remains open, to a lesion limited to a single vertebral level. Of the open NTDs, myelomeningocele is the most common and the most severe birth defect compatible with survival.[3] Recent studies have suggested that periconceptional folic acid supplementation reduces the occurrence and recurrence risk of NTDs by 50% to 70%[4,5]; however, these serious birth defects continue to affect approximately 1 per 1000 live-born infants. In other words, including pregnancies that are electively terminated, approximately 4000 pregnancies per year, or 11 to 12 pregnancies per day, in the United States are affected by an NTD. These devastating birth defects are associated with fetal wastage, infant mortality, lifelong disability, and substantial health care costs. To eradicate NTDs, we must continue to advance our understanding regarding the cellular and molecular mechanisms responsible for normal NT formation through dedicated research efforts.

### EMBRYOLOGY

Most of what we already know about the mechanisms that comprise normal human NT formation comes from extensive descriptive studies on both human and nonhuman embryos and from experimental studies on nonhuman animal models

FIGURE 128-1 Three-hour-old male infant with an L5-S1 myelomeningocele diagnosed prenatally by ultrasound.

such as the chick and mouse, from which much of our current understanding of neurulation is derived. Such studies, which provide insight into the mechanisms underlying early human neural development, have revealed that primary neurulation occurs in four spatially and temporally overlapping stages: (1) formation of the NP, (2) shaping of the NP, (3) bending of the NP, and (4) fusion of the neural folds (Fig. 128-2, *A* to *E*).[6,7] The important stages in embryologic development are further summarized in Figures 128-3 and 128-4.[6–9]

For many years, neurulation was viewed as a simple, intrinsic force-driven, all-or-none process in which the NP either rolled up into a tube or did not. Moreover, a change in neuroendocrine (NE) cell shape from column-like to wedgelike by contraction of apical microfilaments was the intrinsic force proposed to drive this process. However, through more recent advances in research we now know that this "traditional view of neurulation" is incorrect. Instead, neurulation is a highly complex, multifactorial process that requires not only intrinsic forces generated by NE cells but also extrinsic forces generated by epidermal ectoderm cells, with the intrinsic and extrinsic forces acting in concert.[6,7]

A "multifactorial model of neurulation" has been proposed to explain how intrinsic and extrinsic morphogenetic forces generated by fundamental cell behaviors such as changes in cell shape, position, and number interact during neurulation to transform a flat pseudostratified sheet of ectodermal cells, the NP, into an elongated NT, the precursor of the entire adult CNS.[7] According to this model, intrinsic forces generated by elongation, rearrangement, and nonrandomly oriented rostrocaudal division of NE cells drive shaping of the NP and intrinsic forces generated by NE cell wedging drive furrowing of the NP. Extrinsic forces are generated by changes in epidermal ectoderm cell shape from low cuboidal to squamous, rearrangement of epidermal ectoderm cells with caudal-to-medial convergent extension, and nonrandomly oriented rostrocaudal and mediolateral cell division. Such changes in epidermal ectoderm cell behavior drive rostrocaudal lengthening of the epidermal ectoderm, as well as medial epidermal ectoderm expansion, which in turn drives neural fold elevation, convergence, and fusion. Failure of this process at any step along the way presumably will generate a neural tube defect.

## EPIDEMIOLOGY

The incidence of spina bifida is estimated at one to two cases per 1000 population, with certain populations having a significantly higher incidence based on genetic predilection. There is also a marked geographic variation in incidence.

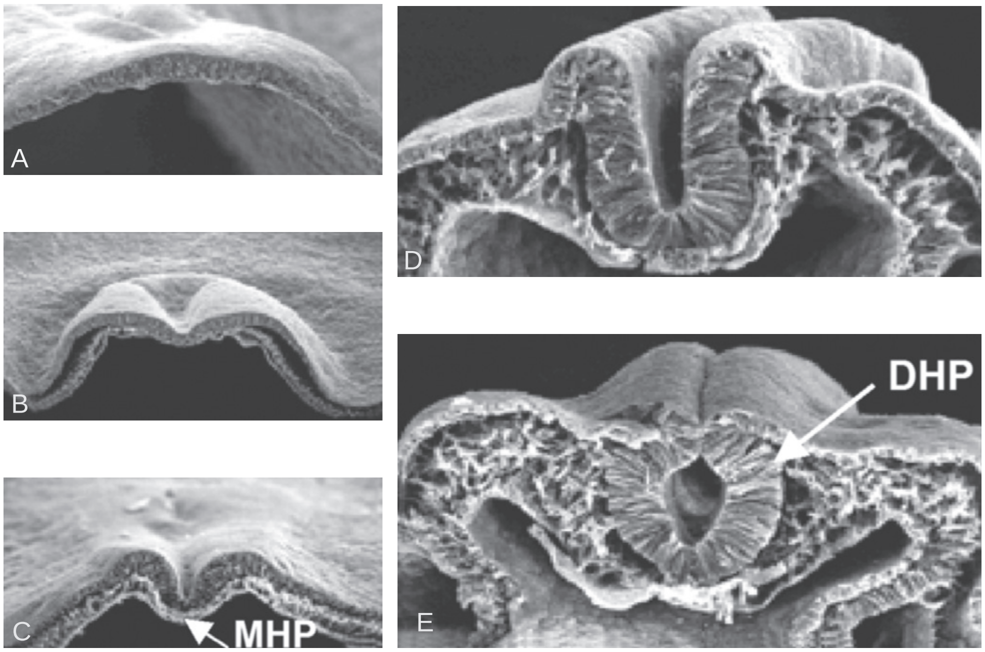

FIGURE 128-2 **A-E,** Scanning electron micrographs of transverse sections through the chick blastoderm demonstrating the four stages of primary neurulation—formation, shaping, and bending of the neural plate and fusion of the neural folds. During primary neurulation, the neural tube, the precursor of the entire adult central nervous system, develops from the ectodermal flat neural plate. DHP, dorsolateral hinge point; MHP, median hinge point. (Modified from Smith JL, Schoenwolf GC: Neurulation: Coming to closure. Trends Neurosci 1997;20:510.)

For instance, the highest rates occur in parts of the British Isles, mainly Ireland and Wales, where the incidence of myelomeningocele is as high as three to four cases per 1000 population and the incidence of anencephaly is more than six cases per 1000 population for both live births and stillbirths. In the United States, the prevalence is declining, with African Americans having a rate of 0.1 to 0.4 per 1000 live births versus 1 per 1000 live births in the white population. The two main reasons for the decline of NTDs in the United States are pregnancy termination and periconceptional use of folic acid. Finally, the risk of giving birth to a second child with an NTD in the United States is 1% to 3%.

## ETIOLOGY

The precise etiology and specific genes responsible for the generation of NTDs such as myelomeningocele have not yet been elucidated. The cause of such defects is probably multifactorial, with both genetic and environmental factors playing a role. Besides problems occurring during neurulation that prevent NT closure, problems in the postneurulation period (e.g., as a result of exposure of the unprotected nervous system to amniotic fluid) may also have a deleterious effect on NT development and subsequent neural function. In addition, numerous teratogens have been implicated in the etiology of NTDs. Of all the teratogens evaluated thus far, carbamazepine, valproic acid, and folic acid deficiency have been most strongly tied to the development of NTDs. In support of this association, periconceptional folic acid supplementation has been shown to reduce the occurrence and recurrence risks of NTDs,[4,5] suggesting that NTDs result, at least in part, from folic acid deficiency. However, the precise role of folic acid in preventing NTDs remains unclear. Nevertheless, the U.S. Public Health Service made a strong recommendation in September 1992 that all women of childbearing age in the United States who are capable of becoming pregnant should consume 0.4 mg of folic acid per day for the purpose of reducing the risk of having a pregnancy affected with an NTD. Furthermore, valproic acid (a known folate antagonist), if taken during pregnancy, results in a 1% to 2% estimated risk of having a child with an NTD.

## PATHOLOGY

The two most common types of NTDs seen with spina bifida aperta or cystica are myelomeningocele and meningocele. Myelomeningocele, the most common NTD compatible with

life, consists of an open neural placode surrounded by an intermediate zone of thin epithelium, which in turn is surrounded by normal skin (see Fig. 128-1). The dorsal (i.e., exposed) surface of the neural placode constitutes the everted interior of the NT and is continuous with the central canal of the SC rostrally. In contrast, the ventral surface constitutes the outside of what should have been a closed NT. Ventral or motor roots exit from the ventral surface of the placode just lateral to the midline on both sides; dorsal or sensory roots enter the periphery of the placode lateral to the motor roots. An arachnoid sac and subarachnoid space underlie the neural placode, and the junction between the skin and dura underlies the skin within a few millimeters from the skin edge. Subjacent to the dura is an epidural space that contains fat. The spinous processes are absent, and the paraspinous muscle masses, hypoplastic laminae, and pedicles are everted. In most cases, the SC rostral to the neural placode is normal; however, additional anomalies such as a split cord malformation (i.e., diastematomyelia), arteriovenous malformation, epidermoid, or lipoma may be present. In addition, most neonates with myelomeningocele have associated neurologic malformations such as hydrocephalus and Chiari II malformation (deformity of the hindbrain, cervical SC, and craniovertebral junction), as well as orthopedic anomalies of their lower extremities and urogenital anomalies caused by involvement of the sacral nerve roots. A meningocele is a skin-covered anomaly characterized by herniation of just the meninges through a dorsal bony defect (spina bifida). However, unlike myelomeningocele, the SC and nerve roots do not herniate into the skin-covered dural sac and neonates with these lesions typically do not have associated neurologic malformations.

## DIAGNOSIS OF NEURAL TUBE DEFECTS

Open NTDs such as anencephaly and myelomeningocele can be diagnosed prenatally by measuring alpha-fetoprotein (AFP) in the amniotic fluid or maternal bloodstream. AFP, the major serum protein in early embryonic life, can leak into the amniotic fluid from an open NTD. The first step in prenatal screening for open NTDs is drawing blood to measure maternal serum AFP between 15 and 20 weeks of gestation. A patient-specific risk is then calculated on the basis of gestational age and AFP level. For example, at an estimated gestational age of 20 weeks, a maternal serum AFP concentration higher than 1000 ng/mL would be consistent with the diagnosis of an open NTD. Measurement of maternal serum AFP is more than 75% accurate in detecting an open NTD when gestational age is greater than 15 weeks. If the diagnosis is uncertain with maternal serum AFP, an amniotic AFP level can be obtained, which will detect approximately 98% of all open NTDs. Moreover, fetal ultrasound can detect open and sometimes closed NTDs prenatally, especially in the hands of a skilled ultrasonographer. If the diagnosis of myelomeningocele is made prenatally, the parent or parents undergo extensive prenatal counseling and cesarean delivery is planned.

## EVALUATION AND TREATMENT

Neonates with myelomeningocele have a saclike protrusion containing a neural placode bathed in cerebrospinal fluid (CSF) (see Fig. 128-1). The size of the sac on the child's back at the time of birth depends on the amount of CSF that has collected ventral to the neural placode. These children may also have other associated CNS abnormalities including Chiari II malformation, hydrocephalus, syringomyelia, brainstem malformations, agenesis of the corpus callosum, and polymicrogyria. Shortly after birth, a thorough physical examination is performed that includes measurement of head circumference and assessment of general vigor (especially cry and suck); anal sphincter function (anocutaneous reflex or anal wink); upper and lower extremity motor and sensory function; the site, level, and size of the myelomeningocele defect; and whether or not the defect is leaking CSF. In addition, the neonate should be evaluated for signs and symptoms of hydrocephalus and brainstem compression (i.e., Chiari II malformation), as well as for associated orthopedic deformities such as clubfeet and kyphoscoliosis.

Before repair, the neonate is kept prone to prevent rupture of the sac and avoid trauma to the neural placode. In addition, the myelomeningocele defect should be covered with sterile saline-soaked gauze to prevent desiccation of the exposed neural tissue. The gauze, in turn, should be covered with a plastic wrap to prevent heat loss.[3] An intravenous catheter is placed, and broad-spectrum antibiotics are administered to reduce the risk of CNS infection. Head ultrasonography or computed tomography (CT) is performed to evaluate the extent of ventricular enlargement and determine the need for shunt placement. Initially, the ventricles may be normal or only slightly enlarged. However, after the NTD is closed, the ventricles often enlarge. The incidence of hydrocephalus associated with myelomeningocele ranges from 80% to 95%.

A myelomeningocele is typically closed within 24 to 72 hours following birth unless the infant has associated medical conditions that prevent administration of a general anesthetic or surgery.[10] The goal of surgery is to close the neural placode into an NT to establish a microenvironment conducive to neuronal function.[11] Closure involves (1) separation of the neural placode from the intermediate zone of epithelium and reconstruction of the placode into a tube with preservation of all neural tissue; (2) separation of the dura from the epidural space at the lateral margins of the defect and closure of the dura in a watertight but patulous fashion around the newly created NT; (3) surgical correction of any significant kyphotic deformity; (4) mobilization and midline approximation of the paraspinal muscles and fascia; and (5) tension-free closure of the skin in the midline, which often requires mobilization of the skin and subcutaneous tissue from the underlying fascia rostrally, caudally, and bilaterally.

Common postoperative complications include CSF leak, wound-healing problems, and tethered SC. The incidence of CSF leak may be reduced by careful closure of the dura and by placement of a shunt to treat associated hydrocephalus. Wound-healing problems may occur, especially in patients with large myelomeningoceles, and can be managed by keeping the patient prone and performing moist-to-dry dressing changes. Currently, no techniques are available to reduce the incidence of SC tethering after myelomeningocele repair.

### Fetal Surgery for the Treatment of Neural Tube Defects

Intrauterine repair of myelomeningocele has been advocated as a means of improving the neurologic outcome and reducing hindbrain herniation in infants with myelomeningocele. This is based on the idea that secondary damage and resultant

disability, which may occur when exposed neural tissue is in contact with amniotic fluid, may be reduced or even completely eliminated by closing the defect as early as possible in utero. Moreover, halting CSF loss by in utero closure of the neural placode may reverse some of the potentially devastating neurologic sequelae of NTDs such as shunt-dependent hydrocephalus and Chiari II malformation, by reducing hindbrain herniation.

A single-institution, nonrandomized observational study conducted between 1990 and 1999 compared outcomes including the requirement for ventriculoperitoneal shunt placement, obstetric complications, gestational age at delivery, and birth weight in 29 patients who underwent intrauterine myelomeningocele repair between 24 and 30 weeks of gestation with 23 lesion-matched controls who underwent standard postnatal repair.[12] The results of this study suggested that intrauterine repair decreased the incidence of hindbrain herniation and shunt-dependent hydrocephalus. However, this study also demonstrated an increased risk of oligohydramnios and admission to the hospital for preterm uterine contractions, an earlier estimated gestational age at delivery (33.2 vs. 37.0 weeks), and a smaller birth weight (2171 vs. 3075 g) in patients who underwent intrauterine repair. Other problems with this study included relatively short follow-up times, small sample size, varied selection criteria, and lack of a comparable control group of children with myelomeningocele who did not undergo intrauterine repair.

Thus, the study by Bruner and others[12] provided preliminary evidence that suggested that intrauterine myelomeningocele repair may decrease the incidence of hydrocephalus and reduce the severity of hindbrain herniation (including the incidence of Chiari II malformation). However, this study also showed that intrauterine repair involved substantial risks not associated with standard postnatal repair. Moreover, another study demonstrated that intrauterine repair between 20 and 28 weeks of gestation did not statistically improve lower extremity function when compared with lower extremity function in patients undergoing postnatal closure.[13] For the risks and benefits of intrauterine repair to be more clearly established, a multicenter, prospective, randomized controlled trial of intrauterine and conventional therapies, the management of myelomeningocele study (MOMs), was funded by the National Institutes of Health.[14–16] The MOMs trial began in 2003 and was carried out at three hospitals in the United States. In this trial, fetuses were randomized to surgery at 19–25 weeks of gestation or to standard postnatal repair. The primary objective of the trial was to ascertain whether intrauterine repair of myelomeningocele at 19 to 25 weeks of gestation improved outcome as measured by death or the need for a shunt by one year of life.[15] Other outcomes included a composite of mental development and motor function at 30 months, the degree of Chiari II malformation, and maternal morbidity. The trial was stopped for efficacy of prenatal surgery after 183 of a planned 200 patients were recruited, and the results of the study were based on 158 patients whose children were evaluated at 12 months. This study provided evidence that prenatal repair of myelomeningocele reduced the need for shunting and improved motor outcomes at 30 months when compared with standard postnatal repair. However, in contrast to postnatal repair, prenatal surgery was associated with an increased risk of preterm delivery, as well as uterine dehiscence at delivery.

### Associated Anomalies

Children with myelomeningocele often have other anomalies of the CNS that require attention. For example, more than 90% of children with myelomeningocele have a Chiari II malformation and hydrocephalus. Chiari II malformation is a complex deformity involving the calvarium, dura, and hindbrain. The spectrum of abnormalities observed in Chiari II malformation includes a lacunar skull (i.e., thinning and scalloping of the calvaria producing a "copper-beaten" appearance), small posterior fossa, low-lying transverse sinuses and torcular Herophili, fenestrated falx, heart-shaped tentorial incisura with upward herniation of the cerebellum, medullary kinking, beaking of the tectal plate, prominence of the massa intermedia, enlargement of the suprapineal recess, elongation of the fourth ventricle, syringomyelia, and downward displacement of the cerebellar vermis, fourth ventricle, medulla, and pons through the foramen magnum (Fig. 128-5, *A* and *B*). Neonates with symptomatic Chiari II malformation commonly have inspiratory stridor, apnea, dysphagia or nasal regurgitation, aspiration, weak or absent cry, weakness/spasticity in the upper or lower extremities (or both), and opisthotonic posturing. Older children and adolescents have a more insidious manifestation consisting of syncopal episodes, nystagmus, oscillopsia, lower cranial nerve palsies, hyperreflexia, and spastic quadriparesis. Radiologic diagnosis of Chiari II malformation is best made by brain magnetic resonance imaging (MRI).Treatment of patients with symptomatic Chiari II malformation (i.e., those with signs and symptoms of brainstem compression) involves decompression of the posterior fossa or cervical SC, or both, which can be surgically challenging because the torcular Herophili and transverse sinuses are low lying (i.e., near the foramen magnum), the cerebellum is often adherent to the medulla, and the fourth ventricle is displaced caudally and dorsally. Before subjecting the patient to a Chiari decompression, one must make certain that the patient has a functioning shunt because shunt malfunction can produce signs and symptoms of brainstem compression similar to those observed in a Chiari II malformation. When evaluating shunt function, it is important to remember that CT findings can be misleading because the ventricles may remain small or fail to show an increase in size despite a high-grade shunt obstruction. Therefore a shunt tap, radionuclide shunt injection, or shunt exploration should be performed to evaluate shunt function before decompressing a Chiari II malformation in a patient with myelomeningocele. Unfortunately, many patients fail to respond to surgical decompression of their Chiari II malformation. This is thought to be related at least in part to the possibility that their symptoms arise from incomplete formation of the brainstem nuclei rather than to brainstem compression from the Chiari II malformation.[17]

Hydrocephalus, which is discussed in this chapter in greater detail later, is present in 80% to 95% of children with myelomeningocele. Factors contributing to the development of hydrocephalus in this patient population include the Chiari type II malformation, aqueductal stenosis, fourth ventricle outlet obstruction, anomalous venous drainage in the posterior fossa caused by compression of the dural venous sinuses, open myelomeningocele with associated CSF leak, and the presence of other CNS malformations. Hydrocephalus is usually treated with a ventriculoperitoneal shunt, which diverts CSF from the brain to the peritoneal cavity for reabsorption.

**FIGURE 128-5** Five-year-old girl with myelomeningocele repaired in utero. **A,** Sagittal brain magnetic resonance image (MRI) showing a Chiari II malformation with upward herniation of the cerebellum and tectal plate beaking (*asterisk*), as well as downward displacement of the cerebellar tonsils through the foramen magnum (*arrow*). **B,** Sagittal spine MRI showing syringomyelia extending from C5 to L2 (*upper arrow*). The spinal cord and conus end at L4 (*lower arrow*), consistent with a tethered spinal cord.

A shunt may be placed at the time of myelomeningocele closure in patients with severe symptomatic hydrocephalus with associated macrocrania and massive ventriculomegaly apparent at birth or several days later under separate anesthesia to reduce the risk of shunt infection. CSF diversion is indicated in patients with rapidly progressive hydrocephalus and in those manifesting acute neurologic change such as stridor, swallowing dysfunction, or central apnea, with or without significant change in the size of the ventricles.[3]

## OCCULT SPINAL DYSRAPHISM-CLOSED NEURAL TUBE DEFECTS

During secondary neurulation, the caudal part of the NT develops from the tail bud, a mesenchymal mass of cells derived from remnants of the cranial part of the primitive streak. Secondary neurulation occurs in three stages: (1) formation of the medullary cord from the tail bud; (2) cavitation of the central aspect of the medullary cord, which results in the formation of multiple lumina; and (3) coalescence of the lumina into a single, central cavity surrounded by a peripheral layer of radially oriented medullary cord cells.[18] When secondary neurulation goes awry, closed NTDs result in which the overlying skin is intact but the caudal NT and its membranous coverings develop abnormally. Developmental anomalies of the caudal SC include spina bifida occulta; tight or thickened filum terminale; split cord malformations (also known as *diastematomyelia, diplomyelia*); neurenteric cysts; dermal sinuses; sacral agenesis/caudal regression; and lipomatous malformations such as lumbosacral lipoma, leptomyelolipoma, lipomyelomeningocele, and fatty filum. Such anomalies may lead to SC tethering, which, in turn, can cause progressive neurologic deterioration secondary to traction on the conus medullaris and resultant ischemic injury.[19]

Cutaneous stigmata are often found in association with occult spinal dysraphism and thus serve as markers for SC tethering, especially when they occur above the gluteal cleft. Such skin lesions include lumbosacral hypertrichosis (i.e., hairy patch), dermal sinus tract, sacral dimple, capillary hemangioma, caudal appendage, and subcutaneous lipoma. Patients with one or more of these lesions above the gluteal cleft should undergo further evaluation including a full spine MRI to look for SC tethering. In contrast, a skin lesion such as a dimple or pit below the gluteal cleft most likely represents a benign, nonneurologic finding that requires no further workup.

Besides cutaneous stigmata, children with tethered cord syndrome and occult spinal dysraphism frequently have (1) dysraphic posterior spinal elements and vertebral abnormalities; (2) orthopedic abnormalities such as scoliosis, lower extremity atrophy or asymmetry, and foot deformities; (3) progressive neurologic dysfunction such as lower extremity weakness, loss of sensation, radiculopathy, spasticity, hyperreflexia, and abnormal gait; (4) urologic dysfunction such as neurogenic bladder and urinary incontinence; and (5) bowel dysfunction. In addition, there is a high incidence of caudal SC abnormalities and associated SC tethering in patients with anorectal and urogenital malformations including cloacal exstrophy, persistent cloaca, penoscrotal transposition,

imperforate anus, the Currarino syndrome, and the VATER/VACTERL association (vertebral defects, imperforate anus, tracheoesophageal fistula with esophageal atresia, and radial and renal dysplasia with or without cardiac and limb abnormalities).[20] Although the explanation for the simultaneous development of cloacal and caudal SC malformations remains unknown, it is likely related at least in part to the intimate temporospatial relationship of urogenital, anorectal, and caudal NT development. Because of the high incidence of coexistent malformations and SC tethering, patients with anorectal and urogenital malformations should undergo a routine screening lumbosacral spine ultrasound or MRI to evaluate for asymptomatic tethering of the SC.

Lipomatous SC malformations such as fatty filum, lipomyelomeningocele, and leptomyelolipoma cause tethering of the SC and are the most common types of closed NTDs requiring neurosurgical treatment.[19,21,22] A fatty filum consists of a short, thickened filum terminale in which there is partial or complete fatty infiltration. A lipomyelomeningocele consists of a skin-covered subcutaneous lipoma that extends through a defect in the lumbosacral fascia, lamina, dura, and pia into a low-lying SC. Leptomyelolipoma, a type of lipomyelomeningocele, consists of a conus lipoma. Most children with lipomatous malformations have intact neurologic function at birth and are brought to medical attention for evaluation of a subcutaneous lipoma or other cutaneous stigmata as described earlier.

The natural history of tethered SC is that of progressive neurologic deterioration with deficits in sensory, motor, bowel, and bladder function arising during periods of rapid growth and weight gain.[21] As a consequence, early prophylactic untethering is recommended for all patients to stabilize neurologic function and prevent irreversible injury. Surgery involves microsurgical technique with monitoring of anal sphincter electromyography and somatosensory evoked potentials. Intraoperative stimulation of nerve roots helps distinguish functional from nonfunctional roots. In the case of a fatty filum, surgical treatment consists of a partial laminectomy at L4-L5 or L5-S1 through a short posterior midline incision and opening of the dura in the midline to expose the filum. After stimulating the filum to ensure that no neural function is present, the filum is sectioned at the rostral and caudal ends of the exposure and the intervening segment is sent to pathology for evaluation. In the case of lipomyelomeningocele or leptomyelolipoma, surgical treatment involves detaching the subcutaneous lipoma from the SC or conus lipoma at the point where it emerges through the defect in the lumbosacral fascia. It is unnecessary to resect the subcutaneous fatty mass completely because doing so can result in devascularization of the overlying skin, which in turn can compromise wound healing.[22] A laminectomy is performed rostral to the dural defect to identify normal anatomy, followed by careful dissection progressively more caudally to the region where the lipoma traverses the dural defect and enters the SC or conus. Subsequent steps include (1) releasing the conus from its attachments to the lipoma, leptomeninges, and dura; (2) decompressing the SC and conus by debulking the intramedullary lipomatous mass with the laser or ultrasonic aspirator; (3) sectioning the filum; (4) closing the dura in a watertight but patulous fashion; and (5) closing the paraspinal muscles, lumbosacral fascia, and skin using meticulous technique. Surgery-related complications include anesthesia-related risks, worsening of neurologic or urologic function (or both), CSF leak, and infection.

Other types of occult spinal dysraphism include split cord malformations (a.k.a. diastematomyelia), dermal sinus tracts, and neurenteric cysts. In split cord malformations, the SC is split into two halves in the sagittal plane, with each hemicord residing either together in a single dural tube (type I malformation) or in separate dural tubes (type II malformation).[23] A hairy patch usually overlies the region of the split cord malformation, and tethering of the SC may occur as a consequence of a thickened filum or a midline bony spur, or both, in the case of type II malformations or dorsal tethering bands/fibrous median septum between the dura and hemicords in the case of type I malformations. To prevent neurologic and urologic deterioration, the SC is untethered by first resecting the midline bony spur or sectioning the dorsal bands/fibrous septum between the dura and hemicords followed by sectioning of the filum.

Dermal sinus tracts often present in childhood with cutaneous findings, neurologic deficits, or infectious or chemical meningitis, or any combination of these findings.[24,25] Dermal sinus tracts represent remnants of incomplete NT closure, developing as a consequence of localized failure of dysjunction, the process whereby the surface ectoderm and dermal elements separate from the neuroectoderm. Failure of dysjunction generates an epithelial-lined tract that extends from an opening on the surface of the skin to the fascia, dura, or SC. Dermal sinus tracts can be found anywhere along the midline of the neuraxis and may be associated with drainage of CSF, intradural dermoid or epidermoid cysts, split cord malformations,[23] and tethering of the SC. Skin lesions associated with dermal sinus tracts are typically found in the lumbodorsal midline rostral to the gluteal cleft and include a dimple, pit, capillary hemangioma, hairy patch, skin tag, and subcutaneous lipoma. In the case of a dimple or pit, there may be drainage of cyst contents or CSF or local signs of infection such as erythema or induration. MRI is the neurodiagnostic tool of choice because it enables visualization of the dermal sinus tract and associated pathology such as a tethered SC, inclusion tumor, syrinx, or split cord malformation. However, some dermal sinus tracts may not be well visualized on MRI if they are small or out of the plane of imaging.[24] Hence if a patient has a cutaneous finding overlying the midline neuraxis that is above the gluteal cleft, surgical exploration may be warranted even if the MRI appearance is normal. Treatment consists of complete excision of the dimple and tract, intradural exploration with resection of any intradural connections or masses, and untethering of the SC. Timely diagnosis and appropriate surgical intervention with intradural exploration are essential in preventing infection including meningitis and preserving or improving neurologic function.

Spinal neurenteric cysts are rare congenital malformations lined by alimentary tract mucosa.[19] They form as a consequence of a persistent abnormal connection between the primitive ectoderm and endoderm[26] and are often accompanied by vertebral abnormalities and other forms of occult spinal dysraphism such as split cord malformation, lipoma, dermal sinus tract, and tethered SC. Patients with spinal neurenteric cysts may have cutaneous stigmata or signs of SC compression such as pain and neurologic deficits. Treatment involves complete excision of the neurenteric cyst, as well as appropriate surgical management of other associated congenital abnormalities including untethering of the SC. Gross total resection is essential because there is a high incidence of cyst recurrence associated with subtotal resection of neurenteric cysts.[26]

In patients with occult spinal dysraphism and tethered SC who have undergone an untethering procedure, progressive neurologic or urologic deterioration may signal recurrent tethering of the SC, which can occur in up to 15% of patients.[27] Therefore long-term neurologic and urologic follow-up is warranted to determine patients who may benefit from reoperation.

### OUTCOME AND PROGNOSIS

Treatment of NTDs has evolved over the past 50 years. Previously, neonates with NTDs either were left untreated or were treated selectively; however, most of them died of meningitis, hydrocephalus, and/or sepsis. In contrast, during the past 3 decades, neonates with NTDs have received prompt, aggressive treatment in almost all pediatric centers in the North America. Such treatment including early closure of open NTDs and aggressive shunting of hydrocephalus leads to survival with nearly normal intelligence in many patients.

Initial closure of an open NTD is just the beginning of the medical care typically required. In general, such patients require frequent and consistent follow-up in a comprehensive multidisciplinary clinic where they can be evaluated by a team of pediatric specialists. The team would include a developmental pediatrician, neurosurgeon, urologist, orthopedic surgeon, physiatrist, physical therapist, occupational therapist, nurse, and nutritionist. The multidisciplinary team approach is critical to the ultimate success and long-term management of these patients. With proper medical care, children with open NTDs can lead active and productive lives. For example, in a 20- to 25-year follow-up study of children with open spina bifida who were treated aggressively in a nonselective, prospective manner, these children entered college in the same proportion as the general population and many were actively employed.[28] With aggressive treatment and a multidisciplinary clinical approach, long-term survival into adulthood and advanced age is now common.

The goal of treating children with myelomeningocele is to maintain stable neurologic functioning throughout their lifetime.[3] Neurosurgeons must always be on the alert for neurologic deterioration in children and adults with myelomeningocele. Besides shunt malfunction, the most common cause of neurologic deterioration is symptomatic SC tethering in which there is tension on the SC resulting from fixation of the SC due to adhesions between the previously exposed neural tissue and the surrounding tissues. In almost all patients with myelomeningocele, the SC is low lying and ends in the lumbar or sacral region. This may be observed in patients without any new neurologic complaints. However, symptomatic tethering of the SC develops in at least 20% of all patients with myelomeningocele despite careful surgical closure of the original neural placode. Such patients often have one or more of the following signs/symptoms: gait difficulty, back pain, leg weakness, sensory loss, a new foot deformity, a change in urodynamic data, or urinary incontinence. When one or more of these signs/symptoms occur in patients with shunted hydrocephalus, the shunt must be evaluated first to confirm that it is functioning appropriately. After this has been established, surgery is performed to free the neural placode and nerve roots from the dorsal surface of the dura and thereby untether the SC. In contrast, asymptomatic patients who demonstrate SC tethering on routine MRI do not require reoperation.

## Hydrocephalus

Hydrocephalus is a common pediatric disorder in which there is an increase in CSF volume, which in turn causes enlargement of the ventricles, thinning of the cortical mantle (Fig. 128-6), and elevation of intracranial pressure (ICP). The incidence of congenital hydrocephalus is approximately 0.9 to 1.8 per 1000 births,[29] and the mortality rate is approximately 1% per year. To prevent neurologic deterioration associated with increased ICP, CSF diversion is required. Treatment with CSF diversion techniques such as valve-regulated CSF shunt systems and endoscopic third ventriculostomy increases life expectancy in pediatric patients with hydrocephalus and improves their intellectual outcome.

Hydrocephalus results from a disparity between CSF production and absorption. Most cases of hydrocephalus occur as a consequence of impaired CSF absorption. The exception to this rule is hydrocephalus in patients with a choroid plexus papilloma, which results, at least in part, from overproduction

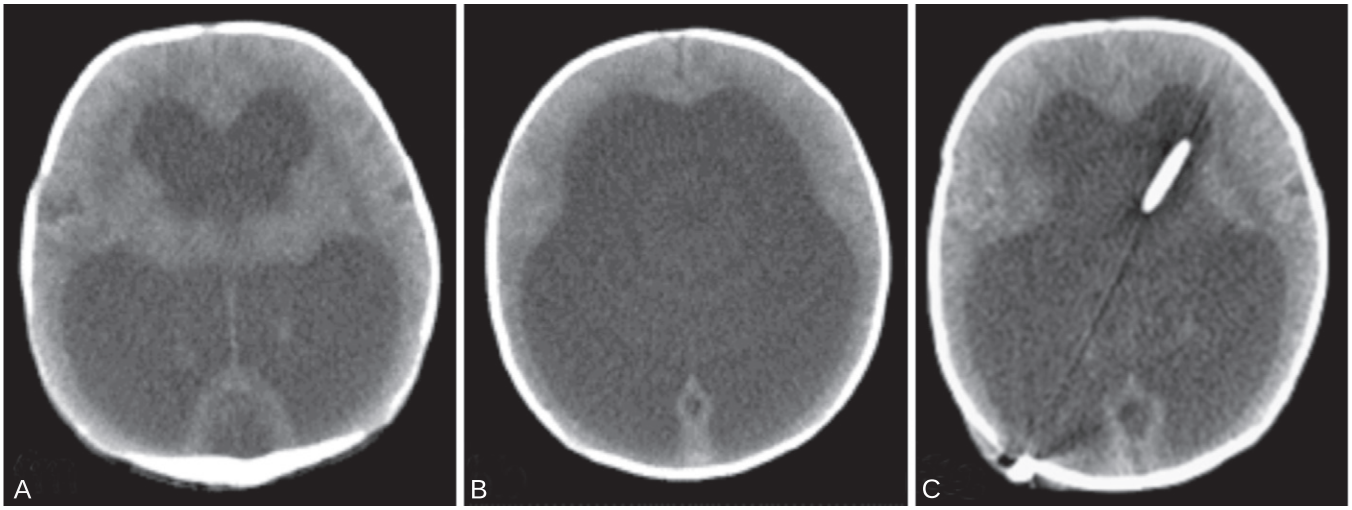

**FIGURE 128-6** One-day-old girl with severe obstructive hydrocephalus secondary to congenital aqueductal stenosis. **A** and **B,** Head computed tomography (CT) scan showing severe ventriculomegaly. **C,** Head CT scan 1 day after shunt placement.

of CSF. Increased CSF volume secondary to impaired absorption or increased production (or both) leads to progressive ventricular dilatation. In some children, CSF absorption can occur through alternative pathways, thereby resulting in stabilization of their ventricular enlargement. This, in turn, leads to arrested or compensated hydrocephalus. In support of this, a detailed analysis of the natural history of unoperated hydrocephalus has shown that arrest of the progressive ventricular enlargement eventually occurs in up to 45% of children with hydrocephalus.[30] Children with compensated hydrocephalus do not require CSF diversion; however, many factors such as fever and infection can cause sudden decompensation of the hydrocephalus and elevated ICP. Therefore children with suspected shunt-independent "compensated" or "arrested" hydrocephalus must be monitored closely for signs and symptoms suggesting decompensation such as headaches, vomiting, ataxia, and visual symptoms.

Formation of CSF is an energy-dependent, ICP-independent process that requires carbonic anhydrase and occurs at a rate of approximately 450 mL/day, or 0.3 mL/min. Choroid plexus in the lateral, third, and fourth ventricles produces 50% to 80% of the CSF; the remaining 20% to 50% of CSF is produced by the ventricular ependyma and brain parenchyma as a byproduct of cerebral metabolism. CSF flows in a caudal direction through the ventricular system and exits by way of the foramina of Luschka and Magendie into the cortical and spinal subarachnoid space. CSF then travels through the tentorial incisura, passes over the hemispheric convexity, and is absorbed into the venous system at the level of the arachnoid villi.

CSF absorption is an energy-independent process that occurs predominantly by bulk flow through the arachnoid villi, which represent the interface between the cortical subarachnoid space and the intradural venous sinuses. The rate of CSF absorption depends on a pressure gradient from the subarachnoid space across the arachnoid villi to the venous space in the dural venous sinuses. When ICP is normal (i.e., 7 cm $H_2O$ or 5 mm Hg), CSF is produced at a rate of 0.3 mL/min but no CSF absorption occurs. When ICP increases, CSF absorption occurs in direct proportion to the increase in ICP. Other pathways for CSF absorption have been proposed. Such pathways including the lymphatic system, nasal mucosa, paranasal sinuses, and the nerve root sleeves of cranial and spinal nerves are probably recruited for CSF absorption when ICP is elevated; however, definitive evidence for these alternative pathways is currently lacking.

Obstruction of CSF flow at any point along the ventricular pathway or impaired absorption of CSF generates increased intraventricular pressure, which in turn results in progressive dilatation of the ventricular system proximal to the block. The pathologic effects of ventricular obstruction or impaired CSF absorption include ventricular dilatation, which is often more pronounced initially in the occipital horns, thinning of the cortical mantle, disruption of the ependymal membrane, transependymal absorption of CSF into the periventricular white matter, white matter injury and scarring, elevation of ICP, brain herniation, coma, and ultimately, death.

## ETIOLOGY

The etiology of hydrocephalus depends on the site of the obstruction of CSF flow. If the obstruction is proximal to the arachnoid villi, there is selective enlargement of the ventricles proximal to the obstruction and the resultant hydrocephalus is termed *noncommunicating* or *obstructive hydrocephalus*. For example, obstruction of the aqueduct of Sylvius results in enlargement of the lateral and third ventricles out of proportion to the fourth ventricle. In contrast, when the block is at the level of the arachnoid villi and CSF absorption is impaired, the lateral, third, and fourth ventricles become dilated and the volume of CSF in the subarachnoid space is increased. The resultant hydrocephalus is referred to as *communicating* or *nonobstructive hydrocephalus*. Of note, hydrocephalus ex vacuo, a condition in which the ventricles become enlarged as a consequence of cerebral atrophy, is not true hydrocephalus.

Obstructive hydrocephalus can be caused by blockage at the foramen of Monro. Common causes include congenital atresia or stenosis; intracranial cysts such as arachnoid cysts within the subarachnoid space or ventricle, porencephalic cysts within the brain adjacent to the ventricle, and colloid cysts; tumors such as hypothalamic gliomas, craniopharyngiomas, and subependymal giant cell astrocytomas; and cavernous malformations. Obstruction at the level of the aqueduct of Sylvius is another common cause of obstructive hydrocephalus (see Fig. 128-6). Causes of aqueductal obstruction include upward herniation of the cerebellum through the tentorial incisura in patients with myelomeningocele and associated Chiari II malformation, vein of Galen vascular malformations, gliosis of the aqueduct from infection or hemorrhage, tumors of the pineal region, and tectal plate gliomas. In addition, obstructive hydrocephalus can occur as a consequence of fourth ventricle outflow obstruction from posterior fossa and fourth ventricle tumors such as medulloblastomas, ependymomas, and pilocytic astrocytomas; a Dandy-Walker malformation, in which there is a large posterior fossa cyst that communicates with an enlarged fourth ventricle, as well as atresia of the outlet foramina (i.e., lateral foramina of Luschka and midline foramen of Magendie); and a Chiari II malformation, in which there is herniation of the fourth ventricle through the foramen magnum because of a small posterior fossa.

In communicating or nonobstructive hydrocephalus, the block can occur at the level of the basal cisterns. When this occurs, CSF is blocked between the spinal and cortical subarachnoid spaces and cannot reach the arachnoid villi for absorption. As a consequence, the lateral, third, and fourth ventricles become dilated. Common causes include congenital infections; meningitis from acquired pyogenic, tuberculous, and fungal infections; subarachnoid hemorrhage from aneurysm rupture, a vascular malformation, or trauma; intraventricular hemorrhage associated with a germinal matrix hemorrhage in a preterm infant; basal arachnoiditis; leptomeningeal carcinomatosis; neurosarcoidosis; and tumors producing high protein levels in the CSF. The block can also occur at the level of the arachnoid villi from occlusion or atresia of the arachnoid villi, which results in dilatation of the subarachnoid space and ventricles. Furthermore, the block can occur at the level of the dural venous sinus from venous outflow obstruction. Such a block can be seen in patients with achondroplasia or multisutural craniosynostosis who have stenosis of the jugular foramina, in patients with high right atrial pressure from congenital heart disease, and in those with thrombosis of the dural venous sinuses or superior vena cava. Venous outflow obstruction causes increased venous pressure, which in turn results in decreased drainage of cortical veins,

increased cerebral blood volume, elevated ICP, increased brain stiffness, and decreased CSF absorption. In infants with an open anterior fontanelle and cranial sutures, increased venous pressure and decreased CSF absorption result in macrocephaly, with splitting of the cranial sutures and ventricular enlargement. In contrast, when the cranial sutures and anterior fontanelle are closed, the elevated venous pressure produces venous engorgement, which in turn raises ICP. In such patients the ventricular system is compressed despite decreased CSF absorption, and the clinical entity known as *pseudotumor cerebri* is produced.

Maximal hydrocephalus is characterized by extreme ventricular enlargement with only a thin rim of cortical mantle, the presence of background cortical activity throughout the brain on electroencephalography (EEG), and at least some restitution of the cortical mantle with CSF diversion (see Fig. 128-6). In contrast, hydranencephaly is a condition in which the intracranial cavity is filled with CSF instead of brain because of a total or nearly total loss of brain tissue supplied by the anterior and middle cerebral arteries bilaterally (Fig. 128-7). The cranial vault and meninges remain intact along with the thalamus, brainstem, and a small amount of occipital lobe supplied by the posterior cerebral artery. The most common causes of hydranencephaly are bilateral internal carotid artery infarcts and infection. Cortical activity is absent on EEG. Such infants cry, suck, and feed; they are typically hyperirritable; they retain primitive reflexes; and rarely progress beyond spontaneous vowel production or a social smile. CSF shunting may be performed to control head size in the face of progressive head enlargement; however, shunting does not improve neurologic function or reduce hyperirritability.

## CLINICAL FEATURES

In infants, hydrocephalus results in irritability, lethargy, failure to thrive (with or without vomiting), delayed development, apnea, bradycardia, hyperreflexia, hypertonia, increasing head circumference, bulging anterior fontanelle, splaying of the cranial sutures, thin scalp with distended scalp veins, frontal bossing, impaired upward gaze with eyelid retraction (i.e., "setting sun" sign from pressure on the tectal plate), decreased levels of consciousness, and papilledema, as well as third, fourth, and sixth nerve palsies. In older children with a rigid cranial vault, hydrocephalus can cause headache (especially in the morning), nausea, vomiting, lethargy, papilledema, deterioration in vision, decline in cognitive function or behavior, memory problems, decreased attention span, worsening of school performance, gait changes, upgaze palsy, diplopia (especially from sixth nerve palsy), and seizures.

## RADIOLOGIC FEATURES OF HYDROCEPHALUS

Plain skull films from patients with hydrocephalus often demonstrate a beaten-copper appearance and splitting of the coronal sutures. CT and MRI frequently reveal dilated temporal horns; obliteration of the sylvian and interhemispheric fissures, sulci, and basilar cisterns; ballooning of the frontal horns and third ventricle; upward bowing or atrophy of the corpus callosum, or both; and periventricular edema related to transependymal absorption of CSF.

Benign external hydrocephalus (also known as *benign extra-axial fluid of infancy*), a condition that rarely requires CSF diversion, is characterized by enlargement of the anterior cortical subarachnoid spaces (i.e., sulci and cisterns) bilaterally; normal or mildly dilated ventricles; a prominent pulsatile anterior fontanelle; and progressive enlargement of head circumference, with crossing of percentile lines when head circumference is plotted with respect to age. Infants with benign external hydrocephalus have large heads and may demonstrate slight delays in motor development related to their large head size. The etiology of this clinical entity is unclear; however, defective CSF absorption has been proposed. Frequently, the family history is significant for large heads. At approximately 12 to 18 months of age, the enlarging head circumference tends to plateau, which allows the child's body growth to catch up with head growth, and the hydrocephalus typically resolves spontaneously by 2 years of age without a need for shunting. Although shunting is not usually required, these children should be monitored closely with serial head circumference measurements and head CT or ultrasound to evaluate for abnormal ventricular enlargement.

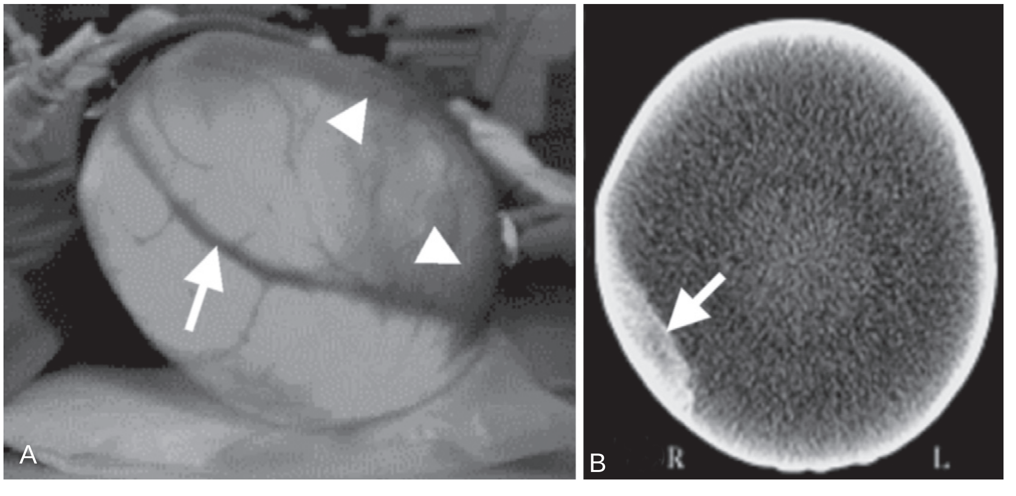

**FIGURE 128-7** Two-day-old girl with hydranencephaly. **A,** Transcranial illumination showing the superior sagittal sinus (*arrow*) and a scant amount of right inferior temporal and occipital cortex (*arrowheads*). **B,** Head computed tomographic scan shortly after birth revealing a scant amount of right cerebral cortex posteriorly (*arrow*). The cerebral hemispheres are replaced almost entirely by cerebrospinal fluid.

## MANAGEMENT

The goal of treatment is to achieve optimum neurologic function and prevent or reverse neurologic damage caused by distortion of the brain from ventricular enlargement. The best predictor of a good outcome is postoperative reconstitution of the cerebral mantle to at least 2.8 cm.[31] This is more likely to occur if a symptomatic hydrocephalic infant undergoes shunting by 5 months of age. The treatment of hydrocephalus is surgical, and the type of surgery depends on the cause of the hydrocephalus. For example, in patients with obstructive hydrocephalus, surgery is performed to remove the obstruction (e.g., tumor). In patients with communicating hydrocephalus or obstructive hydrocephalus in which the obstruction cannot be removed, CSF is shunted from the site of its secretion within the ventricle proximal to the obstruction to a distal site capable of reabsorption. The most commonly used distal sites include the peritoneal cavity, right atrium, pleural cavity, gallbladder, bladder/ureter, and basilar cisterns (i.e., third ventriculostomy). The preferred site for the distal catheter is the peritoneal cavity (i.e., ventriculoperitoneal shunt), unless there is a problem with absorption or abdominal sepsis. When abdominal abnormalities such as extensive postsurgical abdominal adhesions, peritonitis, morbid obesity, and necrotizing enterocolitis are present in preterm infants, a ventriculoatrial shunt is the treatment of choice. Alternatively, if the peritoneum and atrium are not available, a ventriculopleural shunt can be placed in children who are 7 years of age or older.

CSF shunt systems consist of at least three components: a ventricular catheter, which is usually placed in the occipital or frontal horn of the lateral ventricle (see Fig. 128-6, *C*); distal shunt tubing to drain CSF into a distal site for reabsorption; and a valve. Conventional differential pressure shunt valves control unidirectional CSF flow by opening at a fixed pressure differential across the valve. This pressure differential is determined by the characteristics of the valve and is designated as low, medium, or high (typically 5, 10, and 15 cm $H_2O$, respectively). Once the valve is open, it provides little resistance to CSF flow. Consequently, the gravitational effects of an upright posture can lead to high CSF flow rates, which in turn can generate a large negative ICP, a process referred to as "siphoning."

Because siphoning can result in slit ventricles, which in turn are associated with a higher incidence of proximal shunt obstruction, some shunt valves have been designed to limit excess CSF flow, particularly in the upright position.[32] For example, the Delta valve (Medtronic PS Medical, Goleta, CA) is a standard diaphragm-type, differential pressure shunt valve with an integral siphon control device to diminish overdrainage in upright positions. The Orbis-Sigma valve (Cordis, Miami) contains a variable-resistance, flow-limiting component that limits excess CSF flow by progressively narrowing the flow orifice with increasing pressure. Although use of these valves has been advocated as a means of preventing overdrainage and improving treatment results, a randomized trial comparing three different shunt valve designs (i.e., standard differential pressure valve, Delta valve, and Orbis-Sigma valve) in the treatment of children with newly diagnosed hydrocephalus showed no significant difference in shunt failure rates among the valves tested.[33] Currently, there are also three types of programmable differential pressure shunt valves available for use. Such valves, which allow the pressure setting to be altered after implantation, are commonly used in the treatment of pediatric hydrocephalus. Despite the vast array of shunt systems available to treat hydrocephalus, no prospective, randomized, controlled, double-blind, multicenter trial has ever proved a particular shunt system to be more effective than any other.

Ventriculoperitoneal shunting is commonly used to treat childhood hydrocephalus. Placement of a ventriculoperitoneal shunt is performed under general anesthesia after prophylactic intravenous antibiotics are administered. The role of antibiotic prophylaxis has been studied by meta-analysis, and antibiotic coverage is recommended.[34,35] The head of the patient is positioned on a gel donut at the top edge of the operating table in close proximity to the surgeon and turned to the side opposite the shunt insertion. The neck and trunk are extended with a gel roll under the shoulders to assist subcutaneous tunneling of the shunt. Skin incisions are delineated before skin preparation, depending on the desired location of the burr hole for placement of the ventricular catheter (e.g., frontal or occipital). A meticulous skin preparation (e.g., with povidone-iodine scrub and paint solution or chlorhexidine 2% in 70% alcohol) is performed, and the incisions are marked again. The abdominal incision is typically marked in the right upper quadrant or in the midline approximately two to three fingerbreadths below the xiphoid process. Surgical drapes including an iodine-impregnated sterile adhesive drape are placed over the incisions and tunneling site. A curvilinear incision is made in the scalp overlying the proposed burr hole site, and the scalp is retracted. The pericranium is opened at the base of the incision, and a burr hole is drilled. The dura, arachnoid, and pia are then coagulated and opened.

Next, the abdominal incision is opened and entrance into the peritoneal cavity is achieved and confirmed by gently probing the opening into the peritoneal cavity. A shunt tunneling device is then used to create a subcutaneous tunnel extending between the two incisions. The shunt components are removed from their sterile packages just before shunt placement and placed into antibiotic solution. The distal shunt system including the valve is passed within the subcutaneous tunnel, and the proximal and distal ends of the shunt are covered with sponges soaked in antibiotic solution. Care is taken to prevent contact of the shunt tubing with the skin during this portion of the procedure. After this, the ventricular catheter is passed on a wire stylet into the ventricle. Intraoperative ultrasound or ventricular endoscopy, or both, can be used to accurately place the catheter within the ventricle. Ventriculoscopy can also be used to fenestrate intraventricular cysts and provide communication between loculated ventricles.

Once the catheter is in the ventricle and CSF flow has been confirmed, the catheter is cut to the desired length, guided by measurements obtained from the preoperative head CT scan, and then connected to the distal shunt system, usually by way of a reservoir. Silk ties (2-0 or 3-0) are used to secure the catheter to the reservoir. After this, the distal shunt tubing is evaluated for CSF flow. Once confirmed, the distal shunt tubing is passed into the peritoneal cavity; it should pass freely without resistance. The incisions are then irrigated with antibiotic solution, closed in a meticulous, two-layered fashion with good approximation of the skin edges, and covered with sterile dressings.

## COMPLICATIONS OF SHUNT MANAGEMENT

Most children are shunt dependent after shunt implantation. Consequently, children with shunts require lifelong follow-up to make certain that their shunt is functioning adequately,

especially in light of the high incidence of failure over the life of a shunt. For example, in a previous retrospective study in which 1719 hydrocephalic children were evaluated in an attempt to understand why shunts fail,[36] the actuarial probability of the occurrence of shunt failure was 70% at 10 years after the initial shunt insertion, with the highest risk for shunt failure occurring in the immediate postoperative period (i.e., a 30% risk of shunt failure during the first year and a 2% to 5% risk per year thereafter). In addition, the actuarial probability of the occurrence of a shunt infection was 9% over the same 10-year period and the time of shunt failure varied significantly according to the cause of the shunt failure. Other studies have reported shunt failure rates of approximately 40% within the first year for standard CSF shunts implanted for the treatment of pediatric hydrocephalus.[37,38] Moreover, in a randomized trial of CSF shunt valve design,[33] the shunt failure rate was 40% at 1 year and 60% at 2 years and the infection rate was 8% in the hands of experienced pediatric neurosurgeons working in centers where many shunts are implanted each year.

CSF shunt systems malfunction due to three main factors: (1) mechanical failure, (2) infection, and (3) overdrainage or underdrainage (i.e., "functional" failure). Proximal obstruction (i.e., obstruction of the ventricular catheter) is the most frequent cause of mechanical shunt failure.[36] Other causes include obstruction of the distal catheter or any accessory part of the shunt (e.g., antisiphon device); formation of a peritoneal pseudocyst, which is usually associated with infection and causes obstruction of the peritoneal catheter; ascites resulting from failure of intraperitoneal reabsorption of CSF; fracture of the shunt tubing; disconnection of the shunt at a junction point of shunt components (e.g., proximal or distal to a straight connector); migration of the shunt; inadequate length of the distal catheter; improper proximal or distal catheter placement; infection; and overdrainage, which can lead to the formation of subdural fluid collections, slit ventricles, craniosynostosis, or intracranial hypotension. In a study by Sainte-Rose and colleagues,[36] two thirds of the shunt failures were due to obstruction or fracture, with obstruction responsible for 56.1% of shunt failures and fractures occurring almost exclusively at sites of connectors. Moreover, they found that a significantly higher percentage of shunt failure was due to proximal obstruction in patients with slit ventricles than in those with normal or enlarged ventricles and to distal obstruction in patients with slit-ended peritoneal catheters than in those with open-ended catheters.

Repeated shunt failures are common in pediatric patients and are associated with significant morbidity and occasionally death. A prospective, single-institution, observational study designed to identify risk factors predisposing pediatric patients to repeated shunt failures[39] revealed that the timing of the previous shunt procedure is significant, with shunt revisions performed within less than 6 months from the time of the preceding implantation having a significantly increased risk for failure. Furthermore, in this study the age of the patient at the time of first shunt insertion was a significant risk factor for subsequent shunt failure, with patients younger than 40 weeks and those between 40 weeks and 1 year of age at the time of shunt insertion having a higher risk for subsequent shunt failure than those older than 1 year. With respect to the effect of the cause of hydrocephalus on repeated shunt failure, this study showed a higher risk for recurrent shunt failure in patients with intraventricular hemorrhage, meningitis, and tumor. Finally, concurrent surgical procedures also increased the risk for shunt failure in this study.

In most cases of shunt malfunction, the diagnosis is obvious because the child has acute and overt signs and symptoms of elevated ICP such as irritability, headache, vomiting, and lethargy and will progress to stupor, coma, and death if the shunt is not revised promptly. In the study by Sainte-Rose and colleagues,[36] there was a 1.05% mortality rate directly related to shunt failure. Alternatively, some children with shunt failure will have more subtle signs of deterioration such as a decline in school performance, change in attention span, or change in behavior. These "subtle deteriorators" often demonstrate a gradual increase in ventricular size over time and may have a marked increase in ventricular size at the time of presentation. In contrast, acute deteriorators often have only a slight increase in ventricular size. When a child has a suspected shunt malfunction, a head CT is performed to evaluate for interval enlargement of the ventricles. This must be compared with a previous scan obtained when the patient was doing well. A shunt series is also performed to look for continuity of the shunt, especially at sites of connectors, the position of the ventricular catheter or catheters, and the length of the distal shunt tubing.

When a shunt malfunction is suspected, the site of shunt failure must be determined. The most common cause of shunt failure is obstruction of the ventricular catheter by choroid plexus, glial tissue, connective tissue, leptomeninges, ependyma, or brain tissue (or any combination of these tissues), especially in patients with slitlike ventricles.[36] Proximal obstruction is typically associated with precipitous development of intracranial hypertension, which necessitates immediate shunt revision. To reduce the incidence of proximal catheter obstruction, surgeons attempt to place the ventricular catheter with the use of external anatomic landmarks either within the frontal horn of the lateral ventricle anterior to the foramen of Monro or within the occipital horn to keep the catheter away from choroid plexus.[36] With the introduction of fiberoptic endoscopes in the early 1990s, surgeons began using ventricular endoscopy to insert the ventricular catheter away from choroid plexus under direct visualization. Although evidence from uncontrolled series suggested that endoscopic insertion of the ventricular catheter decreased the incidence of shunt failure,[40] a multicenter randomized trial evaluating time to first shunt failure after endoscopic versus nonendoscopic placement of the ventricular catheter in children with hydrocephalus showed no reduction in the incidence of shunt failure with endoscopically assisted placement of the ventricular catheter.[41] However, in this trial, ventricular catheters that were thought by surgeons to be placed away from choroid plexus at the time of shunt insertion were actually found to be located away from choroid plexus on postoperative imaging studies only two thirds of the time in both endoscopic and nonendoscopic insertions. This suggests that the endoscope did not help achieve the goal of placing ventricular catheters away from choroid plexus in this trial. However, a secondary analysis of catheter position in this trial did demonstrate a reduced incidence of shunt failure when the ventricular catheter was positioned away from choroid plexus on the basis of postoperative imaging studies.

Distal shunt malfunctions can occur as a consequence of shunt fracture, inadequate length of the distal shunt tubing, shunt infection, and impaired absorption of CSF at the distal site. Shunt tubing is made of silicone elastomers, which can calcify and break over time. Breakage often occurs above the clavicle, where there is increased motion, or in the region of a connector. Consequently, a shunt series (i.e., anteroposterior and lateral skull, chest, and abdominal radiographs) should be evaluated carefully to look for discontinuity in the shunt system, particularly at sites of connectors. If a shunt fracture is found, the shunt should be revised. The shunt series can also detect whether the distal shunt tubing is too short and a distal lengthening procedure is necessary.

Shunt infection can also cause a distal shunt malfunction and is the second leading cause of shunt failure after mechanical obstruction. With each shunt operation, there is a 2% to 8% incidence of shunt infection,[33] with 5% to 15% of shunts becoming infected over the life of a shunt. The consequences of shunt infection are devastating and can include intellectual and focal neurologic deficits, enormous health care costs, and death. Most shunt infections occur within the first 6 months after a shunt operation,[34] with approximately 70% of shunt infections diagnosed within the first month after surgery and 90% by 6 months. The most common pathogens are staphylococci (*Staphylococcus epidermidis,* 40%; *Staphylococcus aureus,* 20%). Others include coryneforms, streptococci, enterococci, aerobic gram-negative rods, and yeasts. Although shunt infections can occur after 6 months, they are rare and almost always result from indolent bacteria that are a normal part of skin flora, such as *S. epidermidis* or *Propionibacter acnes.* The fact that most shunt infections occur as a consequence of contamination with the patient's own skin flora underscores the need for meticulous attention to surgical technique at the time of shunt insertion.

Shunt infections can range from isolated wound infections and colonization of the shunt tubing to ventriculitis, peritonitis, and an infected pseudocyst. Risk factors implicated in shunt infection include young age of patient, poor skin condition, prolonged surgery, an open NTD, CSF leakage from an incision or wound breakdown postoperatively, increased number of shunt revisions, and concomitant infection. Patients with a shunt infection typically have a low-grade fever (i.e., between 100° F and 102° F) or evidence of shunt malfunction. However, they can also manifest signs of meningitis, ventriculitis, peritonitis, or cellulitis, or any combination of such signs. Symptoms include irritability, headache, nausea and vomiting, lethargy, decreased appetite, abdominal pain, erythema and tenderness along the shunt tract, photophobia, and neck stiffness. A head CT may or may not show a change in ventricular size. It is important for pediatric surgeons to be aware that shunt infection may present only as an acute surgical abdomen, often mimicking appendicitis.[40a]

If shunt infection is suspected, the patient should undergo a radiologic evaluation that includes a shunt series and a head CT scan. The shunt series provides information regarding the continuity of the shunt tubing and location of the shunt reservoir for tapping, possible sources of shunt-related problems, and other potential sources of infection such as pneumonia. The head CT reveals ventricular catheter location, size, and contents including loculations and purulent fluid collections, which can be seen in cases of severe gram-negative ventriculitis. If the patient complains of abdominal pain or abdominal distention is present, an abdominal CT or ultrasound should be performed to evaluate for a CSF pseudocyst. In addition, a peripheral white blood cell count and blood cultures should be obtained because patients with shunt infections often have leukocytosis and positive blood cultures. Finally, a multisystem fever workup should be performed to evaluate for concurrent infections.

If the initial evaluation suggests possible shunt infection, a shunt tap is performed to obtain CSF for study. To do this, the area over the shunt reservoir is shaved and prepared with povidone-iodine or chlorhexidine solution. A 25-gauge butterfly needle is then passed percutaneously into the reservoir using sterile technique. Proximal and distal shunt flow dynamics are evaluated, and CSF is obtained and sent for cell count and differential, protein, glucose, Gram stain, and culture and sensitivity studies. Broad-spectrum intravenous antibiotics are then started.

If CSF studies demonstrate a shunt infection (i.e., isolation of bacteria in CSF obtained from the shunt tap, elevated neutrophils and protein in CSF, or decreased CSF glucose), the entire shunt is removed and an external ventricular drain and central venous line are placed. The patient is treated with the appropriate systemic antibiotics (i.e., antibiotics that have good activity against the isolated organism and adequate CSF penetration) until the shunt infection has cleared, at which time a new shunt may be placed. Monitoring of CSF during treatment is essential. At present, significant variation exists in the duration of antibiotic therapy, with treatment regimens ranging from 2 days to 3 weeks.[42] Studies are currently under way to determine the most effective duration of antibiotic therapy in an effort to shorten hospitalization and minimize complications without sacrificing efficacy. It is the practice at the author's institution to treat with antibiotics until at least two consecutive CSF cultures, at least 48 hours apart, are negative and the inflammatory component of the infection has resolved. Aside from the practical problems associated with their treatment, shunt infections have been linked to an increase in the development of loculated CSF compartments, impaired intellectual outcome (with as high as an 8- to 10-point decrease in IQ), an increased risk for seizures, and an increased mortality rate.[34]

Shunt overdrainage, or "overshunting," can also be associated with shunt failure. Most shunts with differential pressure valves will overdrain regardless of whether the valve pressure is high or low.[32] Overdrainage can lead to the formation of subdural hematomas, a low-ICP syndrome, or slit ventricle syndrome. Subdural hematomas result from the tearing of bridging veins as the ventricles collapse and the cortical surface pulls away from the dura. Although they often resolve without treatment, symptomatic or progressive subdural hematomas from overshunting may require a reduction in the degree of shunting to allow the ventricles to re-expand and the subdural space to become obliterated. Alternatively, drainage of the subdural space either by placing burr holes or by shunting the subdural space with a low-pressure valve may be required. Overshunting can also lead to an intracranial hypotension syndrome with symptoms such as headache, nausea, vomiting, tachycardia, and lethargy that are sensitive to changes in position. In such patients, overdrainage occurs when the patient assumes an upright position. This produces a negative ICP, which in turn leads to intense postural headaches that are relieved by recumbency.[43,44] If symptoms

persist and are frequent or recurrent enough to interfere with daily activities, especially school, the shunt should be revised by placing a higher-resistance valve or adding an antisiphon device, or both.

Overshunting can also lead to the formation of slitlike ventricles. Ventricles commonly become small or slitlike after placement of a shunt. In a previous retrospective study, slit ventricles developed in 80% of the total population of shunted patients.[32] Interestingly, 88.5% of the patients in whom slitlike ventricles developed were completely asymptomatic. Moreover, of the 11.5% of patients with slit ventricles who were symptomatic, only 6.5% required surgical intervention. Symptomatic slit ventricle syndrome occurs infrequently and is associated with intermittent episodes of vomiting, headache, and lethargy. Patients with symptomatic slit ventricle syndrome tend to have small ventricles, diminished extraventricular CSF spaces, a thick skull, and no room for intracranial accumulation of CSF. In this syndrome the ventricular walls collapse around the ventricular catheter, which becomes obstructed, and the shunt fails to drain.[32] Eventually, intraventricular pressure builds up, the ventricles dilate slightly, and the shunt begins to drain. These patients often experience acute neurologic deterioration related to waves of elevated ICP that occur during periods of intermittent shunt obstruction. Moreover, because of the tight intracranial space in these patients, there is no room for any increase in intracranial volume including cerebral blood volume. Consequently, any event that leads to cerebral vasodilatation such as migraine headaches or to an increase in cerebral blood flow such as exercise or playing outside in the hot summer sun will cause symptoms of elevated ICP.[32] Patients with slit ventricle syndrome become symptomatic early in the phase of shunt obstruction, and head CT scans obtained in symptomatic patients frequently reveal no change in ventricular size when compared with their usual slitlike state.

Patients with acute neurologic deterioration in the face of a functioning shunt may benefit from treatment with medications such as furosemide (Lasix) or acetazolamide (Diamox) to lower ICP until the elevated pressure waves subside. Some patients may also benefit from taking antimigraine medications such as cyproheptadine (Periactin) or propranolol (Inderal). If symptoms persist despite conservative treatment, surgical intervention may be necessary. Such interventions include ventricular catheter revision, shunt valve upgrade to increase resistance, addition of an antisiphon or flow control device, decompressive subtemporal craniectomy ipsilateral to the ventricular catheter, or any combination of these interventions. ICP monitoring is useful to differentiate between high-pressure headaches caused by waves of elevated ICP in the face of a functioning shunt and low-pressure headaches caused by negative ICP in patients with true overdrainage.[45] ICP monitoring can also be helpful in identifying children with normal ICP physiology who are having headaches unrelated to shunt function.

Trapping of the fourth ventricle can occur in children with chronic shunting of the lateral ventricles, especially in those with a history of posthemorrhagic hydrocephalus from intraventricular hemorrhage related to prematurity, postinfectious hydrocephalus, or repeated shunt infections/ventriculitis. In this condition, overdrainage of CSF leads to slit ventricles, aqueductal narrowing, or both. When aqueductal stenosis occurs, the fourth ventricle does not communicate with the third ventricle. Likewise, the fourth ventricle does not communicate with the basilar cisterns because of occlusion of the outlets (i.e., foramina of Luschka and Magendie). Production of CSF by choroid plexus in the trapped fourth ventricle results in progressive ventricular enlargement, which may lead to headache, swallowing difficulty, lower cranial nerve palsies, ataxia, lethargy, spastic quadriparesis, and nausea/vomiting. Infants may have apneic spells and bradycardia. In symptomatic patients, the isolated fourth ventricle can be shunted with a separate shunt system or by adding a fourth ventricular catheter into an existing supratentorial shunt system above the valve. However, as the fourth ventricle is decompressed with CSF drainage, the brainstem moves posteriorly into a more normal position and the catheter can injure the brainstem.[46] In addition, approximately 40% of patients require a shunt revision within 1 year.[47] Alternatively, a suboccipital craniotomy with open fenestration of the fourth ventricle to the subarachnoid space and basal cisterns may be performed with or without placement of a shunt from the fourth ventricle to the spinal subarachnoid space.[48,49] Endoscopic aqueductoplasty and interventriculostomy with stent placement have also been proposed as treatment options to reestablish communication between the supratentorial ventricular system and the isolated fourth ventricle.[50]

## ENDOSCOPIC THIRD VENTRICULOSTOMY—AN ALTERNATIVE TO SHUNTING

Endoscopic third ventriculostomy (ETV) can be performed to treat certain types of obstructive hydrocephalus such as primary untreated aqueductal stenosis from tectal plate and pineal region tumors. This technique eliminates the need for a shunt and thereby avoids the complications associated with shunting. It is contraindicated in patients with communicating hydrocephalus, and the success rate is poorer in patients younger than 1 year of age. The highest success rate occurs in older children and adults with acquired obstructive hydrocephalus, with approximately 70% of patients achieving shunt independence.[51,52] In contrast, in children younger than 3 years of age, the success rate has traditionally been poorer, ranging from 40% to 50%. However, in a more recent study, the outcome of ETV was analyzed in patients younger 2 years of age.[53] ETV was successful in 71.4% of procedures in children younger than 2 years of age and in 75% of procedures in infants. The results of this study suggested that success of ETV in infants and young children depends primarily on the thickness of the floor of the third ventricle and the patient's age at the time they initially manifested their hydrocephalus. The success rate is also lower in patients with preexisting pathology such as a tumor, previous shunt, prior subarachnoid hemorrhage, previous whole-brain irradiation, and significant scarring of the third ventricle floor, with as little as 20% of third ventriculostomies remaining patent in such patients.[53]

ETV is performed through a frontal burr hole that is made approximately 2.5 to 3 cm lateral to the midline, just anterior to the coronal suture.[52] A peel-away sheath is passed through the foramen of Monro to protect bordering structures from damage caused by repeated passage of the endoscope. A rigid endoscope is passed by way of the peel-away

sheath through the foramen of Monro into the third ventricle, and the floor of the third ventricle is fenestrated in the midline just anterior to the cleavage plane of the mammillary bodies, which delineate the posterior border of the third ventricular floor. The fenestration is then dilated with a 2-Fr Fogarty balloon catheter by means of repeated inflation and deflation of the balloon. The endoscope is then passed through the fenestration into the interpeduncular cistern to evaluate the arachnoid membranes and make certain there are no redundant arachnoid membranes impeding CSF flow into the subarachnoid cistern.

Complications related to ETV include failure to complete the procedure for technical reasons, which has been reported in up to 26% of patients,[54] hemorrhage secondary to vascular injury,[55] cardiac arrest, diabetes insipidus, the syndrome of inappropriate antidiuretic hormone secretion, subdural hematoma, meningitis, cerebral infarction, transient third and sixth nerve palsies, and disturbances in short-term memory.[54,55] Risks of ETV include infection; injury to adjacent neural structures (e.g., hypothalamus, pituitary gland, optic chiasm); and arterial injury with intraoperative rupture or delayed hemorrhage related to traumatic aneurysm formation. In a small number of patients, delayed closure of the ETV has been described related to scar formation or metastatic tumor seeding.[56] In patients with recurrent symptoms of intracranial hypertension, cine-MRI can be performed to assess the patency of the third ventriculostomy by evaluating CSF flow across the floor of the third ventricle. If the floor of the third ventricle is no longer patent, endoscopic exploration with an attempt at repeat fenestration is reasonable. If postoperative scarring precludes safe repeat fenestration of the third ventricular floor, a ventricular shunt system should be placed.

Late rapid deterioration is an infrequent but deadly complication of ETV in which deterioration can occur long after the ETV becomes occluded.[57] It is imperative that patients and caregivers be counseled about this potential complication. As a means of avoiding this type of complication, the author places a permanent ventricular access device in patients undergoing ETV.

### OUTCOME AND PROGNOSIS

The natural history of untreated hydrocephalus is poor. In one study, 50% of children with untreated hydrocephalus died before 3 years of age[58] and only 20% to 23% reached adult life. Of the survivors, only 38% had normal intelligence.[30] The development of CSF diversion techniques has improved the prognosis for children with hydrocephalus. Many patients with shunted hydrocephalus have normal intelligence and participate in all aspects of social life, with cognitive development and life expectancy determined primarily by the nature of the underlying condition. Overall, about 50% to 55% of shunt-dependent children will achieve an IQ greater than 80, with verbal cognitive skills being superior to nonverbal ones.[59–61] Not surprisingly, epilepsy appears to be an important predictor of poor intellectual outcome in children with shunted hydrocephalus, with an IQ higher than 90 occurring in 66% of children without epilepsy versus in 24% of children with epilepsy.[62] Unfortunately, repeated shunt complications in pediatric patients with hydrocephalus carry significant morbidity.

## Epilepsy Surgery in Children

Epilepsy is a common childhood disorder.[63] It affects approximately 0.5% to 1% of the population in the United States and Canada,[63–65] and up to 50% of epilepsy cases begin before 5 years of age.[63,66] Children with epilepsy are usually managed with antiepileptic medications initially. However, 20% to 25% of children with epilepsy have inadequate control of their seizures with pharmacotherapy[67,68] and it is now recognized that seizures starting in childhood that are caused by a known structural lesion and are not controlled by medication rarely remit spontaneously as the child matures.[69] Repeated seizures and the side effects of seizure medications have a negative impact on the developing brain and can lead to severe impairment of neurocognitive function.[69–75] Moreover, recurring seizures can have a negative impact on a child's education as a consequence of learning difficulties and the associated psychosocial effects such as poor peer relationships, behavioral difficulties, poor school performance, depression, anxiety, and poor self-esteem.[73,76,77] Because refractory epilepsy in childhood is a progressive, debilitating condition associated with eventual deterioration in both intellectual and behavioral function, aggressive treatment is warranted. Seizure surgery provides an effective alternative therapeutic option for children who suffer from intractable seizures. The goal of surgery is to remove the seizure focus as completely as possible without creating a new neurologic deficit or worsening an existing one.

Epilepsy surgery is indicated when (1) a child's seizures persist despite an adequate trial of at least two appropriate anticonvulsants, alone or in combination, with each drug pushed to the maximum tolerated dosage; (2) the seizures significantly reduce the child's quality of life; (3) there is a unilateral seizure focus that can be reliably and reproducibly identified; and (4) resection of the seizure focus does not cause unacceptable neurologic deficits.[69,78–80] A preoperative workup is initiated as soon as a child fails medical therapy because early operative intervention is paramount to a good functional outcome.[69,80,81]

### PREOPERATIVE EVALUATION

The primary objective of the preoperative evaluation is to identify the area of seizure onset (i.e., the seizure focus) and its relationship to eloquent cortex.[69,74] This begins with noninvasive characterization of the seizure syndrome and optimization of medical management. Patients undergo a thorough neurologic history and physical examination, baseline EEG, and high-resolution brain MRI with thin coronal cuts through the temporal lobe (e.g., three-dimensional spoiled gradient echo [3D-SPGR] scan), fluid-attenuated inversion recovery (FLAIR) sequences, and MR spectroscopy. EEG can provide important information by confirming the presence of an epileptogenic focus, by helping to characterize the seizures and epilepsy syndrome, and by localizing the seizure focus.[82] Helpful localizing features on EEG include focal slowing, focal attenuation of fast activity, and focal epileptiform discharges (e.g., spikes or sharp waves). A good prognostic indicator for success with focal resective surgery is the presence of a single focus of epileptiform activity.[82] The MRI is evaluated for focal structural abnormalities (e.g., cytoarchitectural) or

abnormal lesions (e.g., neoplastic) that could be causing the child's seizures. The presence of a focal abnormality on MRI, especially when it corresponds to the location of seizure onset on EEG, increases confidence that the epileptogenic region has been identified and also increases the likelihood of achieving seizure control with surgery.[80,82,83,] Structural abnormalities that can be visualized on MRI and that are associated with medically refractory seizures include low-grade tumors such as a ganglioglioma (Fig. 128-8), dysembryoplastic neuroepithelial tumor (DNET), astrocytoma, oligodendroglioma, and pleomorphic xanthoastrocytoma; developmental abnormalities such as cortical dysplasia and focal neuronal migration abnormalities (e.g., gray matter heterotopia); vascular malformations such as cavernomas and arteriovenous malformations; secondary post-traumatic or postischemic encephalomalacia lesions; and mesial temporal sclerosis.[82]

If the initial evaluation suggests a possible seizure focus, additional studies are performed to define the seizure focus further including prolonged video-EEG monitoring with surface (i.e., scalp) electrodes, functional neuroimaging studies (positron emission tomography [PET] or single-photon computed emission tomography [SPECT], or both), and neuropsychological testing, with or without intracarotid injection of sodium amobarbital (i.e., Wada testing). Prolonged video-EEG monitoring involves the simultaneous recording of brain activity and clinical behavior and is the cornerstone of the presurgical evaluation.[82,84] It combines simultaneous EEG recording via scalp electrodes with a synchronized, continuous real-time audio/video recording of a child's typical seizures and thereby enables lateralization and localization of the child's seizure focus. When a temporal focus is suspected, sphenoidal electrodes can be placed to record activity from the mesial temporal lobes. In addition, antiepileptic medications can be withdrawn gradually while continuously monitoring for seizures until several of the child's "habitual events" are recorded. In the majority of cases, the video-EEG study enables one to determine whether a patient has epilepsy, whether the patient has partial or generalized seizures, and where the partial seizures arise.[78,80] When considering a child for epilepsy surgery, the ideal circumstance is to find that the seizures are highly stereotyped on EEG and that all seizures arise from the same region.[80]

Occasionally, video-EEG recording will demonstrate the presence of independent, bilateral seizure onset, especially in children with epilepsy secondary to multifocal abnormalities, as seen in tuberous sclerosis.[85] In such cases a child may still be considered a candidate for epilepsy surgery if a majority of the seizures come from one side; however, complete seizure control may not be possible.[80] Additionally, in children with tuberous sclerosis complex who have multiple and oftentimes bilateral epileptogenic tubers, a novel surgical approach has been proposed using multistaged and bilateral invasive intracranial monitoring to identify both primary and secondary epileptogenic zones.[86,87] In contrast to the typical epilepsy surgery approach where electrodes are placed to map the location of seizure onset during the first operative stage and surgical resection follows during the second stage, the multistaged approach involves resection of the primary seizure focus during the second operative stage followed by replacement of the electrodes during that same stage to determine whether a second epileptogenic region requires resection at the third and final stage. With such an approach, multiple

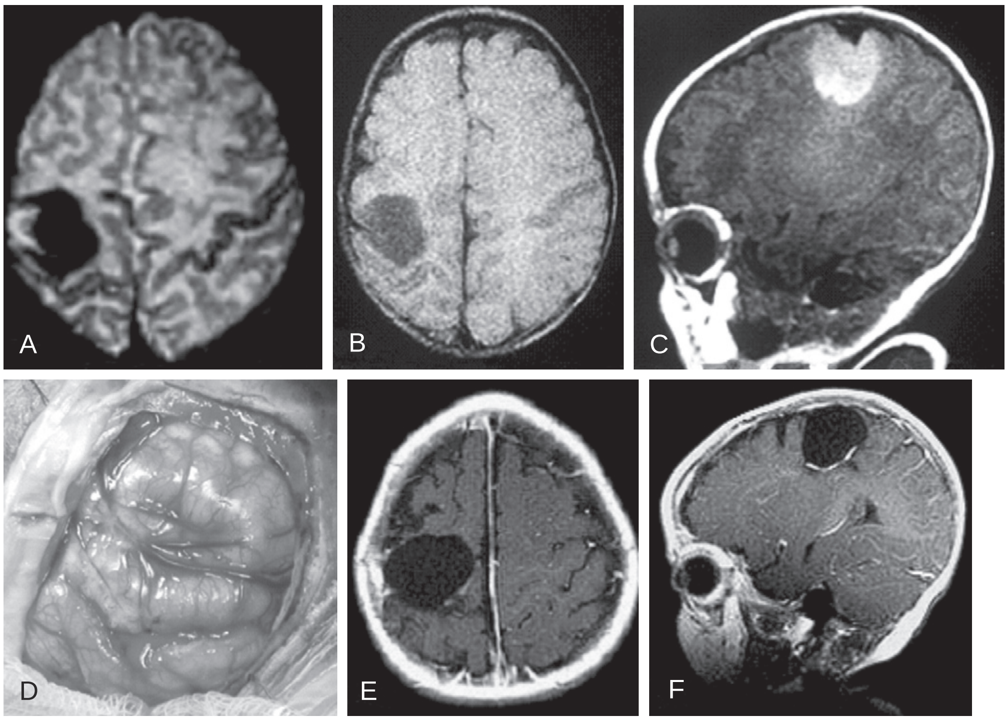

**FIGURE 128-8** Three-month-old girl with 30 to 60 seizures per day on three anticonvulsants. **A** to **F,** Brain magnetic resonance image (MRI) showing a 2.5 × 2.5 × 2-cm right posterior frontal mass. Preoperative video electroencephalographic studies localized her seizures to the region of the abnormality on MRI. She underwent complete resection of the mass and adjacent epileptogenic zone, which was localized via intraoperative electrocorticography. The final pathology was a ganglioglioma. She is now 33 months of age with no evidence of tumor recurrence, has mild residual spastic left hemiparesis, and is completely seizure free and off all anticonvulsants.

or bilateral seizure foci have been successfully resected to achieve good seizure control, suggesting that multiple or bilateral seizure foci are not necessarily a contraindication to surgery in selected patients. However, long-term follow-up is necessary to determine the durability of the effects of this novel surgical approach.

Functional neuroimaging with PET[88–90] and SPECT[91] also provides valuable localizing information by detecting generalized and focal functional brain abnormalities. This information can then be compared with the electrophysiologic dysfunction observed on EEG and the anatomic abnormalities on MRI. PET is a noninvasive functional imaging study that measures regional cerebral glucose utilization or metabolism by determining the extent of uptake of the radionuclide [$^{18}$F]deoxyglucose (FDG). Interictally, an epileptic focus is seen on PET as an area of glucose hypometabolism. This study is especially helpful in localizing focal areas of cortical dysplasia, mesial temporal sclerosis, and other structural abnormalities that correspond to surface EEG localization of epileptogenic regions. SPECT is another noninvasive functional imaging study that measures regional cerebral blood flow by using perfusion radiotracers such as technetium Tc 99m hexamethylpropyleneamine oxine ($^{99m}$Tc-HMPAO). It provides a snapshot of local cerebral blood flow at a specific point in time.[70] Between seizures, a seizure focus is hypometabolic and receives less blood flow. Consequently, relative hypoperfusion is observed in this region on a SPECT scan.[92] In contrast, hyperperfusion is observed in the region of the seizure focus on an ictal SPECT study if the tracer is injected at the time of seizure onset because local blood flow to the seizure focus increases significantly during a seizure as a consequence of increased metabolic demands. Ictal SPECT is more reliable than interictal SPECT in localizing the epileptogenic zone,[93–95] and ictal SPECT is more feasible than ictal PET because, unlike the ictal PET scan, which must be performed shortly after the tracer is given, the ictal SPECT scan can be performed at a convenient time after the tracer is injected.[105] Functional imaging studies such as PET and SPECT have reduced the need for invasive intracranial monitoring in children by up to 90%.[88,93,94]

Another important component of the presurgical evaluation is the identification of areas of brain function relative to the location of the seizure focus. This helps predict the risks associated with removal of the seizure focus. Neuropsychological testing plays an important role in this part of the presurgical evaluation.[82] Such testing can provide lateralizing and localizing information by identifying areas of neurologic dysfunction that correlate with the patient's underlying lesion.[96] For example, patients with seizures arising from their dominant temporal lobe may have deficits in verbal memory or language acquisition, whereas deficits in visuospatial memory suggest seizure onset in the nondominant temporal lobe. Significant deficits in both verbal and visuospatial memory suggest bilateral temporal lobe damage and probable bilateral seizure foci. In addition, preoperative neuropsychological testing can help predict the prognosis for cognitive functioning after surgery and can be used as a baseline to monitor disease progression, successful therapy, and the adverse effects of treatment.[70,82] Moreover, postoperative neuropsychological testing can be performed to identify residual or resultant cognitive deficits and to assist in planning psychoeducational interventions to address any impairments.

Intracarotid amobarbital injection (i.e., Wada testing) can also be used, especially in older children, to determine which cerebral hemisphere is dominant for language and to ascertain the relative contributions of each cerebral hemisphere to memory function.[70,78,97,98] During this study, a cerebral angiogram is performed and amobarbital is injected into each internal carotid artery individually. Intracarotid injection of amobarbital results in arrest of ipsilateral cerebral function, which mimics the effect of surgical removal of the ipsilateral cerebral hemisphere. A successful injection is demonstrated by contralateral hemiparesis and ipsilateral slowing of the EEG. Speech and memory are then tested to determine whether the hemisphere contralateral to a planned resection can adequately support language and memory function. Wada testing is the most reliable means of ascertaining lateralization of language dominance and assessing residual memory capacity after temporal lobectomy; however, it is often difficult to perform in young children because it is necessary for them to be awake and cooperative.

Results from the preoperative investigation determine whether a patient is a candidate for epilepsy surgery or whether additional studies are required to more accurately pinpoint the location of the seizure focus and areas of eloquent cortex. The results of the presurgical studies are reviewed in a multidisciplinary clinical conference attended by epileptologists, neurosurgeons, neuroradiologists, neuropsychologists, and other members of the epilepsy surgery team to determine whether the patient is a candidate for surgery. The pediatric neurosurgeon discusses the risks and benefits of surgery, determines the surgical approach, and makes the final decision on whether or not to proceed.[82] Results obtained from video-EEG, MRI, and PET are typically given the strongest consideration,[78] and surgery is recommended when there is a clearly defined focal area of seizure onset that is consistent with EEG, radiographic, neuropsychological, and clinical evidence.[79] The likelihood of a successful outcome from seizure surgery increases with the number of independent elements that converge toward a single localization.[78,95,99,100]

In some patients surgery appears to be a good option, but the data are inconclusive or discordant. Such patients include those with normal or nonlocalizing imaging studies and a video-EEG that regionalizes the seizure onset without sufficiently localizing it, patients with a seizure focus that is more extensive than the structural lesion observed on imaging studies, and those with a seizure focus in the vicinity of eloquent cortex. For these patients, prolonged, invasive intracranial EEG monitoring may be required to obtain more precise localizing information.[78,79,101–104] Intracranial EEG monitoring has the following advantages: (1) it helps define the boundaries of the epileptogenic zone around the lesion, which in turn guides the extent of resection; (2) it helps determine whether children with multiple structural lesions and multifocal interictal spike discharges are surgical candidates by ascertaining whether their seizures arise from a single operable epileptogenic zone; and (3) it enables mapping of areas of eloquent cortex that are contiguous to the seizure focus to determine whether resection of the seizure focus can be performed safely without creating new deficits or worsening existing ones.

This technique involves placing surface electrodes such as grid and strip electrodes embedded in a thin pliable sheet of plastic, directly onto the cortical surface through a craniotomy

and dural opening in the case of subdural grids or through burr holes in the case of subdural strips.[105] Before closing the dura, an ICP monitor can be placed in patients with subdural grids to assist postoperative monitoring and management of elevated ICP related to grid placement. ICP monitoring is particularly beneficial in the case of a prolonged postictal state because it can help differentiate postictal lethargy from neurologic deterioration as a result of hemorrhage or edema.[79] In addition, the strips and grids are sutured to the dura to minimize the risk of postoperative movement and the electrode leads are tunneled to a distant exit site to minimize the risk of infection. Duraplasty is performed in cases in which the subdural space must be enlarged to accommodate the electrodes, the bone flap is replaced loosely, and the scalp incision is closed in a two-layered fashion. The skin around the exiting leads is closed tightly to avoid a CSF leak, and the leads are secured to the scalp with 4-0 nylon suture to minimize movement of the electrodes. If necessary, multicontact depth electrodes can be placed stereotactically with a frame-based system to achieve accurate EEG recordings from structures located deep to the cortical surface. Depth electrodes survey restricted areas of cortex and are not helpful in delineating large epileptogenic zones. However, monitoring with depth electrodes can be advantageous in children when the seizures are thought to arise from mesial temporal lobe structures such as the hippocampus and amygdala, but the side of origin is uncertain.[102]

After implanting the surface electrodes, a postoperative skull radiograph is obtained to document electrode position, prophylactic intravenous antibiotics and low-dose corticosteroids are administered, and continuous video-EEG monitoring is performed. The child is monitored until several typical seizures are recorded. Once an adequate number of the child's typical seizures have been recorded, cortical stimulation studies are carried out to map functional cortex and induce auras or seizures that can be of further help in localizing the seizure focus.[70,78,79] A surgical plan is then formulated on the basis of the electrical, structural, and functional data, and the child is taken back to the operating room, where the craniotomy is reopened and the planned resection is performed. A repeat skull radiograph is performed before the second operation and compared with the initial skull film to document electrode position and evaluate for electrode movement. Occasionally, an epileptogenic focus cannot be found or resection of the epileptogenic focus may lead to an unacceptable neurologic deficit. In such cases, the subdural electrodes are removed and the craniotomy is closed without performing resective surgery.[79]

Although intracranial EEG monitoring can help determine the feasibility and safety of epilepsy surgery, it is an invasive procedure associated with a number of possible risks including hemorrhage, infection, CSF leak, electrode migration, increased ICP, and even death.[104,106] The complication rate for strips is 1% to 3%,[107] whereas that for depth electrodes is 3% to 10%.[108] Complications occur more commonly with grids than with strips. The risk of infection increases with the duration of invasive monitoring and may be decreased by administering prophylactic intravenous antibiotics. In many cases, extraoperative electrode grid placement is unnecessary.[102,103,109] Instead, intraoperative electrocorticography can be carried out at the time of surgery to define the precise limits of the cortical resection on the basis of the location of interictal spike discharges, differences in background EEG patterns, and identification of critical functional cortex (e.g., primary sensorimotor cortex) by intraoperative somatosensory evoked potentials.[102,110]

## TYPES OF EPILEPSY SURGERY

Three main types of surgery are used to treat intractable seizures in children: (1) resections, in which the epileptogenic cortex is removed; (2) disconnections, in which critical pathways involved in the propagation of epileptiform discharges are interrupted; and (3) implantations, in which electrical stimulation is used.[74,82,111] The type of surgery performed is determined by the results of the presurgical workup.

### Resection Surgery

Specific types of resection surgery include anterior temporal lobectomy with amygdalohippocampectomy for intractable complex partial seizures; extratemporal resections for nonlesional epilepsy[79]; multilobar, lobar, and focal cortical resections for intractable seizures caused by structural lesions such as cortical malformations, intracerebral hamartomas, tumors (see Fig. 128-8), and vascular malformations[74]; and hemispherectomy, the extreme of resection surgery, which involves either complete removal (anatomic) or isolation (functional) of the abnormal cerebral hemisphere and is reported to be one of the most successful of all operations for the relief of epilepsy.[111–113] Hemispherectomy is reserved for patients who have severe damage to one hemisphere and a relatively intact contralateral hemisphere. It is particularly effective in children with severe unilateral motor seizures who already have contralateral hemiparesis and hemianopsia. Candidates for hemispherectomy include patients with Rasmussen syndrome,[114] Sturge-Weber syndrome,[115] hemimegalencephaly,[116] diffuse hemispheric cortical dysplasia, infantile hemiplegia, and cerebral infarction. When the presurgical workup reveals that a child's seizures are arising from the entire hemisphere and that hemisphere is removed with sparing of the ipsilateral basal ganglia (anatomic hemispherectomy) or disconnected with removal of less cortical tissue (functional hemispherectomy or hemispherotomy), 75% to 80% of patients have a marked reduction (80% or more) in seizure frequency with improvement in cognitive function.[74,114,117,118]

Temporal lobe epilepsy (TLE) is the most common localization-related epilepsy in adult and adolescent surgical candidates but is less common than extratemporal epilepsy in infants and children.[119,120] In TLE, patients generally experience complex partial seizures with oral and gestural automatisms, which may be preceded by an aura.[78] Although the most common cause of TLE in adults and adolescents is mesial temporal sclerosis, such is not the case for infants and children.[121,122] Instead, TLE in this age group is more commonly caused by congenital abnormalities in cerebral development such as cortical dysplasia, low-grade neoplasms, and vascular malformations.[81,123] In patients with lesion-related TLE, which occurs as a result of a temporal lobe mass, the source of the seizures is not generally the lesion itself but the margins around the lesion[124] and a successful outcome in such patients depends on adequately defining the extent of the epileptogenic zone around the lesion and resecting this region along with the lesion.

When the results of diagnostic studies indicate that the seizures are arising from a single temporal lobe, surgery is recommended. Both the lateral neocortex and the medial basal portion of the temporal lobe can cause temporal lobe seizures in children.[69,70] The medial basal portion of the temporal lobe consists of the fusiform and parahippocampal gyri and the amygdalohippocampal complex. Several surgical approaches have been described for resecting epileptic foci arising from the medial temporal lobe in children with medically refractory mesial TLE of unilateral origin.[74] For example, an anterior temporal lobectomy with amygdalohippocampectomy can be performed.[70,111,125] This two-step approach involves the initial removal of approximately 3.5 cm of anterolateral temporal lobe (measured with a ruler from the temporal tip along the middle temporal gyrus) below the superior temporal gyrus with a subpial dissection technique. This results in exposure of the temporal horn and mesial temporal lobe structures including the hippocampus, amygdala, and parahippocampal gyrus. The mesial structures are then removed by subpial dissection under the operating microscope, with the posterior limit of the dissection extending to the level of the tectal plate. In children with medically refractory mesial TLE of unilateral origin, removal of the affected mesial temporal lobe, with complete removal of the medial temporal structures, has a greater than 75% chance of significantly reducing a child's seizures or rendering a child seizure free off medication.[69,70,74,81,126]

Extratemporal epilepsy is found more frequently than TLE in pediatric epilepsy surgery candidates.[119] The epileptiform abnormalities can be frontal, parietal, or occipital and are often poorly localized.[127–129] Moreover, it is not uncommon for more than one lobe to be involved in children with intractable epilepsy.[79] When the seizure focus is outside the temporal lobe and is not associated with a lesion on imaging studies (nonlesional, extratemporal epilepsy), patients often require invasive intracranial monitoring and stimulation studies to define and accurately localize the seizure focus, as well as to map areas of eloquent brain function relative to the epileptogenic cortex.[78,79] Such seizures may be clinically silent and suggest a parietal or lateral frontal focus, complex partial and suggest a frontal lobe focus, or associated with amaurosis and suggest an occipital lobe focus. Resection margins are defined on the basis of the epileptogenic gyri identified during preoperative intracranial monitoring and stimulation studies with implanted subdural electrodes, as well as by intraoperative electrocorticography and functional cortical mapping. Corticectomy is then carried out under the operating microscope, and the entire epileptogenic focus is resected en bloc using a subpial dissection technique. Roughly two thirds of children with extratemporal (both lesional and nonlesional) epilepsy derive significant improvement from surgical intervention.[130,131]

The risks associated with resection procedures are generally related to the area or areas of brain resected and include visual field cuts (e.g., contralateral superior quadrantanopsia or "pie-in-the-sky" defect caused by an injury to Meyer loop/optic radiation during posterior temporal lobe resection), manipulation hemiplegia, speech and memory deficits, stroke from injury to nearby blood vessels (e.g., sylvian branches of the middle cerebral artery during temporal lobectomy), and cranial nerve palsies (e.g., injury to the third nerve during resection of the hippocampus). The incidence of major complications such as stroke or paresis ranges from 2% to 5%.[131,132]

## Disconnection Surgery

Resection of an epileptogenic focus is the mainstay of epilepsy surgery. However, in some children, the epileptogenic area is in a functionally critical cortical region (e.g., sensorimotor, language, or visual cortex, or more than one of these regions) and cannot be resected safely. Such children may be candidates for disconnection surgery—surgery in which the seizure focus is isolated from the rest of the brain.[111] For example, if the presurgical workup reveals that a child has a seizure focus in an area of eloquent brain such as the motor cortex, resection of the focus might cause unacceptable deficits such as contralateral paralysis or weakness. To prevent this, children with seizures arising in eloquent cortex can undergo a type of "disconnection" procedure called *multiple subpial transection*.[79,111,133] The efficacy of this type of surgery is based on the observation that normal cortical function is transmitted vertically, whereas seizures are transmitted through horizontal pathways. A small ball-tipped probe is used to transect the horizontal fibers in regions of eloquent cortex, thereby interrupting the horizontal spread of the ictal discharge without damaging the vertical columns of functional cortex. The cuts are made within the superficial convexity of the cortex under direct vision through the operating microscope, with each cut occurring at a right angle to the long axis of the gyrus at 5-mm intervals in a parallel fashion until the entire epileptogenic zone has been covered. With this technique, selected patients can achieve a substantial reduction in seizure frequency, without sustaining any persistent neurologic deficits. In extratemporal epilepsy, seizure control with multiple subpial transection is comparable with that achieved with resective surgery.[134]

Corpus callosotomy is another type of disconnection surgery that can be performed in the absence of an identifiable seizure focus or in the presence of multiple foci. During this procedure, the anterior two thirds or the entire corpus callosum is sectioned through a bifrontal craniotomy approach.[23,74,135] It is typically reserved for patients who have symptomatic generalized epilepsy with multiple seizure types and foci of epileptogenicity, as well as some degree of developmental delay or mental retardation.[78,82] Sectioning the corpus callosum results in separation of the cerebral hemispheres and prevents rapid bilateral generalization of epileptic discharges. Candidates for operative intervention include patients with atonic seizures ("drop attacks") who are prone to violent falls and closed head injuries and patients with Lennox-Gastaut syndrome. In appropriate patients, this type of procedure can be effective. For example, in patients with atonic seizures, up to 80% may experience complete or nearly complete cessation of attacks.[82] However, rarely do seizures totally remit, and patients with absence or myoclonic seizures either derive no benefit or experience an inconsistent response with corpus callosotomy. In addition, corpus callosotomy is associated with a number of possible adverse effects, some of which can be quite devastating, including language disturbances (e.g., complete mutism vs. slowness in initiating speech), weakness, increased frequency or intensity of partial seizures, and a disconnection syndrome. This syndrome, which can occur in patients with a dominant left hemisphere, consists of left tactile anomia, left-sided dyspraxia, pseudohemianopsia, right-sided anomia for smell, impaired spatial synthesis of the right hand resulting in difficulty copying complex figures, decreased spontaneity of speech, and incontinence.[74]

***Outcome*** Successful outcome from epilepsy surgery depends on (1) proper and timely patient selection guided by a thorough presurgical evaluation; (2) good correlation among clinical, electrophysiologic, and neuroradiologic data; (3) complete or nearly complete resection of the seizure focus; and (4) lack of surgery-related injury. Patients undergo routine EEG, MRI, and neuropsychological testing postoperatively and are graded in terms of percentage of seizure reduction and length of time since surgery. Results from preoperative neuropsychological testing can also be compared with those from postoperative testing to ascertain the effects of surgery on the child's behavior and cognition. In this manner, postoperative neuropsychological testing can help identify residual or resultant cognitive deficits and assist in planning psychoeducational interventions to address these deficits. Patients continue taking anticonvulsants for 1 to 2 years postoperatively. Those who are seizure free at that time, with a relatively benign-appearing EEG, are gradually weaned from their seizure medications.

Some studies have shown that outcome after epilepsy surgery (especially in the case of multilobar, lobar, and focal cortical resections for intractable seizures caused by structural lesions) is related to the pathology and location of the lesion.[74,82] Structural lesions associated with intractable epilepsy in children include developmental lesions such as focal cortical dysplasia and hamartomas; vascular lesions such as cavernomas and arteriovenous malformations; low-grade tumors such as DNET, ganglioglioma, ganglioneuroma, astrocytoma, pleomorphic xanthoastrocytoma, and oligodendroglioma; ischemic or hypoxic lesions; traumatic lesions; and mesial temporal sclerosis.[74,82] With focal cortical dysplasia, an important cause of intractable epilepsy in children, the outcome after surgical intervention is good within the first 2 years after surgery; however, the percentage of patients who remain seizure free declines over time. For example, in one series,[136] although 65% of patients with cortical dysplasia were seizure free at 2 years, only 40% remained seizure free at 5 years and just 33% were seizure free at 10 years. In another series with a mean follow-up period of 3.6 years, children with cortical dysplasia had seizure-free rates of 52%.[137] With mesial temporal sclerosis, a relatively rare pathologic entity in children, seizure-free rates are excellent for the vast majority of children and adolescents, with surgical results comparable with those observed in adults.[136,137] A DNET is a benign cortical tumor that has cystic or microcystic components and is frequently associated with cortical dysplasia.[82] In contrast to cortical dysplasia, the epileptogenic area associated with a DNET resides within the cortex immediately adjacent to the lesion rather than within the DNET itself.[138] Total resection of these lesions, aided by preresection electrocorticography to identify adjacent epileptogenic cortex, can result in complete seizure freedom in about 75% of patients.[139] In patients with ganglioglioma who have seizures (see Fig. 128-8), complete surgical resection is the preferred management and the most important factor predicting a seizure-free outcome,[140] with about 78% of patients becoming seizure free off anticonvulsants.[141]

The goal of surgical management is complete elimination of seizures or excellent seizure control with seizure medications and an improvement in the child's long-term cognitive, behavioral, and social development. Surgical treatment of epilepsy in children can reduce seizure frequency and limit the cognitive and psychologic impairment that often occurs as a consequence of chronic uncontrolled seizures. However, surgical intervention must be timed appropriately to enable children to develop their maximal potential and reach their educational, vocational, and social goals.[82]

As with any surgical procedure, epilepsy ablative procedures are not risk free and the risk of creating a new permanent neurologic deficit or worsening an existing deficit must be balanced against the potential benefit of completely eliminating a patient's seizures or significantly reducing the frequency of seizures. Risks of epilepsy surgery include removal of or injury to eloquent cortex; injury to projection fibers, association fibers, or commissural fibers underlying the cortical resection; injury to the Meyer loop causing a contralateral "pie-in-the-sky" visual field defect; injury to vessels in the area of the resection causing ischemic damage or stroke in the corresponding areas of vascular distribution; and injury to nearby cranial nerves. Despite the risks of the procedure, early surgical intervention in appropriate cases can arrest progressive deleterious changes in the developing brain including progressive psychologic and intellectual impairment, allow for optimum brain development, reduce the undesirable side effects of medical therapy, and allow many children with seizures to lead normal, productive lives. Currently, surgery is the only therapy that offers the chance of a cure and early identification of appropriate surgical candidates by means of a comprehensive preoperative evaluation is paramount to achieving a successful outcome.[82]

## Vagus Nerve Stimulation

Vagus nerve stimulation by means of the implantable NeuroCybernetic Prosthesis (NCP; Cyberonics, Houston) is a relatively recent development in the surgical treatment of childhood epilepsy and is gaining increasing popularity as an effective treatment option for children with drug-resistant epilepsy who have failed medical therapy and are not candidates for resection or disconnection procedures. Such children often have many generalized or focal seizures (or both) every day that arise from multiple areas on both sides of the brain, and they are not candidates for or have already failed previous cortical resection. The FDA limits its use to patients older than 12 years of age; however, it is also commonly used in children younger than 12 years of age because earlier control of seizures generally results in improved long-term outcomes.

Placement of a vagal nerve stimulator involves wrapping helical, platinum, bifurcated ribbon electrodes around the left vagus nerve in the cervical region and connecting the bifurcated helical lead to a pulse generator, which in turn is inserted into a subcutaneous or submuscular pocket in the left pectoral region.[111,142] Together, they deliver intermittent electrical stimulation to the left cervical vagus nerve—usually for 30 seconds every 5 minutes. Electrical impulses, which travel to the cerebral cortex by way of ascending sensory nuclei (e.g., nucleus tractus solitarius), exert widespread effects on neuronal excitability throughout the CNS.[143] Although it has been postulated that these rostral impulses stop seizure activity by disrupting the abnormal electrical activity caused by abnormal

groups of neurons firing in an uncontrolled synchronous fashion, the exact mechanism of seizure modulation remains unknown.[64,144,145]

The pulse generator has eight programmable parameters that are adjusted noninvasively through the skin by a telemetry programming wand controlled by a hand-held computer. The stimulation parameters are adjusted according to patient tolerance and seizure frequency, and seizure medications are weaned as tolerated. An additional benefit of vagus nerve stimulation is the ability to control seizure activity with the use of a hand-held magnet. For example, at the beginning of an aura or seizure, the patient or a family member may pass a hand-held magnet across the chest pocket where the generator resides. This triggers a train of stimulation superimposed on the baseline output that can attenuate or even abort an impending seizure.[143] Other advantages of vagus nerve stimulation include guaranteed treatment compliance, sustained efficacy over time,[146] and global improvement in quality of life and cognitive function.[143] Adverse effects of vagus nerve stimulation can occur and include hoarseness, throat pain, cough, dyspnea, and paresthesias. Such effects tend to occur intermittently, concomitantly with stimulus delivery, and are typically transient.[146,147] Surgical complications of vagus nerve stimulation are rare and include left vocal cord injury, lower facial paresis, bradycardia, and infection requiring explantation in 1.1%.[143] Although the vagus nerve is the principal efferent component of the parasympathetic nervous system, vagus nerve stimulation by the NCP system has not been shown to adversely influence pulmonary function, gastrointestinal motility, or secretion.[147] Nevertheless, there is a case report in the literature of bradyarrhythmia, perfectly correlated with VNS stimulation periods, which suddenly occurred 2 years and 4 months after VNS implantation in a pediatric patient who presented with syncope-like episodes.[148]

Previous studies have shown that children and adolescents with medically and surgically refractory epilepsy derive substantial benefit from vagus nerve stimulation, with many patients achieving a significant reduction in seizure frequency and some being able to reduce the number of anticonvulsants.[149,150] Patients with idiopathic epilepsy, as well as those with seizures arising from a structural etiology, are considered appropriate candidates.[143] In particular, vagal nerve stimulation has been shown to be highly effective in patients with Lennox-Gastaut syndrome, with five of six children in one series achieving a 90% reduction in seizure frequency.[151] Moreover, use of the magnet in pediatric patients has been shown to reduce seizure duration in some patients and improve postictal lethargy in others.[150] In a previous retrospective analysis of seizure frequency and quality of life in pediatric patients with medically refractory epilepsy,[150] 29% of children achieved a greater than 90% reduction in seizure frequency, 39% had a 50% to 90% reduction, and 13% had less than a 50% reduction with vagus nerve stimulation. When compared with the efficacy in adult patients, multiple studies have shown an equivalent or slightly higher response rate in children with about 45% to 55% of patients deriving a greater than 50% reduction in seizure frequency. Moreover, there is a suggestion that these patients also showed significant improvement in quality of life measures.[152–156] Although complete seizure control is possible with vagus nerve stimulation, the likelihood of complete control is low.[143]

# Suppurative Central Nervous System Infections

Suppurative infections of the CNS include intracranial infections such as brain abscess, subdural empyema, epidural abscess, osteomyelitis of the skull, Pott puffy tumor, and acute pyogenic meningitis,[157] as well as intraspinal infections such as SC abscess, spinal epidural abscess, diskitis, and vertebral osteomyelitis. Intracranial infections can be life threatening and must be considered in the differential diagnosis in children with fever, headache, and cranial wounds or sinus disease. Similarly, intraspinal infections can result in devastating neurologic impairment, especially if the diagnosis is delayed, and must be considered in the differential diagnosis in children with back pain, spinal tenderness, and fever. The remainder of this chapter discusses suppurative CNS infections.

## INTRACRANIAL INFECTIONS

Suppurative processes in the epidural and subdural spaces and brain parenchyma are classic neurosurgical complications of otorhinologic, middle ear, and post-traumatic infections, as well as immunosuppression, and they commonly manifest as neurosurgical emergencies.[158] An epidural abscess refers to suppuration in the epidural space between the dura and calvaria or skull base, a subdural empyema refers to suppuration in the subdural space between the dura and arachnoid, and a brain abscess refers to a circumscribed focus of suppurative tissue necrosis within the brain parenchyma.

### Incidence

The reported incidence of intracranial infections in children remains low. In busy pediatric neurosurgical centers, the incidence of an isolated epidural abscess is about one case per year and that of a subdural empyema is one to two cases per year.[159,160] The incidence of brain abscess is less than one to three cases per year.[158] Although intracranial infections are relatively uncommon in children, they can be rapidly fatal if not recognized promptly and managed appropriately. Successful treatment requires early diagnosis, guided by CT or MRI (or both), aggressive antibiotic therapy, and timely and adequate surgical intervention targeted to maximal areas of suppuration. Response to treatment must also be monitored neuroradiographically to ensure that the infection is resolving.

### Etiology

Intracranial infections occur as a consequence of (1) direct extension from contiguous infection, such as paranasal sinusitis, otitis media, or mastoiditis, or propagation through venous channels; (2) direct inoculation of the brain after penetrating cranial trauma or a neurosurgical procedure; and (3) hematogenous spread from a distant focus of infection. Contiguous infection in the paranasal sinuses, mastoid air cells, orbit, or skull is the most commonly reported cause of suppuration in the epidural space.[161] Epidural abscess can also occur as a complication of a congenital dermal sinus, trauma (especially penetrating wounds), craniotomy, application of skull pins or tongs, and paranasal sinus and skull base operative procedures.[162] Subdural empyema commonly occurs as a result of infection in the frontal and ethmoidal sinuses, middle ear, and mastoid air cells.[163,164] Other causes of subdural

empyema include spread from contiguous infections of the scalp, subgaleal space, calvaria, or epidural space (or any combination of these regions); meningitis; hematogenous infection of a preexisting subdural effusion or hematoma[165]; rupture of a parenchymal brain abscess into the subdural space; and subdural puncture or subdural shunt placement.

In the pediatric population, the most common cause of brain abscess is direct or indirect spread from infection in the paranasal sinuses, middle ear, and teeth.[166] In adolescent boys, frontal lobe abscess is a relatively common complication of acute frontal sinusitis.[158] In children with congenital heart defects or pulmonary right-to-left shunt disease, hematogenous spread from remote sources of infection such as pulmonary infections, cutaneous infections, osteomyelitis, and bacterial endocarditis remains an important pathogenic mechanism of brain abscess formation.[167] In neonates, bacterial meningitis caused by *Citrobacter, Proteus, Serratia,* or *Enterobacter* is complicated by the formation of brain abscesses in a high percentage of patients.[168] Moreover, direct inoculation of the brain after penetrating cranial trauma, penetrating wounds of the orbit, compound skull fractures, scalp wounds, facial sepsis, CSF fistula, and post-traumatic meningitis can lead to the development of brain abscesses in children. The location of the abscess is dependent on the portal of entry. For example, otogenic abscesses or those resulting from mastoiditis often develop in the temporal lobe or cerebellar hemisphere adjacent to the infected ear or mastoid air cells, paranasal sinusitis commonly gives rise to abscess formation in the frontal lobe, and brain abscesses arising from hematogenous spread tend to occur in the distribution of the middle cerebral artery.

Aerobic organisms commonly isolated from suppurative intracranial infections include *Staphylococcus, Streptococcus, Enterobacteriaceae,* and *Haemophilus.* Anaerobic organisms include *Bacteroides, Peptostreptococcus, Fusobacterium, Veillonella, Propionibacterium,* and *Actinomyces.* In many cases, culture of pus obtained from intracranial infections reveals multiple organisms including both anaerobic and aerobic organisms.[158] However, in some cases, no organisms are isolated despite proper handling of specimens. With regard to the causative organisms, the bacteriologic diagnosis often points to the source of the intracranial infection. For example, aerobic or anaerobic streptococci (or both) are often cultured from intracranial infections complicating paranasal sinus infection, gram-negative organisms such as *Bacteroides* and *Haemophilus* are cultured from intracranial infections complicating otogenic infections, and *S. aureus* is cultured from intracranial infections complicating compound skull fractures and neurosurgical procedures. Fungal organisms such as *Candida, Aspergillus, Nocardia,* and *Cryptococcus* commonly cause intracranial infections in children who are immunologically suppressed after organ transplantation or chemotherapy or who have impaired host defenses.[169]

## Pathogenesis

Spread of infection from the paranasal sinuses, mastoid air cells, or middle ear to the epidural and subdural spaces or to the brain parenchyma occurs as a consequence of infective thrombophlebitis of the diploic vessels or nutrient vessels that supply the outer layer of the dura.[158] Once infection enters the diploic space, it spreads rapidly through this space to involve widespread areas of the skull. Occasionally, a subperiosteal abscess (Pott puffy tumor) forms as a result of the osteomyelitis and leads to swelling of the overlying scalp (Fig. 128-9). Once the inflammatory process reaches the subdural space, it can spread rapidly throughout the subdural space because this space is in continuity over the surface of the brain, on each side of the falx and tentorium, and through the foramen magnum with the spinal subdural space. Direct exposure of the brain to subdural infection can lead to occlusion of cortical veins and septic thrombophlebitis. This, in turn, can cause

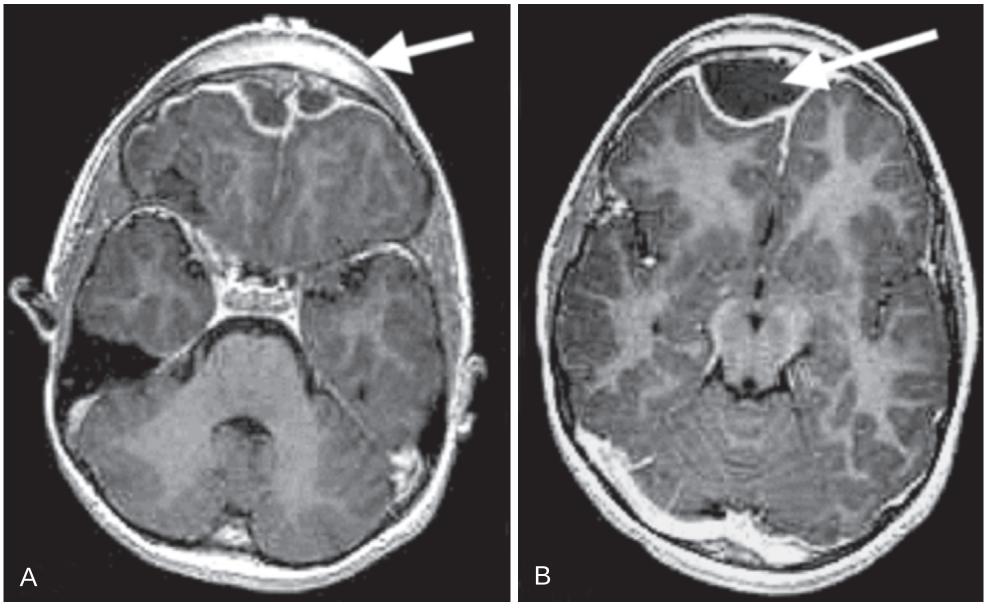

**FIGURE 128-9** **A** and **B,** Axial magnetic resonance images from a 5-year-old boy with a history of strep throat, treated with 2 weeks of oral antibiotics, followed by fever, malaise, headaches, progressive swelling in the midline of his forehead, vomiting, and lethargy. A frontal subperiosteal abscess (i.e., Pott puffy tumor; **A,** *arrow*) and an epidural abscess (**B,** *arrow*) are evident. He was managed by surgical evacuation and aggressive antibiotic therapy; the bone flap was left in place. The infection resolved completely with no neurologic sequelae.

cerebral infarction and edema, and the edema can produce significant mass effect and associated brain compression and herniation.

A brain abscess develops as a consequence of seeding of bacteria in areas of preexisting necrosis or direct traumatic injury, hemorrhage, or infarction from septic thrombophlebitis. Once a nidus of bacteria is established within the brain parenchyma, the organisms produce an acute inflammatory response that results in polymorphonuclear infiltration and edema. The central area eventually undergoes necrosis and liquefaction and becomes surrounded by a peripheral zone of inflammatory cells, neovascularization, and fibroblasts.[158] The fibroblasts, in turn, create a dense collagenous capsule that is surrounded by edema and reactive gliosis. An abscess with its surrounding edema can lead to significantly elevated ICP and cause brain herniation and death. Moreover, sudden deterioration and death can occur from rupture of a brain abscess into the ventricular system[167] or through the cerebral cortex into the subarachnoid space.[170]

### Clinical Features

Children with intracranial infection often have a history of cerebral trauma, purulent nasal or aural discharge, fever, or headache. If there is suppuration within the epidural space, the child typically appears acutely ill with fever, headache, or earache at the time of the initial evaluation. If the epidural abscess is associated with a subperiosteal abscess, patients also commonly have a tender, fluctuant swelling in the scalp overlying the involved frontal sinus, mastoid air cells, or affected area of the diploic space (see Fig. 128-9). As infection spreads within the epidural space, the mass effect on the subjacent dura and brain increases and causes escalating headaches. Eventually, focal neurologic signs and a decreased level of consciousness develop as the abscess increases in size and brain herniation occurs.[160]

With spread of infection into the subdural space, rapid neurologic deterioration occurs as a result of cerebral edema, infarction, and herniation. Patients typically have signs and symptoms of a systemic febrile illness and raised ICP including malaise, fever, chills, meningismus, vomiting, headache, focal neurologic deficits, and altered mental status.[161] In addition, children with subdural empyema can have localized tenderness and swelling overlying the affected sinus or mastoid secondary to subperiosteal abscess formation (Pott puffy tumor; see Fig. 128-9), and focal seizures may be observed in 25% to 50% of patients.[158] Depending on the underlying cause, suppuration within the subdural space may be supratentorial or infratentorial, or both (Fig. 128-10). With subdural empyema in the posterior fossa, children typically have a systemic febrile illness, headaches, and a stiff neck, but focal neurologic signs and seizures are generally lacking.[171]

The clinical manifestations of a brain abscess are influenced by the size and location of the abscess, as well as the number of abscesses present, the virulence of the organism or organisms, and the patient's age and host defenses.[158] Children and adolescents with a brain abscess exhibit signs and symptoms of (1) systemic infection including malaise, fever, chills, and neck stiffness; (2) raised ICP as a result of the mass effect from the abscess and surrounding cerebral edema including headache, vomiting, and a declining level of consciousness; and (3) focal neurologic deficits reflecting the location of the abscess such as hemiparesis with an abscess in the posterior frontal region or as a consequence of uncal herniation, speech difficulty with an abscess in the dominant temporal lobe, a visual field deficit with a posterior temporal or occipital lobe abscess, and nystagmus, defective conjugate eye movements, ataxia, and hypotonia with a cerebellar abscess.[158] Infants with a brain abscess have signs and symptoms of increased ICP including irritability, lethargy, vomiting, a bulging anterior fontanelle, frontal bossing, and increasing head circumference. At least 25% to 50% of pediatric patients with a supratentorial brain abscess also manifest focal or generalized seizures during the course of their disease.[172]

### Diagnostic Studies

If intracranial infection is suspected, the patient should undergo a contrast-enhanced head CT or brain MRI study (or both). A head CT scan with contrast enhancement enables rapid diagnosis, whereas MRI provides accurate preoperative localization and is beneficial for monitoring resolution of

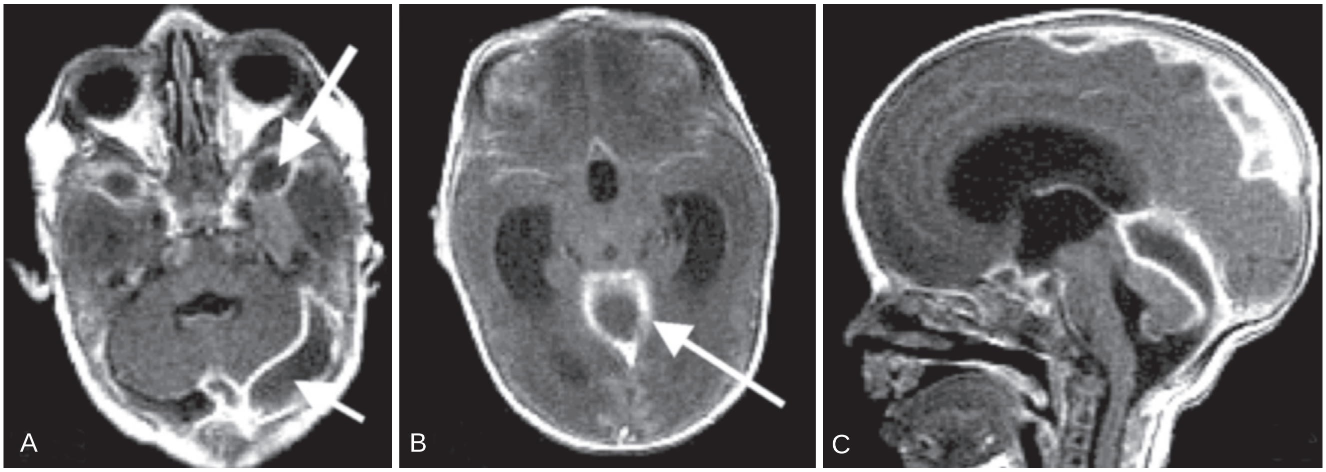

**FIGURE 128-10** Axial (**A** and **B**) and sagittal **(C)** brain magnetic resonance imaging (MRI) in a 35-week preterm male infant with a history of meningitis, organism unknown, who was on multiple antibiotics, but not metronidazole. He began having seizures and respiratory difficulty and required intubation. MRI showed extensive subdural empyema extending bilaterally, both above and below the tentorium (*arrows*). Cultures at the time of drainage grew *Bacteroides fragilis*. The infection eventually cleared with a prolonged course of antibiotics including metronidazole. He is now almost 4 years old, is no longer taking anticonvulsants, and has no neurologic sequelae.

infection. Depending on the type, extent, and stage of the intracranial infection, these studies may reveal dural enhancement, an empyema wall, an abscess capsule, and hypodense areas of cerebral edema, venous infarction, and early cerebritis. Sagittal and coronal views are also helpful for visualizing affected sinuses and suppurative collections at the vertex and skull base. In patients with a brain abscess, contrast-enhanced CT and MRI demonstrate a characteristic ring-enhancing lesion with surrounding edema. In particular, on MRI a brain abscess appears as an area of central hypointensity surrounded by a ring of enhancement after gadolinium administration on T1 weighting and as a hyperintense area of suppuration surrounded by a hypointense capsule and an outer layer of edema on T2 weighting.[173]

Laboratory studies helpful in the diagnosis of intracranial infection include a peripheral white blood cell count, erythrocyte sedimentation rate, and C-reactive protein, all of which may be mildly elevated.[172] Blood cultures may reveal the causative organism, especially in cases of epidural abscess and subdural empyema.[172] Because of the risk of herniation and the low diagnostic yield of CSF studies, a lumbar puncture should not be performed before neuroimaging, especially if a mass-occupying lesion is suspected. Identification of the causative organism(s) is accomplished by culturing purulent material obtained at the time of surgical drainage.[158] Such cultures determine the antibiotic sensitivity of the causative organism(s), which in turn guides antimicrobial therapy. Proper handling of specimens and appropriate aerobic and anaerobic culture techniques are required to achieve positive culture results.

## Treatment

A high index of suspicion is essential to ensure prompt diagnosis. Successful treatment requires surgical drainage, appropriate antimicrobial therapy, and close coordination of care between pediatric neurosurgeons and infectious disease specialists. Systemic antibiotics should be initiated as soon as the diagnosis is considered.[158] Although preoperative antibiotics may achieve some bone penetration, it is unlikely that they will interfere with culture results.

The initial choice of antibiotics is contingent on the microbial spectrum, which varies according to the primary site of infection.[158] Hence knowledge of the primary infection site can be used to guide antimicrobial therapy. For example, if frontal sinusitis is the primary site, the most likely infective agent is a streptococcal species and antibiotic coverage should include metronidazole and penicillin or a third-generation cephalosporin. If the primary site is unknown, the initial choice of antibiotics should include a penicillinase-resistant synthetic penicillin, a third-generation cephalosporin, and metronidazole to provide coverage of aerobic and anaerobic streptococci, other anaerobes, and staphylococci. Although the optimal duration of therapy remains unknown, intravenous antibiotics should be continued until systemic evidence of the infection has resolved and the intracranial infection appears to be diminishing in size.[160,163] An additional 2 to 3 months of oral antibiotics is recommended by some to prevent recurrence.[174]

Besides systemic antibiotics, children with intracranial infections may also require treatment with corticosteroids and anticonvulsants. Corticosteroids such as dexamethasone are effective in reducing the cerebral edema associated with intracranial infection and have not been shown to exacerbate the inflammatory response. Consequently, corticosteroids can be administered during the acute phase of the illness to reduce intracranial hypertension and prevent herniation. Because 25% to 50% of pediatric patients with intracranial infections exhibit seizures during the course of their illness, prophylactic anticonvulsants should also be started as soon as the diagnosis is made.

Besides enabling bacteriologic diagnosis and guiding antimicrobial therapy, surgical treatment permits evacuation of sizable collections of liquefied pus and reduces ICP.[158] If the primary site of infection is known and the patient's clinical condition permits, surgical intervention should also address the primary infection source. Surgical drainage of intracranial pus can be performed through a limited craniotomy, craniectomy, or burr hole. The bone removed should be just large enough to provide access to the abscess or empyema. If an epidural abscess occurs in the face of a previously devascularized bone flap, the devitalized bone is frequently left out and a delayed cranioplasty performed. However, if epidural infection complicates an extensive craniofacial reconstruction in which bone removal would probably generate irreparable defects, the bone is replaced after extensive irrigation of the epidural space with antibiotic solution and debridement, and systemic antibiotics are administered until the infection clears.[158] Follow-up neuroimaging studies are performed on all patients to monitor the progress of treatment.

For a subdural empyema, the subdural space is exposed by craniotomy, craniectomy, or a burr hole, often using stereotactic CT or MRI guidance to accurately localize the purulent fluid collection and keep the bone removal and dural opening to a minimum. Once the dura is opened, specimens are obtained for aerobic and anaerobic culture, the empyema is evacuated, and the subdural space is irrigated thoroughly with antibiotic solution. If a craniotomy has been performed and neither osteomyelitis nor epidural abscess is observed, the bone flap may be replaced. However, healing of the bone flap should be monitored closely because failure of healing can occur and result in reabsorption or sequestration of the bone flap.[175] Repeated drainage may also be necessary if the subdural empyema recurs. Infants in whom subdural fluid collections develop as a complication of *Haemophilus influenzae* meningitis typically do not require surgical intervention unless the fluid collection causes a mass effect and the patient becomes symptomatic from elevated ICP. If surgery is warranted, needle drainage through the lateral aspect of the anterior fontanelle or through a burr hole can be performed to remove the subdural fluid, which is typically sterile.[158]

Conservative management of brain abscesses with intravenous antibiotics, with or without neurosurgical intervention, has been reported. However, antibiotic treatment alone must be accompanied by frequent neuroradiographic follow-up to determine the effectiveness of the treatment. Careful monitoring of the patient's neurologic findings and level of consciousness is also essential. Immediate neurosurgical intervention is required if (1) the patient demonstrates any evidence of neurologic decline, (2) the abscess shows significant mass effect on CT or MRI, or (3) the abscess fails to respond to antibiotics within 2 weeks of the initiation of treatment.

Two surgical options are available to treat brain abscesses including needle aspiration, with or without catheter drainage, and excision. Ultrasound guidance or guidance with frameless or framed stereotaxy can be used to accurately localize an abscess and place a drainage needle or catheter within the abscess cavity. Ultrasound can also be used to visualize

decompression of the abscess cavity as the pus is aspirated. After gentle aspiration with a syringe and irrigation with normal saline, a catheter may be left in the abscess cavity for several days until drainage of purulent fluid ceases. If aspiration fails, as frequently occurs in the case of multiloculated abscesses, surgical excision may be required. To accomplish this, a limited craniotomy bone flap is turned, the dura is opened, a small corticectomy is generated in the closest noneloquent parenchymal area, and the abscess is excised en bloc while leaving the surrounding white matter intact. The craniotomy is closed in the usual fashion after thorough irrigation with saline, and the patient is treated with long-term antibiotics.

### Outcome

Outcome is determined by the rapidity of the diagnosis and initiation of treatment. Moreover, the prognosis for survival and neurologic recovery is contingent on the patient's level of consciousness at the time of diagnosis and institution of treatment. Consequently, early diagnosis and prompt aggressive therapy, with appropriate systemic antibiotics and surgical removal of suppurative collections, are paramount to minimizing the morbidity and mortality associated with suppurative intracranial infections. In support of this, the mortality associated with a brain abscess in older series approached 32% but has decreased to 10% in recent years as a consequence of more rapid diagnosis and treatment with appropriate antibiotics.[158] In contrast, the mortality rates associated with intraventricular rupture of a brain abscess remain high, ranging from 23.8% to 80%.[167,170] Long-term neurologic deficits occur in about 44% of patients who survive surgical treatment of brain abscess.[176] Moreover, children who survive are commonly left with learning disabilities[168] and seizures.[174]

## INTRASPINAL INFECTIONS

Spinal epidural abscess in children is a rare clinical entity[177] that often escapes diagnosis until significant neurologic deficits develop.[178] It is a rapidly progressive, compressive lesion of the SC that often requires rapid decompression to prevent permanent paraplegia. Hematogenous spread of bacteria from cutaneous or mucosal sources of infection such as furuncles, pharyngitis, and dental abscesses is the most commonly reported cause of spinal epidural abscess.[177,179,180] Other potential causes include direct extension from vertebral osteomyelitis, a paraspinal abscess, or a septic focus in the pelvis, retroperitoneum, or posterior mediastinum. Such extension can occur by way of veins passing through the intervertebral foramina or bacterial seeding of an epidural hematoma that forms as a result of blunt trauma.[177] The most common pathogen of a spinal epidural abscess in children is *S. aureus,* although anaerobic and gram-negative bacteria have also been isolated.

Spinal epidural abscesses occur posterior to the SC in about 80% of cases. Posteriorly, the dura is adherent to the posterior longitudinal ligament from C1 to S2. Consequently, pus that accumulates posterior or posterolateral to the dura can spread extensively rostrocaudally but is restricted dorsally by the laminae and ligamenta flava. Although epidural infection can occur anywhere along the spinal axis, lower thoracic and lumbar abscesses are most commonly reported in the literature.[180] Once infection is established in the epidural space, pus collects deep to the laminae and ligamenta flava and is surrounded by thrombosed veins and granulation tissue. The dura provides a formidable barrier to infection. Consequently, meningitis is uncommon unless a spinal tap is performed. However, the SC is defenseless against compression and may be injured as a result of vascular compromise from arterial or venous thrombosis.[180]

Children with spinal epidural abscess may have fever and malaise, and they typically complain of deep-seated back pain, spinal tenderness, or radicular pain. The back pain is usually midthoracic and radiates around the chest wall. The pain is constant and can be exacerbated by coughing or movement. Patients often exhibit nuchal rigidity and exquisite tenderness to percussion over the involved spinal segments. A primary source of infection may be evident. Symptomatic SC compression is manifested by rapidly progressive weakness and sensory loss in the legs and evidence of bladder or bowel dysfunction, or both.

If a child is suspected of having a spinal epidural abscess, a peripheral white blood cell count, erythrocyte sedimentation rate, and C-reactive protein level are obtained and are usually elevated. Moreover, blood cultures are performed because they may reveal the offending organism. A total spine MRI with and without gadolinium enhancement enables visualization of the extent and location of a spinal epidural abscess and is the diagnostic procedure of choice. A spinal tap should not be performed. If a myelogram must be performed as part of the diagnostic workup (e.g., if MRI is not available), the spinal puncture site should be placed as far away from the suspected position of the abscess as possible.

After the diagnosis of spinal epidural abscess is made, treatment must commence immediately to prevent long-term neurologic disability. Aggressive antimicrobial therapy is initiated with intravenous antibiotics that have good coverage against staphylococci, anaerobes, and gram-negative organisms. Parenteral antibiotics are continued for at least 4 to 8 weeks. Although there are a few reports in the literature of neurologically intact children being treated successfully with antibiotics alone,[179] in the majority of cases, successful treatment requires appropriate antibiotic therapy and emergency evacuation of the abscess with decompression of the SC and nerve roots, especially if the abscess is widespread. This is typically performed by means of a posterior decompressive laminectomy with drainage of the purulent material. A one- or two-level laminectomy at one or both ends of the abscess with catheter irrigation and drainage is usually sufficient. If a multilevel laminectomy is required for surgical decompression, the child must be monitored carefully postoperatively for kyphosis and spinal instability, which can occur as a complication of multiple-level laminectomies in children.[179]

The prognosis is related to the patient's preoperative neurologic condition.[181] If the infection is recognized early and the patient receives appropriate treatment, recovery is expected to be excellent. If mild motor weakness has been present for less than 36 hours, a good outcome is also possible.[182] However, once a child develops paraplegia, recovery is highly unlikely. Thus early diagnosis and appropriate treatment are paramount to achieving a good outcome in children with a spinal epidural abscess. Mortality from spinal epidural abscess, which is unquestionably related to a delay in instituting appropriate therapy, has remained stable over the past several decades at about 14%.[182]

CHAPTER 129

# Major Congenital Orthopedic Deformities

Kosmas Kayes and William Didelot

## Developmental Dysplasia of the Hip

### TERMINOLOGY/INCIDENCE/ETIOLOGY

*Developmental dysplasia of the hip* (DDH) is a term used to describe a wide spectrum of pathology related to the hip joint. All cases involve some type of incongruity between the femoral head and acetabulum. This can vary from minimal acetabular dysplasia, in which the acetabulum has not developed fully (with a femoral head that may be normal in position or slightly subluxated), to complete dislocation of the femoral head, in which there is no contact with the acetabulum. Different findings will be present at different ages of the individual. In a newborn the changes vary from an unstable hip that is fully reduced within the acetabulum but can be gently subluxated or fully dislocated to a hip that is subluxated partially out of the acetabulum and may or may not dislocate to a hip that is dislocated completely and may be reducible or not.[1,2] Another variation of dislocation, called a *teratologic hip dislocation,* usually occurs with some type of neuromuscular problem such as myelomeningocele, arthrogryposis, or other type of syndrome. This type of dislocation is a rigid, fixed dislocation that occurs prenatally and will not respond to nonoperative methods of treatment as the more common types of hip dislocation usually will. Most cases of hip dysplasia are evident at birth by physical examination or ultrasound, but, rarely, instability may not develop until later in the first year of life and may have different findings. Still other types will not be identifiable until adolescence, when they are often manifested as pain without other physical examination findings. A change in terminology has occurred in the past 15 years from “congenital dislocation” to “developmental dysplasia” of the hip. This change reflects more accurate information about the less apparent types of dysplasia not identifiable at birth and the variations that are not always complete dislocations of the joint but rather abnormal development or “dysplasia.”[3,4]

Hip dysplasia is the most common hip disorder in children. One in 1000 newborns has a dislocated hip, and 10 in 1000 will have some form of subluxation or dysplasia. The majority of hips will tighten up on their own, usually within the first 2 weeks of life. Approximately 4 in 10,000 will eventually have problems of dislocation, subluxation, or acetabular dysplasia. Females have a higher incidence than males by a ratio of 4:1, which is thought to be due to sensitivity to the relaxin hormone produced by the mother during pregnancy; relaxin causes transient ligamentous laxity in females and not in males (because males are not sensitive to the hormone). The left hip is affected 60% of the time, probably because of pressure on the hip from the mother’s sacrum because most birth presentations are left occiput anterior.

The cause of hip dysplasia is multifactorial. Genetics, physiologic factors, and mechanical factors such as prenatal and postnatal positioning all play a role. Genetics is a factor because babies with a positive family history have a higher incidence of DDH, as do siblings and twins. Mechanical factors are also involved because any form of intrauterine crowding or abnormal positioning such as a first pregnancy, breech presentation, oligohydramnios, or multiple births puts the infant at higher risk. This is also true postnatally because cultures such as Native Americans that swaddle, strap, or papoose their babies have a higher incidence of DDH as well.[2,5–8]

### DIAGNOSIS

#### History and Screening

Early detection of DDH is crucial; the sooner treatment is initiated, the better the expected outcome. Classically, the pertinent history of the newborn consists of whether the newborn is the first child, the presentation in utero (breech), whether there is a family history of DDH, the presence of any associated orthopedic or genitourinary abnormalities, multiple births, and the presence of oligohydramnios. However, more evidence is showing that previous risk factors may no longer be completely accurate and the important risk factors are first born, family history, and oligohydramnios. Some studies show that breech position may not be a significant risk factor and that risk factors are different for early and late diagnosis.[9–11]

Most cases are detected early as a result of the screening protocol for pediatricians developed by the American Academy of Pediatrics; the protocol consists of serial physical examinations at birth, at 2 weeks, and then at every well-baby

follow-up visit at 1, 2, 4, 6, 9, and 12 months of age. New evidence suggests that risk factors alone are not enough to warrant ultrasound screening, so only a child with an abnormal physical examination should be imaged by ultrasound. Physical examination remains the gold standard for screening newborns, and ultrasound can be used after 4 weeks of life. Many hips are over-read on ultrasound as positive findings of dysplasia before 4 weeks in children who will otherwise spontaneously resolve their instability. Also, the accuracy of ultrasound is still operator dependent and variable.[12] A child at risk should have either an ultrasound before 4 months or radiographs of the hip taken after 4 months of age. Screening of the entire newborn population has not been necessary, although some cases of hip dislocation and dysplasia are not detected until later in life.[13–19] There is some thought that screening may even potentially cause harm because well over 90% of newborn hip instability will resolve spontaneously and many children may be overtreated. One meta-analysis showed that there was no clear evidence for or against ultrasound screening in DDH.[20–22]

## Physical Examination

Findings on physical examination vary with the age of the child. From birth to about 3 months of age, the most reliable findings are a positive Barlow or Ortolani maneuver. In the Barlow test the hip is held flexed 90 degrees with neutral adduction, and the knee is flexed 90 degrees. The first web space and the palm of the hand should cradle the knee and be outside the thigh with the long finger down the length of the thigh. The hand should gently push the thigh posteriorly while adducting the hip in an attempt to dislocate a reduced hip out the back of the socket. The Ortolani maneuver is the same, but instead of pushing posteriorly, the thigh is abducted with pressure on the femur toward the middle of the socket while pulling it up anteriorly and trying to reduce a dislocated hip. Symmetric abduction is also important during the evaluation. Any asymmetry of abduction on examination should be evaluated further. Asymmetric skinfolds have been shown to be a less reliable measure of hip dysplasia.

After 3 to 4 months of age, the hip is usually dislocated and no longer reducible. It may occasionally be reduced but is subluxable. The Barlow and Ortolani maneuvers will no longer be useful. Asymmetric abduction is the best indicator, as is leg-length inequality, or the Galeazzi sign, which is positive when both hips and both knees are flexed to 90 degrees and one knee is higher than the other, giving an apparent limb-length inequality. More accurately, the dislocated hip is more posterior in position, thus making it look like the leg is shorter. At walking age the most obvious findings are apparent leg-length inequality with pelvic obliquity and increased lumbar lordosis. The child will have a Trendelenburg gait from shortened (weak) abductors and hip flexion contracture. If the dislocation is bilateral, the child will have increased lumbar lordosis.

## Imaging

Ultrasound and plain radiographs are both useful tools for assessment of hip dysplasia, but their timing is different. Ultrasound is highly dependent on the technician performing the scan and the radiologist interpreting it. General screening of all newborns is not recommended in the United States. Ultrasound can assess the amount of subluxation by identifying the position of the cartilaginous femoral head, as well as evaluating acetabular development by measuring the alpha angle of the posterior wall in relation to the ilium (Fig. 129-1). It can also provide visualization of the labrum, capsule, iliopsoas, and femoral head ossific nucleus. An alpha angle greater than 60 degrees is considered normal.

Plain radiographs of the hip are not reliable before 3 to 4 months of age when the nucleus of the acetabulum is starting to ossify and becomes apparent radiographically. After this age, it is the standard means of diagnosis and the best way to monitor progression of a dysplastic hip.[23] An anteroposterior (AP) view and a “frog-leg” view are both required when ordering any hip radiographs on a child (referred to as “AP and frog pelvis”). Several important parameters should be measured on the AP film (Fig. 129-2). The Shenton line is the continuation of a semicircle drawn on the superior portion of the

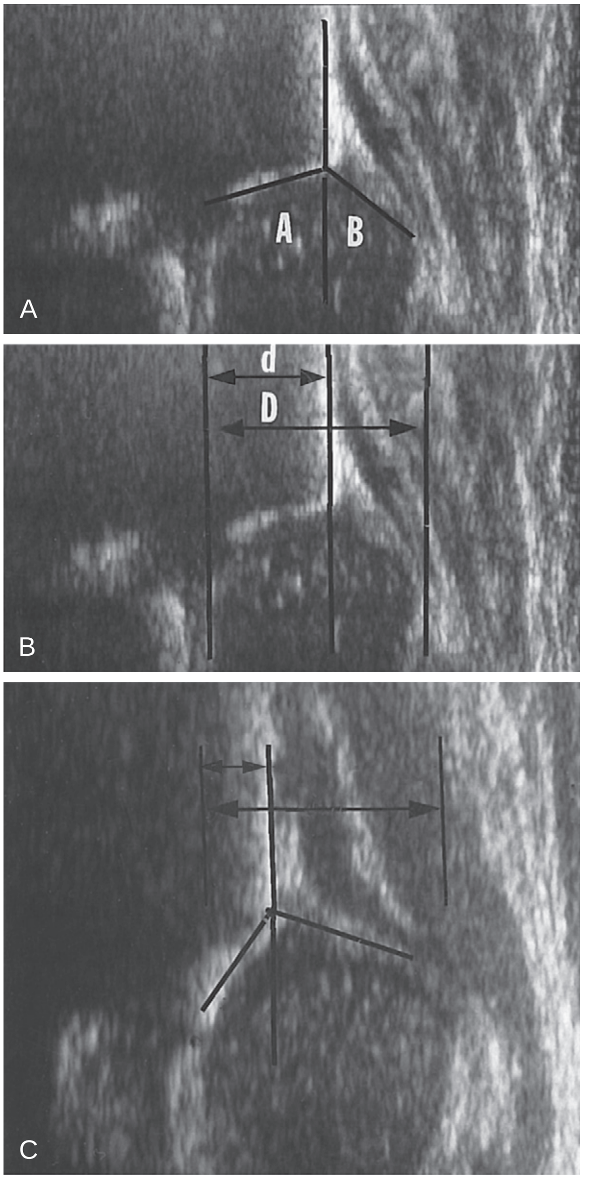

**FIGURE 129-1** **A,** Standard coronal plane ultrasonogram of a normal infant’s hip. The alpha angle *(A)* corresponds to the bony acetabular roof (normal, >60 degrees). The beta angle *(B)* represents the cartilaginous roof (normal, <50 degrees). **B,** Method for determining percent coverage of the femoral head: d/D × 100 (normal, ≥ 50%). **C,** Coronal plane ultrasonogram of a dysplastic hip. The alpha angle was 40 degrees; the femoral head was subluxated with only 25% coverage.

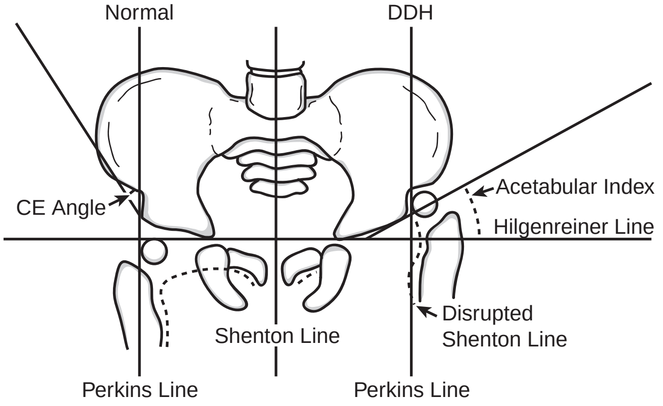

**FIGURE 129-2** Diagram of radiographic measurements. CE, center edge angle; DDH, developmental dysplasia of the hip.

obturator foramen and should be at the same level as the femoral neck. If the line is disrupted, the femur is too superior in the acetabulum. The Hilgenreiner line is a horizontal line drawn through the level of the triradiate cartilage on each side. A perpendicular line is then drawn at the lateral edge of the acetabulum and intersects the Hilgenreiner line to form four quadrants around the hip. The medial metaphyseal beak of the femur should be in the inferior/medial quadrant, or it is not in a reduced position. The acetabular index is the angle formed by the Hilgenreiner line and a line drawn from the triradiate cartilage to the lateral edge of the acetabulum. This angle should be less than 25 degrees by 1 year of age to indicate normal acetabular development. The higher the acetabular index is, the more dysplastic (more vertical) the acetabulum. This measurement has been shown to correlate with future hip osteoarthritis.

The most definitive way to assess a dysplastic hip is by injection of contrast material into the hip joint (hip arthrography); because this requires general anesthesia, it is usually performed at the time of operative reduction. Contrast outlines the cartilaginous femoral head and shows the exact relationship to the acetabulum. It can also show the position of the labrum and ligamentum teres and whether there is a pooling of dye in the medial joint space, which is indicative of laxity of the hip and a less than ideal reduction. Although ultrasound is helpful in assessing the position of the hip, arthrography can be performed if there is any question regarding stability and position of the hip. It is also extremely useful in assessing a closed reduction and in preoperative planning for any reconstructive surgery. Computed tomography (CT) is useful postoperatively to check the position of the hip in the cast after closed or open reduction with immediate casting. CTwith 3-D reconstructions can also be used preoperatively to assess the acetabulum. Magnetic resonance imaging (MRI) has had limited use in DDH, but recent studies show that it may be as useful as CT in postoperative assessment and without the radiation exposure.

## ANATOMY/PATHOANATOMY

Hip development starts with the femoral head and acetabulum being formed as a block of cartilaginous cells. At 7 to 8 weeks a cleft develops between the head and acetabulum and forms the joint. So the hip starts "reduced" in the socket, and other factors, previously discussed, contribute to the later instability.

The hip joint is completely developed by 11 weeks of gestation. The femoral head remains totally cartilaginous until 4 months of age, when the ossific nucleus starts to form bone. The hip is dependent on the femoral head and acetabulum, maintaining concentric reduction for continued normal development until growth ceases. A socket without a reduced femoral head will not form normally. If the hip stabilizes early, the joint will most likely remodel any dysplasia and form a normal joint. The longer the femoral head is not concentrically reduced, the less chance of the hip having normal anatomy at maturity. The acetabulum undergoes the most remodeling and development in the first year of life, but some remodeling continues until year 4 or 5, after which time there is minimal remodeling potential.

The anatomic structures involved in hip dysplasia (Table 129-1) contribute differently in each case. The adductor muscle becomes contracted. The iliopsoas muscle can be a major block to reduction of a completely dislocated hip. It becomes contracted and can exert a powerful obstacle to reduction by forming an hourglass-shaped constriction of the anterior medial capsule. The ligamentum teres connecting the fovea of the femoral head to deep inside the acetabulum can hypertrophy and pose a block to a good concentric reduction as well. The pulvinar is an accumulation of fat and fibrous tissue in the space next to the medial wall of the acetabulum, which can keep the femoral head lateralized during a reduction attempt. The labrum or cartilaginous rim of the acetabulum can become infolded and blunted and also block the femoral head. The anterior-medial joint capsule can become constricted. The transverse acetabular ligament spanning the inferior portion of the hip between the medial and posterior walls can also limit reduction inferiorly. All these problems may become more marked as the child gets older and pose more difficulty in achieving an adequate reduction.

## TREATMENT

There are two goals of treatment. The first is to reduce the hip and allow it to stabilize within the acetabulum. The second goal is to ensure remodeling of any acetabular dysplasia. If the first goal is met at a young age and concentric reduction is achieved, the acetabulum will be able to remodel with further growth. Because the remodeling potential of the acetabulum is greatest in the first year of life, it is important to begin treatment as soon as possible. Treatment protocols depend on the age of the child and the amount of dysplasia of the hip joint. Table 129-2 lists all possible methods to help achieve reduction and stability. Treatment is discussed as it relates to the age of the child. Some of the methods are useful only in certain age groups, whereas others span the entire age range.

**TABLE 129-1**

## 0 to 6 Months

If a positive examination is recorded at birth (positive Barlow or Ortolani maneuver), immediate orthopedic referral is recommended. Evidence suggests that most hips will tighten up and stabilize within the first 2 weeks of life; therefore initiation of treatment before 2 weeks is controversial, and even how and when to screen is uncertain. Either way, close follow-up is mandatory. A Pavlik harness is the gold standard of treatment at this age and can often be used in children up to 6 months of age or less than 20 lb/9 kg (Fig. 129-3). When the hip is still dislocatable or reducible, the harness is the best choice. It is an active method of treatment that allows the baby to still have motion while encouraging the hip to remain in a position of stability. The harness maintains a hip flexion of 90 to 100 degrees (but should not be tightened any more than at 90 degrees to avoid hyperflexion) and abduction to keep the hip reduced in the most stable position. It is worn 24 hours a day, and correct placement and adjustments are crucial to help lower the incidence of complications. The harness can cause avascular necrosis (AVN; discussed later), which is thought to be due to hyperflexion of the hip or overtightening of the abduction straps. Once treatment is initiated, the harness should be checked 1 week later to ensure proper fit and use by the family. The length of treatment is generally twice as many weeks as the child's age at diagnosis, with some authors recommending a minimum of 3 months' treatment regardless of age at initiation of treatment. It can be weaned when the examination and imaging studies have normalized. It is effective in 90% or more children with Barlow-positive hips (reduced but dislocatable).[24–26] If the hip is Ortolani positive (dislocated but reducible), the harness may not be effective and should be discontinued after 3 weeks of treatment.

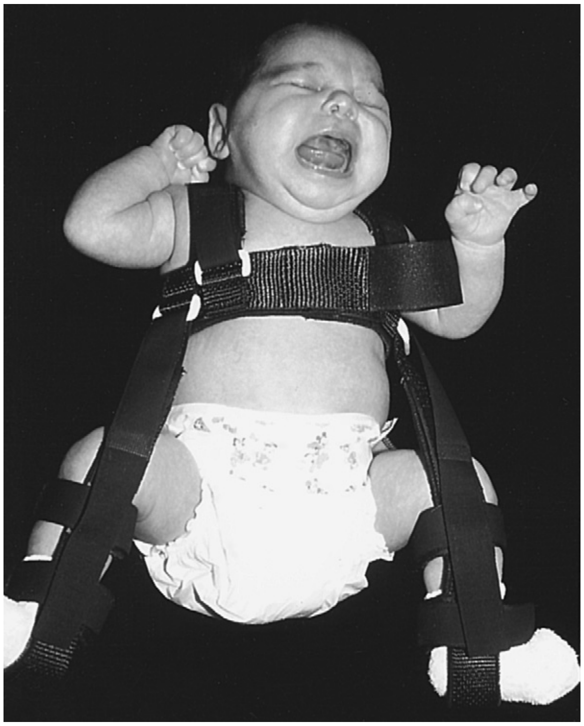

FIGURE 129-3 Infant being treated with a Pavlik harness. Hip flexion of approximately 100 degrees is maintained by anterior straps. Posterior straps (not seen) limit hip adduction.

Closed reduction may also be necessary in this age group if the hip will not easily reduce with gentle manipulation or does not respond to treatment in the Pavlik harness within 2 weeks. Arthrography is usually performed under general anesthesia, and the stability of the hip is checked. The child can then be placed in a hip spica cast if certain criteria are met during arthrography. The hip must be stable within the safe zone of 30 to 60 degrees of abduction and 90 degrees of hip flexion. If excessive abduction is required for stability, open reduction should be performed. The hip is at risk for AVN if extreme abduction is necessary to keep the hip reduced in the cast. There must also be only minimal (<3 to 5 mm) pooling of contrast in the medial aspect of the joint or the closed reduction will be less successful. Prereduction traction is controversial, with studies both supporting and refuting its use in reducing the incidence of AVN.[26–28]

After closed reduction, the child is placed in a hip spica cast in the human position for 6 to 8 weeks. A CT (or MRI) scan is usually checked postoperatively to ensure successful reduction. Another arthrogram is often obtained at the 6- to 8-week mark to assess progress of the hip. Casting may last 6 to 12 weeks, and then abduction bracing is used all day or nighttime only to encourage remodeling of the acetabulum. Some authors recommend some type of abduction bracing until radiographs have normalized.[29]

## 6 to 12 Months

As the child gets older, if the hip has not been reduced (Fig. 129-4), the compensatory changes become more severe and more invasive treatment is often necessary to overcome

FIGURE 129-4 Right hip dislocation. Left hip is normal.

the blocks to reduction. At this age a Pavlik harness is not indicated. Closed reduction is still the preferred method if a gentle, concentric, stable reduction can be obtained. If too aggressive abduction or pressure is necessary to keep the hip reduced easily in the cast, the chance of complications, mainly AVN, increases. At this point surgical open reduction should be considered. Some authors think that unless a closed reduction gives nearly perfect concentricity and is stable, care should proceed immediately to open reduction, which they believe is safer than a forced, incongruous closed reduction. This view may be changing somewhat as closed reduction is becoming more widely used. The goal of open reduction is the same as that of closed reduction, to achieve concentric stable reduction of the femoral head in the acetabulum. During open reduction, as many of the blocks to reduction as possible are corrected.

If the femoral head is superior to the acetabulum on radiographs and the soft tissue is significantly contracted, a femoral shortening osteotomy may be helpful to achieve a more stable reduction with less pressure on the femoral head. It helps decrease the possibility of AVN and improves the stability of the hip. If excessive coxa valga or femoral anteversion is present, the osteotomy can be readily modified to correct these deformities as well. The incision is made at the subtrochanteric level, and the bone is then fixed with a plate and screws to hold the alignment while bony union is achieved. Femoral shortening is almost always necessary in an older child of walking age.

### Walking Age, Older Than 12 Months

Once children have been bearing weight on the hip, adaptive changes occur and closed reduction becomes less successful. Closed reduction may be useful up to 18 months of age or more, but a larger percentage of these older hips will require open reduction and many will need femoral shortening osteotomy (Fig. 129-5).[30,31] The remodeling potential of the acetabulum decreases as the child gets older, and some children may need to undergo pelvic osteotomy to help gain coverage of the femoral head and provide a more stable reduction (see Fig. 129-5). A pelvic osteotomy can be performed in several ways, with most aimed at redirecting the socket to provide more anterior and lateral coverage of the femoral head. If more coverage is obtained and better congruency of the hip is achieved, there is more potential for the hip to form a more normal joint with time.[32,33] Evidence suggests that remodeling will occur until 2 years after surgery; then if it is not adequate, a secondary procedure may be necessary.

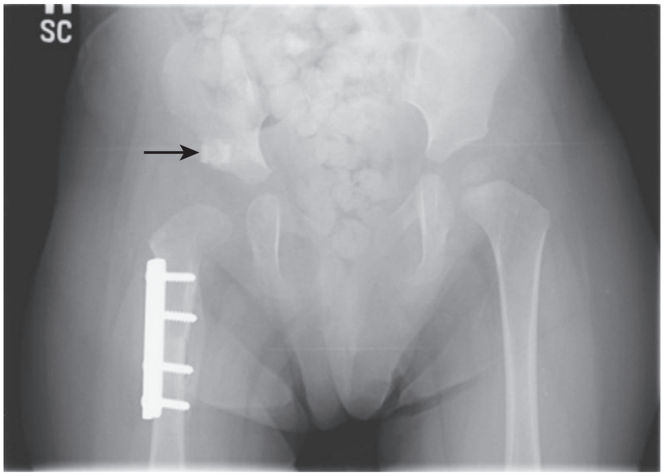

FIGURE 129-5 Femoral osteotomy fixed with plate and screws. Pelvic osteotomy *(arrow)*.

Some cases of hip dysplasia will go undetected until later in life. After 4 years of age, the risks of reducing a hip surgically increase. Some authors recommend attempting reduction up to the age of 8 years. If both hips are dislocated in older children, one must consider leaving them dislocated because they may do well for a long time before osteoarthritis develops. Other variations of DDH will be manifested in the early to late teens as hip pain, and acetabular dysplasia will be detected on radiographs. These hips are not dislocated, but the acetabulum is deficient in coverage of the femoral head and the femoral head may be subluxated to varying degrees. These children will benefit from redirectional acetabuloplasty of some type to provide a more congruous joint and better coverage. This is done in the hope of delaying further arthritic changes in the hip. Evidence supports the natural history of DDH in that any residual dysplasia of the joint will lead to osteoarthritis, which will eventually require total hip replacement. All treatment of DDH is directed at delaying this process for as long as possible.[29,32,33,34]

## COMPLICATIONS

### Avascular Necrosis

AVN of the femoral head can occur in up to 60% of treated hips if the long-term results are looked at critically. All forms of treatment put the blood supply at risk. The exact cause is unknown but is suspected to be a pressure phenomenon on the femoral head during closed reduction and injury to the medial circumflex vessels surgically. In younger children the cartilaginous femoral head is thought to be protective, and younger kids with AVN have a good chance of healing and doing well. AVN can cause growth arrest of the physis as well and give rise to shorter femoral necks or varus or valgus position of the neck at maturity. The final outcome, however, is unpredictable at any age.[34]

### Recurrent Dislocation

Some hips will not stabilize with conventional treatment whether it is the Pavlik harness or surgical intervention. Even after open reduction and bony procedures, the hip may again subluxate over time or even dislocate again. This will necessitate another surgical procedure, which increases the risk for AVN even more and also bodes for a poorer result in the long term.[34,35]

# Congenital Abnormalities of the Feet

## METATARSUS ADDUCTUS

### Terminology/Incidence/Etiology

Metatarsus adductus is a deformity in which an adducted forefoot gives the medial border of the foot a concave appearance and the lateral border looks convex (Fig. 129-6). The hindfoot is normal and has normal range of motion. It occurs in about 1 in 1000 births and has no gender predisposition.[36] The most

**FIGURE 129-6** Metatarsus adductus.

likely cause is intrauterine positioning. Although there was evidence of a positive association with hip dysplasia, this is no longer thought to be true.

### Diagnosis/imaging

The deformity is best identified with the child prone, and on examination the lateral border of the foot will deviate inward and look convex. Its severity is measured by a line called the *heel bisector,* which passes through the heel and is drawn out to the toes. Normally, this line bisects the second and third toe. In mild metatarsus adductus it bisects the third toe, and in severe forms it will bisect the fourth or fifth. The rest of the foot is normal. The hindfoot is normal, and there is normal ankle dorsiflexion. The abductor hallucis muscles may be overactive and pull the big toe into adduction as well (atavistic great toe). Radiographs may be obtained to assess the foot structurally but are not necessary unless there are other concerns.

### Treatment

The natural history is that most feet with metatarsus adductus will correct spontaneously if they are supple and correctable past neutral.[37] If the deformity is more severe and left untreated, it may cause problems with shoe wear later from a prominent base of the fifth metatarsal and medial deviation of the foot. It can also be a source of in-toeing in a child. Most deformities resolve without any treatment or with the parents manipulating the feet. If the deformity persists or the feet are stiff and not passively correctable, stretching casts may fix the deformity. If the problem persists past 5 years of age, consideration may be given to surgery. Correction at a young age by joint release may leave the foot stiff. In the past, metatarsal osteotomies were performed for correction and are still used at times. Waiting until after 5 years of age and then performing opening wedge cuneiform and closing wedge cuboid osteotomies is more reliable.[38–40]

## FLEXIBLE FLATFOOT

### Terminology/Incidence/Etiology

A flatfoot deformity occurs when the medial longitudinal arch is absent. This finding is common in younger children, especially when they first begin walking. Many of these children have ligamentous laxity that contributes to the arch being depressed because the ligaments that support the arch are also lax and unable to support the foot in the weight-bearing position. The posterior tibial tendon may be incompetent and contribute to the deformity.

### Diagnosis/Imaging

Diagnosis is by clinical examination. The medial arch is absent in the weight-bearing position and gives it the “flat-foot” appearance. The foot is flexible, and an arch will be reestablished when the foot is hanging free or the patient stands on tiptoes. As the patient goes up on toes, the heel will normally rotate into varus and the arch will become apparent. Radiographs will show a plantar-flexed talus that is not lined up with the first metatarsal on the lateral projection; however, radiographs are normally unnecessary unless other foot pathology is suspected.

### Treatment

No treatment is necessary if the foot is flexible. The parents need to be reassured that it does not need to be treated and an orthotic device will not help develop an arch—it will only support the arch. Many patients will tighten up over time as the ligamentous laxity improves and reestablish a medial arch as they get older. Arthroereisis or stabilization of the subtalar joint by an implant of some type (usually a Silastic or metal screw or staple) may be considered if the patient is symptomatic. An opening wedge osteotomy of the calcaneus or cuboid can be considered as well.[41–43] Fusion of the subtalar joint is reserved for patients with the most severe cases who continue to have pain despite other treatment options.

If the foot is not flexible and the arch does not reconstitute when the patient goes up on tiptoes (Root sign), it is considered a rigid flatfoot. This deformity may cause problems later in life, and surgery may be indicated in those with pain or significant deformity. Results are variable, and some patients may eventually undergo fusion of the subtalar joint for pain relief.

## CLUBFOOT

### Terminology/Incidence/Etiology

Clubfoot is a condition isolated to the foot and leg, in which the foot has varying degrees of the following deformities: metatarsus adductus, cavus, heel or hindfoot varus, and equinus (Fig. 129-7). Hence it is also called *talipes equinovarus.* It occurs in 1 in 1000 live births. The severity of the deformity is variable and ranges from a positional clubfoot that resolves with minimal stretching and casting to rigid deformities that are difficult to correct without surgery. The exact cause of clubfoot is unknown but multifactorial, and it is becoming more obvious that genetics plays a role.[44] Positioning problems can result from anything that decreases the in-utero space for the fetus (e.g., oligohydramnios, being the first baby, multiple births). Many of the rigid, resistant feet are associated with neuromuscular problems or syndromes such as spina bifida, diastrophic dysplasia, sacral agenesis, and arthrogryposis. Those that are not associated with one of these conditions are thought to result from a defect in formation. Classification was difficult, but recently methods by Dimeglio and Pirani have shown good correlation between the two systems.[45–49]

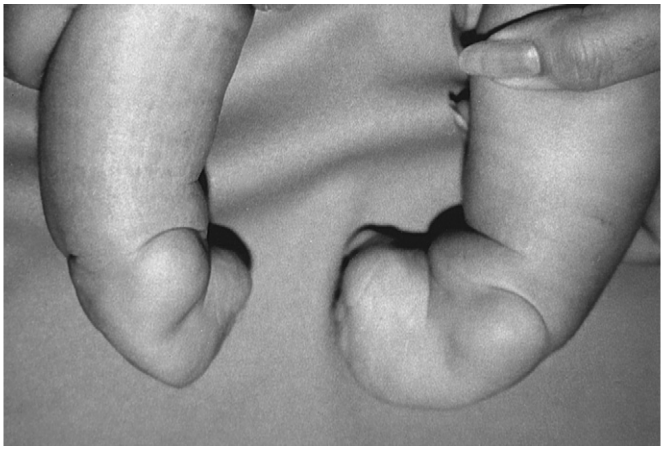

**FIGURE 129-7** An infant with bilateral clubfeet demonstrates the deformities that are part of clubfeet. The infant is prone, a position that reveals the varus deformity of the hindfeet. The crease in the arch shows that these feet have a cavus deformity. The feet are internally rotated and are in equinus.

### Diagnosis/Imaging

The diagnosis is usually apparent from the findings on physical examination discussed earlier. The forefoot is medially deviated as a result of the metatarsus adductus and supinated, which causes the forefoot to be almost touching the tibia. The calcaneus is rotated into varus and is high in the calf and not palpable in the heel pad. There is a medial crease of varying depth in the area of the medial arch. Finally, the Achilles tendon is tight, which causes the high-riding calcaneus. Occasionally, the diagnosis will be subtle if most of these deformities are mild, but such cases are rare. If the foot does not lack dorsiflexion and the heel is not in varus, it is probably not a true clubfoot.

Radiographs are not necessary at birth because most of the midtarsal bones are not yet ossified. Radiographs are helpful as the child gets older to monitor the progress of treatment.

### Anatomy/Pathoanatomy

The calcaneus and talus are normally divergent both in the axial and sagittal planes. In a clubfoot they are more parallel because of the varus deformity of the heel. This, along with the metatarsus adductus, is the major bony deformity. The first ray is also plantar-flexed, and the navicular is subluxated medially and dorsally on the talar head. The talus is often smaller and misshapen with a short neck. The soft tissue deformities consist of a severe contracture of the Achilles tendon, as well as contractures of the posterior tibial tendon, flexor hallucis longus, and flexor digitorum longus. Where these tendons cross in the medial aspect of the foot, they are occasionally confluent with abnormal slips of other tendons. These tendons are often entrapped in scar tissue and form what is called the *knot of Henry*. The plantar fascia is also tight.[50]

### Treatment

Treatment of a clubfoot usually requires some type of manipulation and casting and may require surgery. A technique of manipulation and casting advocated by Ponseti has been around for more than 40 years, but only in the past 10 to 12 years has it been gaining widespread popularity among pediatric orthopedists. There have been good short-term results, and now older patients are showing maintenance of the correction.[51–54] The process consists of the application of a series of four to five long leg casts with manipulation before each casting. The first step is to correct the plantar-flexed first ray and line it up with the other metatarsals in the foot. The next several casts bring the foot out of adduction and over into neutral alignment with the tibia and finally mild overcorrection into valgus. The last cast tries to improve the Achilles contracture by dorsiflexing the foot. Care should be taken to not dorsiflex the foot too quickly or before complete correction of the varus or a rocker-bottom foot deformity may be created. A tenotomy of the Achilles tendon is required in the majority of patients (>90%) to release the heel cord contracture, allow the calcaneus to come down into the heel pad, and permit the foot to dorsiflex. This can be done in the office under local anesthesia with or without sedation, and then a final long leg cast is applied with the foot slightly dorsiflexed and abducted 70 degrees. The cast is worn for 3 weeks, and then the patient goes into abduction bracing to keep the deformities from recurring. These shoes are worn until 4 years of age. Recurrence usually occurs after failure to fully correct the foot or inability to wear the abduction braces.

If supination persists or the heel cord contracture recurs, the patient may need to undergo posterior release with open heel cord lengthening and a transfer of all or half of the anterior tibialis tendon to the lateral side of the foot. This technique is usually successful in keeping the foot in a functional position. However, many centers favor manipulation for any deformity and any recurrence of deformity and avoid surgery if at all possible.

Correction can be achieved surgically, but overcorrection and undercorrection are both possible and over time recurrence or overcorrection of the foot may develop.[55–57] Many studies show deterioration of surgical results leading to arthritis and pain in the foot as the patient gets older.[58] The Ponseti method appears to produce a better foot clinically, both cosmetically and functionally.

In France, a technique developed by Dimeglio has produced good results. The feet are manipulated daily by the therapist and placed in a machine to give passive range of motion to the foot. It is labor intensive and has not been extremely practical in the United States. The Ponseti and Dimeglio techniques are considered to be the gold standards, with surgery having dropped out of favor.

## Congenital Dislocation of the Knee

Congenital knee dislocation covers a spectrum of deformity ranging from simple positional contractures that correct spontaneously to rigid dislocation of the knee joint requiring surgical intervention (Fig. 129-8). The problem often occurs in children with myelomeningocele, arthrogryposis, or other syndromes such as Larsen's. This deformity is frequently associated with DDH, clubfoot, and metatarsus adductus. It is extremely important to look for associated hip dysplasia when a knee dislocation is present. The deformity is recognized at birth in an infant with a knee that is hyperextended and a foot that is up by the infant's head because of a flexed hip. The pathology consists of one or all of the following: contracture of

**FIGURE 129-8** Congenital knee dislocation.

the quadriceps tendon, absent suprapatellar pouch, tight collateral ligaments, and anterior subluxation of the hamstring tendons.

If the problem has resulted from positioning in utero, the deformity is often mild and the knee is still fairly flexible. The knee will correct spontaneously within a few weeks or can be assisted by gentle range-of-motion exercises to accelerate correction. Serial casting may also be helpful, and if hip dysplasia is present, a Pavlik harness can be worn once knee range of motion increases enough to allow the harness to fit properly.

A more severe contracture or true dislocation will be apparent fairly early in the course of treatment because there will be minimal response to stretching and casting. It is usually evident within the first 3 months of treatment. If 30 degrees of knee flexion has not been gained by this time, surgery is indicated. Surgery may consist of one or more of the following procedures, depending on the severity of the condition. The first step is V-Y quadricepsplasty or Z-lengthening of the tendon, followed as needed by release of the anterior joint capsule, posterior transposition of the hamstring tendons, and mobilization of the collateral ligaments. Ninety degrees of knee flexion should be achieved, and then the knee is casted in 45 to 60 degrees of flexion for 3 to 4 weeks.

## Congenital Dislocation of the Patella

True congenital dislocation of the patella is rare. This entity must be distinguished from a recurrent dislocation that occurs later in life. In congenital dislocation of the patella, the patella is hypoplastic or absent and the femoral trochlea is often flattened. The lateral retinaculum is tight, and the patella is completely dislocated laterally. The patella is frequently adherent to the iliotibial band and is often irreducible over the condyle. Genu valgus is frequently present, as is a flexion contracture of the knee. Surgical intervention is required and involves extensive lateral retinacular release, often to the greater trochanter, medial plication, and either hamstring tenodesis or transfer of half of the patellar tendon.

## Congenital Deformities of the Spine

Congenital scoliosis is relatively uncommon. It is a malformation in vertebral column development, typically a failure of formation or a failure of segmentation.[59] Congenital implies that the deformity is present at birth. Even though the vertebral deformity is present at birth, the clinical deformity may not be recognized until years later, depending on the amount of growth imbalance that occurs. Isolated anomalies are usually sporadic, but multiple anomalies can be hereditary.[60] The true incidence is not known because some vertebral anomalies produce little deformity and go unrecognized.

Embryologic development of the spine occurs during the fourth to sixth weeks of gestation. By the sixth week the mesenchymal spinal anlage is complete. Defects in vertebral development occur at this time. They typically stem from failure of segmentation, failure of formation, or a mixed lesion. The resultant clinical deformity is determined by the type and location of vertebral deformity and the potential for asymmetric spinal growth.

Failure of segmentation most commonly occurs in the thoracic or thoracolumbar region. It can be unilateral or bilateral. Unilateral failure of segmentation, or a "bar," results in asymmetric growth of the spine (Fig. 129-9). It may not be evident on initial radiographs; however, there may be associated rib fusions that should raise suspicion. It is often rapidly progressive. The resultant deformity depends on the location of the bony tether. A lateral bar results in scoliosis, an anterior bar results in kyphosis, and a posterior bar results in lordosis. It can also occur in combination and result in kyphoscoliosis or lordoscoliosis. By far the most common is scoliosis, followed by kyphosis. Lordosis is quite rare. Bilateral involvement creates a block vertebra with minimal deformity.

Failure of formation can range from mild wedging to complete absence of half of the vertebra (hemivertebra) (Fig. 129-10). It can occur anywhere along the spinal axis. A hemivertebra is the most common. If present in the thoracic spine, there will be an associated extra rib. The extent of the clinical deformity depends on the location of the

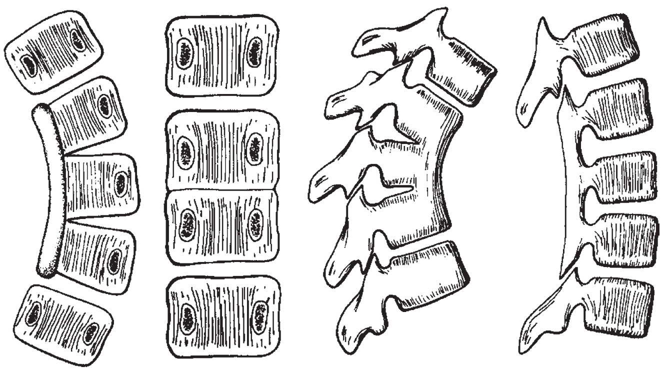

**FIGURE 129-9** Defects of segmentation. **A,** Unilateral unsegmented bar causing scoliosis, which is usually progressive. **B,** Block vertebra caused by bilateral failure of segmentation. **C,** Anterior segmentation defect causing kyphosis. **D,** Failure of segmentation posteriorly causing lordosis. (Modified with permission from Bradford DS, Hensinger RM: The Pediatric Spine. New York, Thieme, 1985.)

hemivertebra and on the potential for growth of the hemivertebra. A lateral hemivertebra will result in scoliosis, whereas a posterior hemivertebra will produce kyphosis.

The remaining deformities are either mixed or cannot be classified because of the extent of their pathology (Fig. 129-11). The amount of clinical deformity is variable, depending on the defect. The most progressive deformity, however, is a combination of a hemivertebra with a contralateral unsegmented bar.[61] Such deformities rapidly progress and will require intervention, usually at the time of diagnosis.

The neural axis forms in conjunction with the bony canal, and the frequency of intraspinal anomalies has been reported to be as high as 40%.[62,63] Abnormality of the overlying skin such as a dimple, lipoma, hairy patch, or nevus may be present 70% of the time. Diastematomyelia is believed to be the most common associated defect.[64] It is a sagittal split in the spinal cord or cauda equina by an osseous or fibrocartilaginous spur protruding posteriorly from the vertebral body. It should be removed if symptomatic or before any corrective spinal surgery. Other intraspinal anomalies include tethered cord, syringomyelia, epidermoid cyst, lipoma, and teratoma.

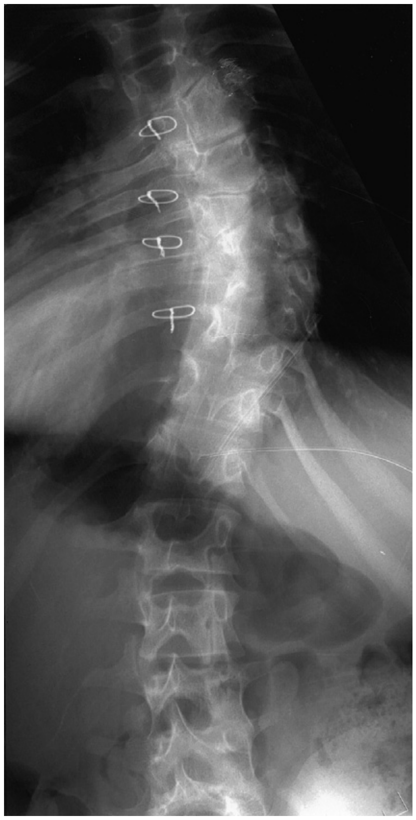

**FIGURE 129-11** Multiple anomalies with combined failure of formation and failure of segmentation. Note the fused ribs in a concavity suggestive of a "bar."

A thorough neurologic examination must be performed, and any clinical suspicion of neurologic abnormality requires imaging with MRI.

Associated anomalies occur in other systems up to 60% of the time[65] including genitourinary, 25%; Klippel-Feil syndrome (cervical spine fusions), 25%; and cardiac, 10%. Abnormalities of the gastrointestinal system can also be seen, as well as esophageal atresia and imperforate anus in connection with the VATER association (in addition to vertebral defects and radial and renal dysplasia).[66] Other musculoskeletal deformities such as Sprengel deformity (congenital elevated scapula), pectus abnormalities, and appendicular skeletal deficiencies are less common. All patients should undergo renal ultrasound screening to exclude underlying abnormalities because the genitourinary system is difficult to assess by physical examination alone.

An infant with congenital scoliosis may or may not have a spinal deformity at birth. If a deformity is present, it is typically a lateral deviation of the spine. It can be confused with congenital muscular torticollis (see Chapter 60) or infantile idiopathic scoliosis (thoracic spinal curvature). Both these conditions can cause clinical deformity at birth, but radiographs will fail to show vertebral anomalies. Most often, vertebral anomalies are incidental findings during the workup for other conditions (Fig. 129-12), and initial detection can occur at any age. The diagnosis is made with radiographs, but MRI or CT may be necessary to better delineate the pathology.

There is little nonoperative treatment to offer other than observation. Unlike other types of scoliosis that may respond to bracing, it is not routinely indicated for congenital scoliosis.

FIGURE 129-12 Incidental finding on a kidney-ureter-bladder radiographic workup for imperforate anus. Note the S1 hemivertebra.

The ideal therapeutic modality is surgical stabilization before spinal deterioration.

The surgical treatment of congenital scoliosis depends on the type of deformity present, the location of the deformity, and the amount of growth remaining. The goal of treatment is to halt progression and achieve spinal balance at maturity. The most rapid vertebral growth occurs up to the age of 2 years and again during adolescence. Thus clinical deformities can change rapidly during these times and require close monitoring. Surgical complications are increased in this population. This type of scoliosis carries the highest risk for neurologic complications with attempts at intraoperative correction. Ideally, patients who have deformities with a high probability of progression should undergo stabilization when their curves are small.[67] Other patients with a lower probability or an unknown probability of progression are managed by close follow-up with serial radiographs. Surgical intervention is delayed as long as the curve is not progressing and the spine remains in balance. Overall, 50% of curves will be stable, 25% will progress slowly, and 25% will have rapid progression.

Surgery is the definitive treatment of congenital scoliosis. It is indicated for rapidly progressive curves, deformities with a high propensity to progress, and deformities that cause spinal imbalance. Numerous surgical techniques are available, depending on the type and location of the deformity. Attempts at correction carry a high risk of neurologic impairment. Fusion in situ is considered the "gold standard"[68] and is indicated for curves that are progressive or prone to progress but still within a range where spinal balance can be maintained. In younger children, anterior and posterior fusion must be performed to balance the remaining growth. Posterior fusion alone is adequate for older children with little remaining spinal growth. Hemiepiphysiodesis is a variation of fusion in situ. It involves fusion of only the convex side of the curve, thus permitting the concave side to continue unopposed growth and allow correction to occur. Because the correction is gradual, the risk for neurologic impairment is decreased. Hemivertebra excision is typically reserved for deformities in the lumbar spine where spinal imbalance is more pronounced and the cauda equina is safer to retract (Fig. 129-13). Excision has been performed in the thoracic and thoracolumbar spine less often, but with favorable results.[69] An anterior and posterior approach is usually necessary. Spinal osteotomy or vertebrectomy is reserved for the most severe curves with imbalance that are not amenable to other more standard techniques. It carries the highest risk for neurologic injury because of the acute correction and is considered a "salvage" procedure by most.

Anterior approaches to the spine require the traditional thoracotomy or thoracoabdominal approaches. Postoperative morbidity can be significant in this population because of other coexisting abnormalities, and pulmonary function may be further diminished after these approaches. Video-assisted thoracoscopic surgery can be useful in some instances.[70] Visualization of the spine is adequate, and the instrumentation continues to improve to allow for more complete diskectomy and anterior fusion. Postoperative pulmonary morbidity should be lessened.

Congenital kyphosis is a variant of congenital scoliosis and usually occurs secondary to failure of formation of the anterior

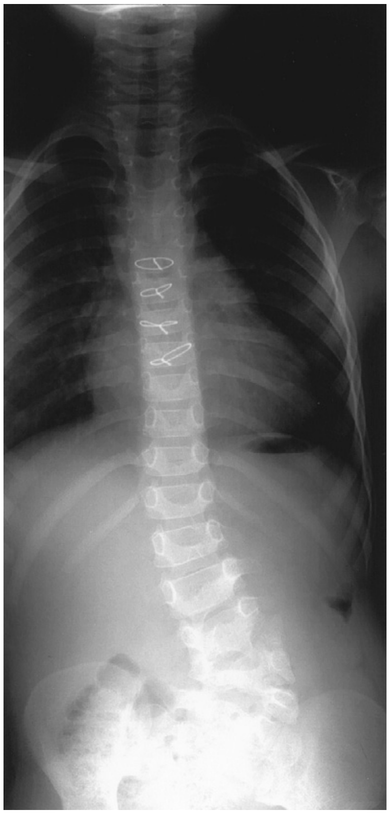

FIGURE 129-13 Left L5 hemivertebra causing spinal imbalance. This is the ideal location for hemivertebra excision.

**FIGURE 129-14** Posterior hemivertebra with anterior failure of formation resulting in kyphosis.

body (Fig. 129-14).[71] It can also result from failure of segmentation with an anterior or, more commonly, an anterolateral bar. This type of deformity has a poor prognosis for progression and neurologic involvement. If unrecognized, it can result in paraplegia. Congenital kyphosis requires surgical stabilization at the time of diagnosis to prevent further deterioration. Bracing is of no value. Because of the variability in deformity, no single surgical approach can be applied to all. Typically, if the patient is younger than 5 years and the kyphosis is less than 50 degrees, posterior fusion will suffice. If older than 5 years or more severe kyphosis exists, anterior and posterior fusion is required.[72]

Sacral agenesis, or complete or partial absence of the sacrum, is another type of congenital spinal anomaly. It has been associated with maternal insulin-dependent diabetes,[73] although this relationship has more recently been questioned.[74] It is often associated with gastrointestinal and genitourinary abnormalities. Neurologic involvement is variable and often results in hip, knee, and foot deformities. The prognosis and treatment depend on the degree of malformation, the stability of the spine, the level of neurologic involvement, and any other associated anomalies. Typically, only patients with stability of the spinal attachment to the pelvis are able to ambulate.[75] They may require surgical procedures to correct their lower extremity deformities. Most others with spinal instability at the spinal-pelvic junction will not ambulate functionally and require treatments aimed at improved sitting balance and positioning.

CHAPTER 130

# Congenital Defects of the Skin and Hands

Edward P. Miranda

The sequence of cellular proliferation, differentiation, and regression that is characteristic of human embryogenesis and subsequent development is complex and possesses little tolerance for error. Errors and injury during gestation do occur quite often as evidenced by spontaneous abortion rates of up to 26.9% when implantation is detected by measurement of human chorionic gonadotropin (HCG).[1] The "failure" of these gestations can also be viewed as "success" because embryos with errors incompatible with life (e.g., major chromosomal abnormalities) are culled out. This selection for major errors is not precise because many gestations continue with sublethal abnormalities.

## General Incidence and Risk

A major malformation has been defined as a structural anomaly with medical and social consequences. The incidence of major malformations has been estimated to be 2% to 3% of live births.[2–5] Minor malformations have been defined as structural alterations that pose no significant medical or social burden. At least one malformation is identifiable in about 15% of newborns. The distinction between major and minor is arbitrary because all human deformities exist on a continuum. However, even the most minor physical aberration can predispose the afflicted person to psychosocial isolation, justifying surgical therapy.

## SKIN AND SOFT TISSUES

### Embryology

The developmental origins of the skin, muscle, connective tissue, and tendons commence during the third week of embryonic life. During this period, a primitive streak appears and facilitates the formation of the trilaminar embryo (ectoderm, mesoderm, and endoderm), notochord, and somites.

### Development of the Epidermis

The skin is the largest organ in the body and is composed of two layers: the dermis and the epidermis. It serves a variety of functions beyond simply providing an interface between the body and the environment. The skin provides temperature regulation, sensory perception, and a barrier against water loss and microbial invasion and is a major neurally regulated immune organ.[6,7] The cutaneous system is also a medium for nonverbal communication, and the appearance of the skin contributes to interpersonal recognition and one's sense of self.

The epidermis originates from a monolayer of ectodermal cells forming the periderm at about 4 weeks of gestation. The early epidermis is a monolayer exposed to the amniotic fluid, with which it participates in significant salt and water exchange. By the third month the epidermis becomes three cell layers thick (basal, intermediate, and superficial layers). The epidermis continues to thicken, and by the sixth month differentiation has progressed far enough to achieve effective barrier function. Upon microscopy the skin is similar to newborn epidermis with several observable layers: the strata basale (inner layer), spinosum, granulosum, and corneum (outer layer). The stratum basale retains the keratinocyte stem cells that will repopulate the other layers over the lifetime of an individual. Keratinocytes over their lifetime progress from the stratum basale to ultimate sloughing from the stratum corneum. This migration is characterized by progressive differentiation and accumulation of keratin granules (in the stratum granulosum) and the intermediate filament filaggrin in the stratum corneum to maintain an effective barrier to the environment.

Several other cell types migrate into the epidermis to assist in its function. Melanocytes are neural crest–derived cells that first migrate into the dermis and then into the epidermis. These cells produce melanin pigment for defense against ultraviolet photoinjury. At approximately 3 months of gestation, Langerhans cells (LCs) are found in the epidermis. LCs are bone marrow derived, professional antigen-presenting cells that arrange themselves in the epidermis to form an immunologic net to detect and present foreign antigen to T cells.

### Development of the Dermis and Other Mesodermal Tissues

During the third week of embryogenesis a primitive knot appears at the cranial end of the primitive streak. Mesenchymal cells migrate cranially from the knot forming a midline cellular

cord known as the *notochordal process*. The process grows until it reaches the oropharyngeal membrane; at this point it can extend no farther because of the densely adherent ectoderm and endoderm. The notochord gives rise to the vertebral column and induces the overlying ectoderm to form the neural plate, the primordium of the nervous system.

As the notochord forms, the intraembryonic mesoderm thickens on each side of the notochord to form paired longitudinal columns of paraxial mesoderm. At the end of the third week, columns of paraxial mesoderm divide into paired cuboidal bodies called *somites*. Eventually, 42 to 44 pairs of somites develop in a craniocaudal sequence. Somites are the segmental precursors to most of the axial skeleton, musculature, and its associated dermis of the skin.

The emergence of mesenchyme at 3 weeks of embryonic life is essential to organogenesis. By 8 weeks of life, the face and hands are recognizably human. At 12 weeks of life, the palate has formed and the sex can be determined by visual inspection of the external genitalia. Interruptions in the development and differentiation of mesodermal events (mesenchymal migrations, notochord, somites) accurately reflect the wider diversity of congenital malformations found in the skin, connective tissues, muscles, and tendons. With such an expansive array of deformities, systematic analysis and anatomic regionalization of the defect are necessary to formulate an effective treatment plan.

## Analysis of Defects and Technical Aspects of Treatment

The structural aspect of any defect can be subdivided into malposition of otherwise normal structures, regional absence of normal tissue, and aberrations of tissue composition.

### MALPOSITIONING OF OTHERWISE NORMAL STRUCTURES

Congenital malpositioning of normal structures can occur from persistence of embryonic lines of fusion, displacement of anatomic landmarks from abnormal growth of adjacent tissues, or developmental malrotation. Visceral malpositioning may be entirely inconsequential to the affected individual. Dextrocardia with situs inversus is an incidental finding in asymptomatic patients. More commonly, malpositioning has more deleterious effects. The magnitude of the mishap depends on the cascade of events resulting from the derailment of normal development. Spina bifida and facial clefts are examples of defects resulting in severe functional and social consequences.[8–11]

### REGIONAL ABSENCE OF NORMAL TISSUE

Structural anomalies resulting from a deficiency or absence of tissue have taxed the ingenuity of plastic surgeons. Traditionally, alloplastic or autologous materials have been used in the reconstruction of congenital defects that are caused by deficient or absent tissues. Benefits of reconstruction with alloplastic materials include unlimited supply, no donor defect, and ease of use. However, reconstruction with autologous tissues is generally superior for congenital malformations because such tissues can fully integrate with living structures, maintain the potential for growth and wound healing, and resist infection after healing. Nevertheless, alloplastic surgical implants, judiciously placed during adolescence, remain an excellent reconstructive standard in special clinical circumstances such as congenital hypoplastic breast deformity.

A wide spectrum of surgical procedures has evolved to optimize the use of autologous tissues. Use of nonvascularized tissue grafts is a simple and effective way to replace skin, muscle, connective tissue, and tendons. This technique is justifiable only when the gain at the recipient site will compensate for the loss sustained at the donor site. Furthermore, a well-vascularized recipient bed is necessary to nourish the graft until neovascularization occurs. When the bed is not suitable for a graft or when specialized tissue is desired for the reconstruction, then en bloc (composite) flap transfer of specialized tissue with its own intrinsic vascular supply should be used. The method of tissue transfer depends on the proximity of the donor and recipient sites. Free microvascular flap transfer is an elegant method of moving tissue when the distance from donor to recipient site is too great for local rearrangement.

More recently, off-the-shelf biologic or combined biologic-synthetic materials have been used to reconstruct congenital and acquired defects of normal tissue. Recent improvements in acellular dermal matrices (ADMs) (e.g., Alloderm or Strattice) and bilayered dermal regeneration templates (combining an outer silicone film to recreate barrier function and a deeper synthetic layer of cross-linked collagen and cartilage, analogous to a synthetic extracellular matrix [ECM]) have bridged the divide between pure autologous tissue and alloplast-only reconstructions. ADMs have been used for reconstructions of the abdominal wall, diaphragmatic hernia, and other defects.[12,13] Postimplantation histologic analyses reveal that ADMs are incorporated by the body and used as a scaffold for the production of new fascia-like tissue with revascularization and ingrowth of fibroblasts.[14]

Bilayered dermal regeneration templates have been used as an intermediate step for reconstruction of full-thickness cutaneous defects followed by thin split-thickness skin grafting including those with limited exposure of tissues that have traditionally fared poorly with skin grafts alone (e.g., bone and tendon). These constructs limit the inflammatory response, decrease scar contracture, and allow for the formation of a neo-dermis via vascular and fibroblast ingrowth without the need for potentially morbid flap harvest (Fig. 130-1).[15]

Tissue expansion is an excellent way to create composite soft tissue for use with fewer donor-site demands. Hair-bearing replacement of deficient scalp in conditions such as aplasia cutis (see later) best illustrates the potential dividends gained from tissue expansion. Distraction osteogenesis is the analogous procedure for bone. The use of this powerful technique for bone lengthening, first described by Ilizarov for the lengthening of long bones, is now being used in the facial skeleton. Gradual facial-bone lengthening without donor deformity has been effective in treating mandibular hypoplasia, which is found in disorders such as hemifacial microsomia.

### ABERRATIONS OF TISSUE COMPOSITION

An imbalance in the relative cellular composition of a tissue may lead to significant malformation without a deficiency in tissue mass. Skin lesions such as congenital giant hairy nevus (see later) and port wine stains are anomalies that express an

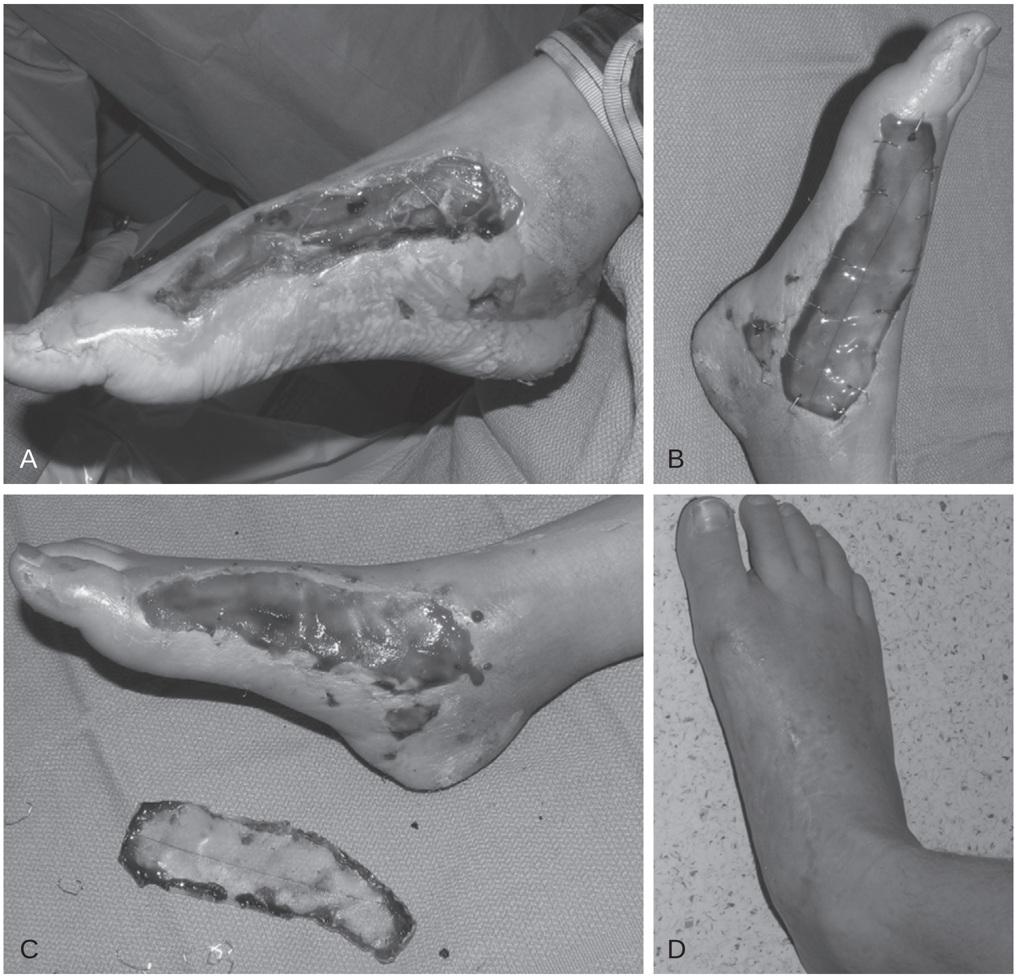

**FIGURE 130-1** Bilayered dermal regeneration matrix (Integra) for reconstruction of soft tissue defects. **A,** Preoperative appearance of a soft tissue defect in a 7-year-old girl with small amounts of exposed bone and tendon visible. **B,** Postoperative (2 weeks) after placement of bilayered dermal regeneration matrix (Integra). **C,** Postoperative (2 weeks) after removal of the silicone outer layer; note the vascularity of the neodermis. The tissue is ready for grafting. **D,** Postoperative appearance after skin grafting over the neodermis. An additional 2-mm dermis is present with decreased contracture and increased suppleness compared with traditional skin grafting. (Courtesy Edward P Miranda.)

excess of a specific cell or tissue type. In congenital giant hairy nevus, the melanocyte-related nevus cell has excessively proliferated in the dermis. After birth, these cells have an increased risk of degenerating into melanomas, leading to the rationale for surgical ablation.[16] Cutaneous capillary vascular malformations (port wine stains) result from an excessive developmental accumulation of abnormal microvascular tissue in the dermis. These lesions are not mitotically active and have no neoplastic potential. However, they are disfiguring and socially disturbing. Direct excision is generally undesirable due to subsequent scarring and deformity. Selective ablation of vascular tissue with laser light is an effective method for treating this disorder.[17]

Many localized congenital malformations are inconsequential and can be considered normal variants. For example, the congenital absence of the palmaris longus tendon has a prevalence of 15% to 20%.[18] Such anomalies require no treatment. However, when function or body image is threatened, a careful analysis of the magnitude of malpositioning of normal structure, degree of tissue deficiency, and composition of the aberrant tissue is essential in planning the reconstruction. Judicious timing of the operation can often interrupt a cascade of predictable secondary deformities.

# Specific Anatomic Regions

## SKIN

### Aplasia Cutis Congenita

Aplasia cutis congenita (ACC) is a rare congenital disorder characterized by full-thickness absence of the skin and underlying tissues over a section of the body. The scalp is involved in approximately 80% to 90% of cases with occasional loss of all cranial tissues including calvarium and dura (15% to 30%). The true incidence is unknown, and approximately 500 cases have been reported in the medical literature. The diagnosis of ACC is clinical and is generally discovered at birth, although diagnosis by prenatal ultrasound has been reported. The lesion generally presents as a thin, transparent membrane or as a dried cicatrix in place of normal skin; no hair follicles are present. The vertex of the scalp is the most common area involved. For small defects, the natural history is that of epithelialization from the lateral edges, but larger defects may not close and generally warrant treatment. The mortality for extensive scalp defects may be as high as 20% to 50%.[19]

The etiology of ACC is not well established. It has been reported to be associated with other defects including limb deformities, omphalocele, and clefts. Surgical treatment is generally indicated immediately for the larger defects and ones in which there is a bony defect. Bony involvement at the vertex of the scalp places the patient at risk for hemorrhage from the sagittal sinus and also mandates operative treatment. The defect is generally repaired with flaps and/or skin grafts. Recently ADM has been used for regeneration/reconstruction of the tissue defect.[20] Bony skull reconstruction is generally delayed until 2 years of age; occasionally the osteogenic dura may spontaneously generate new bone replacing the defect.[19] Reconstruction of a normal hair pattern is accomplished via tissue expansion of the scalp and subsequent coverage of the affected area with local flaps at about 5 to 7 years of age.[21]

### Congenital Melanocytic Nevus and Giant Hairy Nevus

Congenital nevi are composed of large clusters of pigment producing cells of melanocyte lineage that are clustered in the dermis and produce pigment at birth. When compared with the more common acquired nevi, congenital nevi are larger, have increased cellularity, and lie deeper in the dermis. The incidence of congenital nevi has been estimated to be 1 in 100 births for small lesions and 1 in 20,000 for large lesions. After birth it is difficult to distinguish congenital from acquired nevi even by histology. Congenital melanocytic nevi are classified according to size: small, less than 1.5 cm in diameter; medium, 1.5 to 19.9 cm; and large (giant), greater than 20 cm.[22,23]

The potential for congenital nevi to transform into melanoma is the prime reason that these lesions come to surgical attention. However, considerable uncertainty surrounds estimation of the true risk for malignant degeneration. Rates of 1% to 31% have been reported for giant congenital nevi (GCN), although these data may be even less reliable than the range suggests because the total number of patients with GCN is unknown. A metareview calculates an overall melanoma risk of 8.2% in GCN, which is high enough to make surgical ablation a priority. The risk for malignant melanoma is also immediate; 60% of observed GCN-related melanomas occurred in the first decade of life, with several studies suggesting that many malignancies occur by 3 years of age. Melanoma has also been reported in small congenital nevi, and melanoma rates of 2.6% to 4.9% have been estimated.[24]

Giant hairy nevi (GHN) are a special subset of congenital nevi. These melanocytic cutaneous lesions are extensive and encompass entire anatomic regions that may exceed 20% of the body surface area (Fig. 130-2). These nevi are often hairy with benign surface nodularity consisting of focal growths of neuroectodermal tissue.[25] When the head or upper part of the trunk is involved, neurologic abnormalities have been observed in up to 20% of patients. Neurologic findings of leptomeningeal melanosis, hydrocephalus, seizures, and myelopathy in association with GHN are consistent with the developmental origin of the neuroectoderm.[25]

GHN are disfiguring and easily identifiable at birth.[26] Parents of patients with GHN often seek treatment early. Some neonates with GHN have been found to have malignant melanoma shortly after birth, thus justifying early surgical ablation. Serial resection of GHN lesions with the use of subcutaneous tissue expanders is indicated to improve aesthetic appearance and diminish the risk for malignancy.[27] The increased compliance and elasticity of infant skin provide the first opportunity to debulk a large portion of the giant nevus in the first 6 months of life.[28] At this time areas of nodularity or increased pigment are resected. The timing of subsequent resections is based on changes in appearance of the nevus and the parents' decision to proceed with complete resection. Repeated excisions may expedite lesion removal with completion in early childhood. Complete excision of the nevus with skin grafts results in scar and contracture deformities both at the site of nevus resection and the skin graft donor site. The use of sequential excision with expansion of normal adjacent skin allows coverage of areas of nevus excision with normal skin and does not cause additional scarring.

### Nevus Sebaceous of Jadassohn

Sebaceous nevus (SN) is a solitary, well-circumscribed, alopecic plaque of epidermal origin. SN is commonly found on the scalp, temple, or preauricular region and is sometimes diagnosed at birth. Histologic analysis in children reveals epidermal hyperplasia and hypoplastic hair follicles and sebaceous glands. At puberty the sebaceous glands mature, and progression of the epithelial hyperplasia occurs. Progression to basal cell carcinoma (BCC) has been reported in up to 6% to 22% of adults.[29]

Controversy exists in the management of SN in children. Early reports of BCC formation in 10% to 15% of adolescents have been refuted by large retrospective studies that have shown a low incidence of benign epithelioid lesions and very low (0% to 0.8%) incidence of BCC in excised lesions from children up to 16 to 18 years of age.[29,30] However, there is still a well-documented incidence of NS-related BCC in adults. The management of choice remains excision, but delay until later in adolescence is reasonable.[29]

### Congenital Webs

Congenital webs (pterygia) are most commonly found in the neck (pterygium colli). In the neck, thick folds of skin and subcutaneous tissue extend from the mastoid process laterally to the acromion. The lesions are generally bilateral and can distort local structures including the posterior hairline, the border of which is often displaced laterally on the neck, causing a short-neck appearance. Webs have been identified similarly in the axillary folds and crural regions.

Congenital webbing may occur in isolation or in conjunction with other congenital deformities, however the etiology is unknown. Certain regional deformities such as Klippel-Feil syndrome can display this developmental lesion. Neck webbing is often a manifestation of Turner's syndrome. The webs can cause functional and/or aesthetic disabilities. Correction is by lengthening with multiple Z-plasties generally between ages 1 and 6 years.[31]

## CONGENITAL DEFORMITIES OF THE BREASTS

### Embryology

The breast develops in the fetus from ectodermal tissue during the fifth week of gestation. Bilateral *mammary ridges* extend from the axillae to the groins. During the seventh to eighth week of gestation, the mammary ridges undergo involution

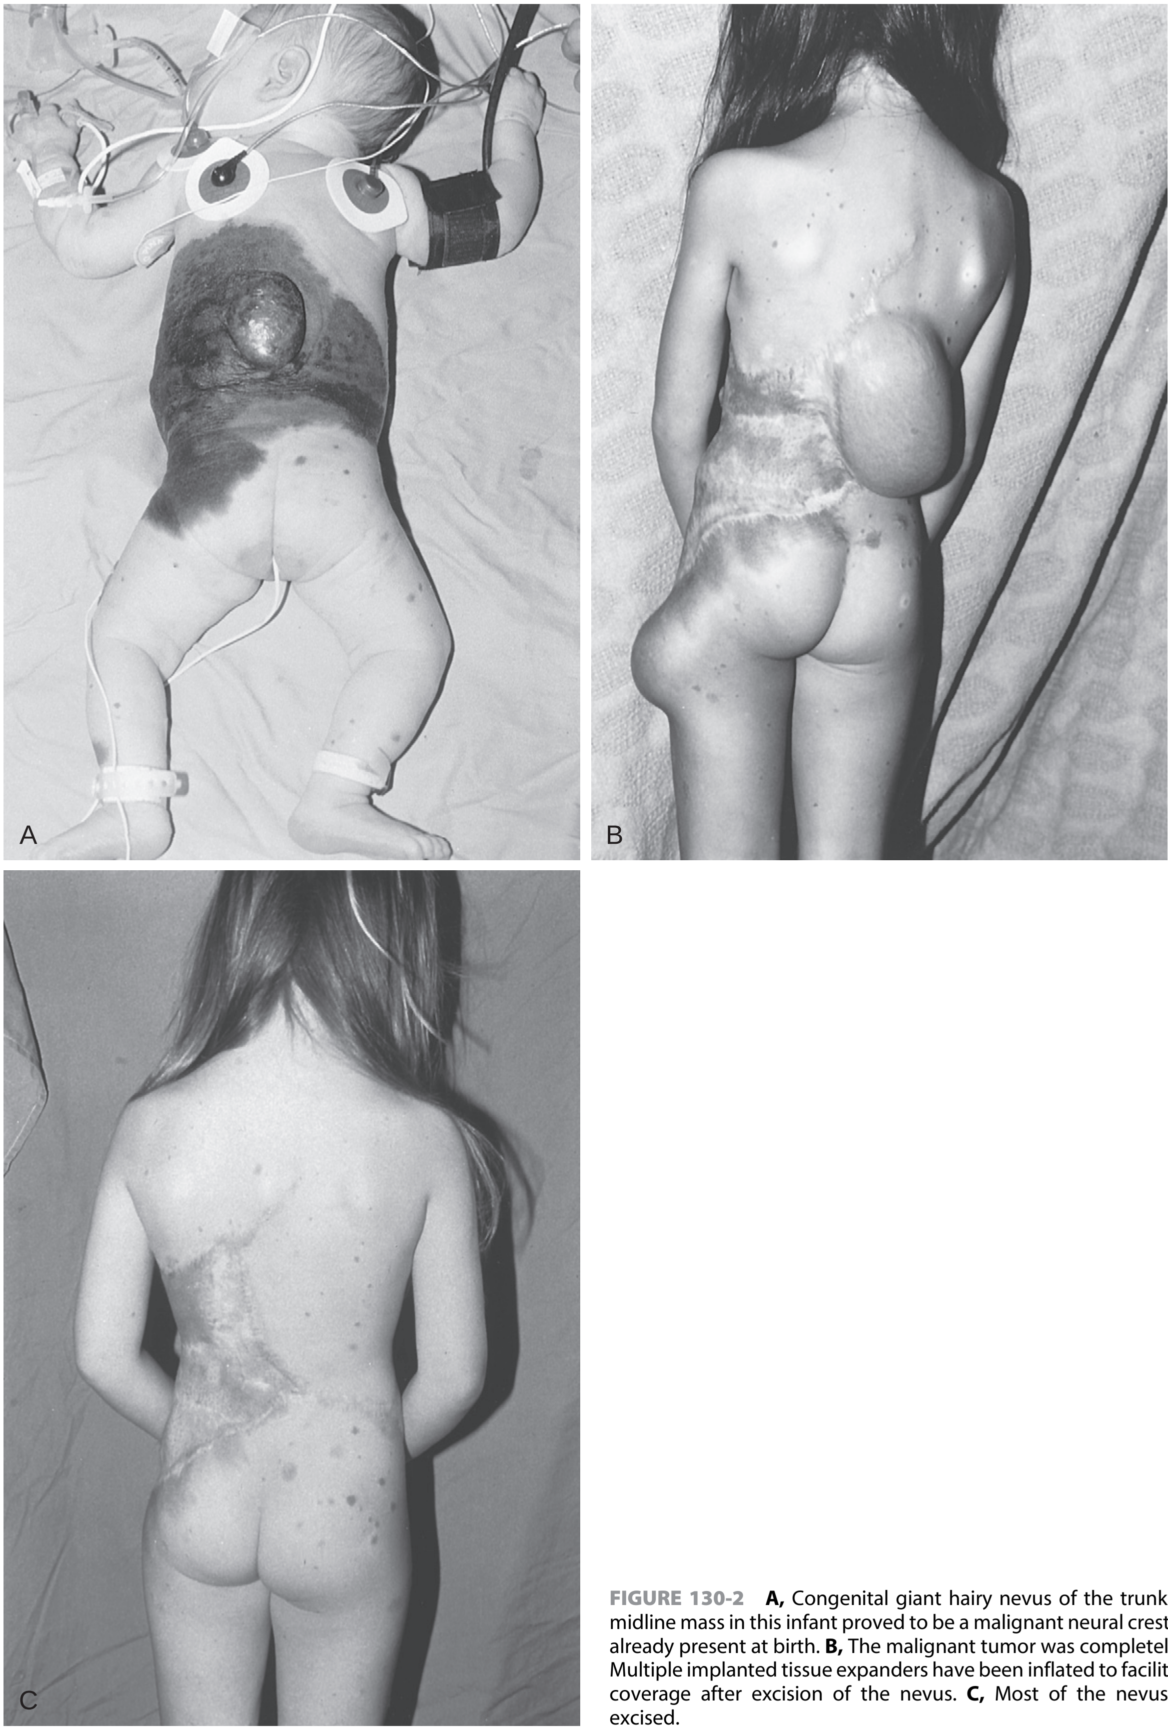

**FIGURE 130-2** **A,** Congenital giant hairy nevus of the trunk. The large midline mass in this infant proved to be a malignant neural crest cell tumor already present at birth. **B,** The malignant tumor was completely resected. Multiple implanted tissue expanders have been inflated to facilitate wound coverage after excision of the nevus. **C,** Most of the nevus has been excised.

in all areas except on the anterior thoracic wall and axillae. After 10 to 14 weeks of gestation, the primordial breast tissue penetrates the thoracic mesenchymal tissue and begins to form glands. The mesenchyme envelops the breast and forms layers in continuity with Camper fascia (outermost layer) and a second layer separating the breast from the underlying thoracic musculature. Camper fascia surrounds the anterior breast in all areas except just deep to the areola. A network of connective tissue runs through the mammary gland forming Cooper ligaments, which suspend the breast. Milk ducts begin to form at about 20 weeks of gestation, and the glandular tissue continues to develop until the end of puberty.[32,33]

### Polythelia and Polymastia

Supernumerary nipples *(polythelia)* and supernumerary breasts *(polymastia)* are relatively common congenital abnormalities with an incidence of approximately 0.2% to 2.5% (polythelia) and 0.1% to 1.0% (polymastia) (see also Chapter 61). Both of these deformities are observed to form along the milk lines that track from the axillae to the groins. Both supernumerary nipples and breasts form from a failure of normal apoptotic regression of the mammary ridges during gestation. Diagnosis of supernumerary nipples can often be made at birth. The most common site for polythelia is just inferior to a normal breast; the most common site for an accessory breast is in the axilla.[33]

Supernumerary nipples and breasts typically present as an aesthetic complaint but can also respond to hormonal changes similar to a normal breast including enlargement during puberty and milk production after pregnancy.[34] Treatment of these lesions is generally simple excision, but it is important to consider that diseases that afflict the normal breast can also affect supernumerary ones.[35] Breast masses must be excluded. Furthermore, several other anomalies have been associated with polythelia and polymastia including a higher rate of testicular tumors in boys.[36] Other more controversial associations include genitourinary tract abnormalities and renal cell carcinoma.[37,38]

### Congenital Absence of the Breast

Complete absence of one or both breasts is an extremely rare anomaly that can occur in isolation or with a variety of other developmental syndromes including Poland syndrome, Ullrich-Turner syndrome, and AREDYLD syndrome (acrorenal field defect, ectodermal dysplasia, lipatrophic diabetes) (Fig. 130-3). Bilateral congenital absence without other associated ectodermal defects is extremely rare, with few cases reported in the literature. Mendelian inheritance is possible but has not been definitively established; teratogen exposure has also been implicated. Due to the rarity of this condition, optimal treatment has not been established. Successful use of autogenous tissues including the use of abdominal or buttock free flaps for construction of a breast de novo has been reported.[38a] Tissue expansion and implant placement may also be reasonable options.[33,39]

### Tuberous Breast Disease

The breast anomaly known as the "tuberous breast" was initially described in 1976 by Rees and Aston for its likeness to a tuber root (Fig. 130-4).[40] Although there has been much confusion in the literature about both the nomenclature and the description of the tuberous breast and breast asymmetries in general, the following facts are known: 88% of women presenting for breast augmentation mammaplasty have breast asymmetry and 29% have breast base constriction.[41] However, the true tuberous breast is much less common and is defined not simply by asymmetry or constriction but also by the herniation of mammary tissue through a constricting fascial ring deep to the areola. The true incidence is uncertain, and there seems to be no heritable genetic component to the disorder.[33]

The presence of the tight fascial ring causes the breast to become asymmetric during pubertal development and ultimately herniate through it, causing areolar enlargement. This may be associated with hypoplasia of one or more quadrants, with the deficiency being most common in the inferior pole. The inferior mammary fold is often variably elevated.[42]

The tuberous breast often presents as an aesthetic concern in the early teen years. Differentiation of this disorder from more common asymmetries is essential because the treatment is generally different. Nearly 90% of cases are bilateral, and significant hypoplasia of the breast tissue is present in approximately one quarter of patients.[33]

Treatment for the tuberous breast is somewhat controversial, although several principles can be relied on. The patient should not be operated on until late in the second decade when breast development has finished. In nearly all cases, the herniated breast tissue causes enlargement of the areola, mandating a circum-areolar incision to reduce its size. This incision also allows for access to the fascial ring, which has constricting bands that must be released. Operative plans subsequent to these two steps are less definitive, although local tissue rearrangement is generally recommended with the establishment of a normal position of the inframammary fold and a natural inferior pole contour.[43] For hypoplastic or asymmetric breasts, tissue expansion and/or implant placement can be a useful adjunct to tissue rearrangement, but the use of an implant alone has been shown to be unsatisfactory with abnormalities of the inframammary crease being common.[33,44,45]

### Gynecomastia (Infantile and Adolescent)

Gynecomastia, or the abnormal presence of breast tissue in males, is a common but complex disorder with both congenital and acquired features (Fig. 130-5). The overall incidence has been reported to be 32% to 40% with a reported incidence of palpable breast tissue of 65% in adolescent boys.[46] Other studies have disputed these data; a cross-sectional study of 3082 healthy boys (aged 10 to 19 years) in Eastern Europe found a 3.93% prevalence of gynecomastia.[47] Variations in estimates are likely to be related to varying thresholds for diagnosis of overt gynecomastia (grade IIb/III gynecomastia) versus the presence of palpable breast tissue on the male chest (grade I/IIa gynecomastia).

Although numerous individual cases of gynecomastia have been identified, breast development in males generally occurs secondary to an excess of estrogens relative to testosterone because of an absolute estrogen excess, a testosterone deficiency, or receptor resistance. A full discussion of the causes of gynecomastia is beyond the scope of this section and is reviewed elsewhere.[48] Gynecomastia can be classified as congenital or acquired, as well as physiologic or pathologic. In boys, most cases are congenital and physiologic and occur in either the neonatal period or during adolescence. In utero, exposure to high maternal estrogen levels can cause the development

of mammary tissue (neonatal gynecomastia), which regresses within a few weeks after birth. In adolescence, elevation of the estradiol-testosterone ratio causes detectable gynecomastia in up to 65% of boys. However, in most it is not noticeable without a focused examination and most noticeable cases occur during pubic Tanner stages 3 and 4.[47] Nearly all cases regress by the end of puberty.[33] Pathologic gynecomastia in children and adolescents is relatively rare but requires special attention, especially in the case of Klinefelter syndrome, which is associated with a 19.2- to 57.8-fold risk for breast cancer (unlike gynecomastia in general, which has no elevated risk).[49]

Although gynecomastia in adolescents is typically self-limited and resolves by the end of puberty, persistent gynecomastia (present for more than 1 year *and* beyond puberty) generally does not resolve without surgical treatment because the abnormal breast inevitably becomes fibrotic.[50] The gynecomastia for which a plastic surgeon is initially contacted is usually an aesthetic complaint; however, this does not obviate the need for a detailed history and physical examination. Although gynecomastia in the general population and even cases examined by a pediatrician are generally uncomplicated and benign, there is good evidence that gynecomastia needing

surgical treatment is a more complicated subset of the disorder. In particular, several large studies have shown an increased incidence of testicular and nonmelanoma skin cancer in males with gynecomastia requiring operative treatment. The risk for testicular cancer is particularly elevated in young men and has a standardized incidence ratio reported at 5.82; 7% to 11% of patients with testicular cancer present to surgical evaluation for gynecomastia.[51,52] Examination of the testicles and skin, as well as education regarding skin cancer, is mandatory.

## Poland Syndrome

In 1841 Alfred Poland, a medical student, reported some unusual anatomic findings on a cadaver, describing unilateral hypoplasia of the pectoralis musculature, upper limb, and hand. The expression of the various components of this trait varies

widely. The incidence has been estimated to be 1:30,000 with a predilection in females of approximately 2-3:1.[53,54]

The etiology of Poland syndrome (PS) has been theorized to be due to obstruction of the subclavian blood supply during the sixth to seventh weeks of gestation. During this time, the ribs grow anterior and medially, depressing the subclavian artery into a U-shaped configuration. Tension on the arterial wall may cause kinking and obstruction. The site of diminished blood flow may determine the tissues involved in the defect, which may involve the thoracic wall, the pectoralis muscle, breast, upper extremity, and hand. Vascular studies have shown diminished blood flow in the subclavian artery on the affected side. More proximal vascular involvement of the subclavian or vertebral arterial systems has been shown to give rise to the bony cervical anomalies found in Klippel-Feil syndrome and the congenital palsies of cranial nerves VI and VII in Moebius syndrome. The synchronous presence of Poland, Klippel-Feil, and Moebius syndromes support a common embryologic event (i.e., vascular accident) in their genesis.[55–58]

The essential feature of PS is the absence of the sternal head of the pectoralis major muscle. Other features are hypoplasia or aplasia of the breast or nipple, deficiency of subcutaneous fat and hair across the chest and axilla, and abnormalities of the ipsilateral limb including shortening and brachysyndactyly. Other muscles may also be involved to variable degrees including absence of the pectoralis muscle (Fig. 130-6) and hypoplasia of the serratus anterior, supraspinatus, latissimus dorsi, and external oblique muscles. The thoracic cage itself may be involved with absence of the anterolateral ribs with possible lung herniation or symptomatic depressions in the chest wall. The hand deformities can be more involved with symphalangism occurring with syndactyly and hypoplasia or absence of the middle phalanges. Detection of syndactyly in a patient should make PS a consideration because 10% of all cases of syndactyly have been reported to have features of PS.[53,59,60]

Despite the hand deformities, the functional disability is generally mild and related to the presence of syndactyly. In milder forms of PS, treatment is primarily for aesthetic reasons. For more severe presentations, particularly in which the thoracic cage is involved, stabilization of the protective chest wall is warranted first because all other chest reconstructions will be placed on top of this foundation. Minor chest wall deformities are generally reconstructed with an ipsilateral latissimus dorsi muscle flap. Major chest wall deformities require better stabilization with either bone or prosthetic mesh. Split rib homografts and Marlex mesh have been used for moderate and severe defects and are covered with a latissimus dorsi muscle transfer. The transferred latissimus dorsi muscle replicates the missing anterior axillary fold of the pectoralis muscle and improves soft tissue coverage. Remaining major contour irregularities may be treated using a custom alloplastic implant.[53,61]

The reconstruction of the female breast in PS often presents a challenging problem. In severe cases the breast reconstruction generally occurs as a second-stage procedure late in adolescence, years after stabilization of the chest wall. The placement of an implant behind a latissimus dorsi muscle transposition has been effective. The successful use of free-tissue transfer has also been reported. In cases where the cutaneous envelope is hypoplastic, tissue expansion early in puberty will augment the soft tissues for later final repair and may guard against the psychologic distress of an absent breast.[62–65]

# HAND

## Embryology

Arm buds appear at 31 days, the fourteenth stage in embryonic development, coincident with the formation of the marginal vein beneath the surface ectoderm. The paddle-like hand segment forms on approximately day 33. Finger rays are evident at 41 days but do not begin to separate until day 47. Interdigital zones destined for apoptosis determine the separation of the fingers. The median artery supplying the embryonic hand is replaced by the radial and ulnar arteries between the fifth and sixth weeks. The reduced median artery maintains only the median nerve and interosseous blood supply. Dorsal and ventral blastemas differentiate into dorsal and volar forearm musculature, respectively, from the fifth to the eighth week, and are formed superficially and deeply. Intrinsic hand muscles arise from five embryonic layers; the deep hypothenar and thenar muscles in the seventh week are the last to separate. Condensation and then chondrification of the mesenchyme begins in the fifth week, ending with chondrification of the phalanges at week 6 and sesamoids at week 7. The eighth week marks the end of embryogenesis; much of the final form is in place. During weeks 4 to 8 of gestation, the embryo is at the highest risk of hand anomalies. Growth dominates the rest of fetal development, during which the fingernail fields develop and cartilaginous bones ossify.[66]

## Incidence

The estimated incidence of upper limb deformities has been studied in a longitudinal study of 261,914 live births in Sweden with a recorded incidence of 21.5 per 10,000 live births.[67] This result confirmed an earlier study from Western Australia, where an incidence of 19.8 per 10,000 was reported without an observed difference between Caucasian and non-Caucasian individuals.[68] The Centers for Disease Control and Prevention reported the following rates per 1000 live births: 0.8 for transverse deficiencies, 0.9 for syndactyly, 0.2 for polydactyly in Caucasians, and 0.12 for polydactyly in black persons.[69] In 40% to 50% of the cases, no clear cause can be determined. It is estimated that environmental factors account for 10% of limb anomalies. Rubella, cytomegalovirus (CMV), toxoplasma, and varicella in the first trimester have been linked to longitudinal deficiencies. Chemicals affecting limb development include thalidomide, ethanol, phenytoin, and warfarin. Many genetic syndromes (of Mendelian inheritance patterns or otherwise) have been associated with skeletal anomalies. Brachydactyly, clinodactyly, syndactyly, and polydactyly have been noted in trisomy 21; camptodactyly in trisomy 18; and polydactyly in trisomy 13.

## Congenital Hand Deformities: Classification and Treatment

The International Federation for Surgery of the Hand (IFSH) has established a seven-category classification system for hand deformities in 1976 (Table 130-1).[70]

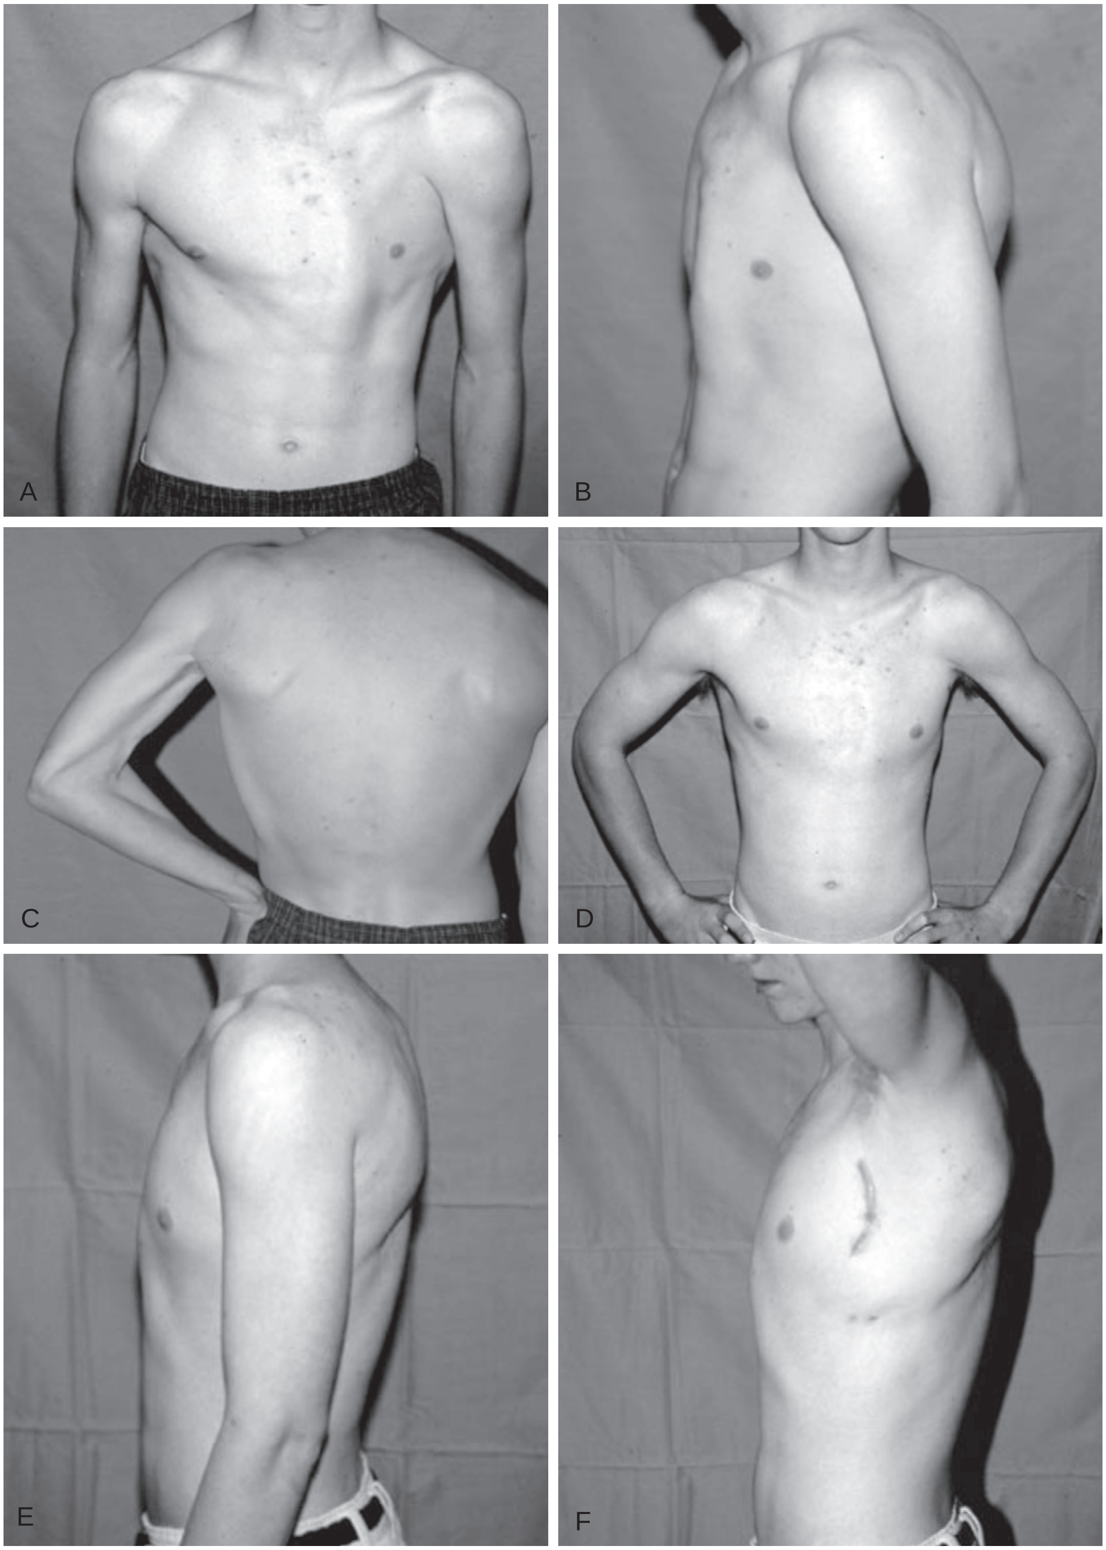

**FIGURE 130-6** Poland syndrome on the left side of the chest with an associated asymmetric pectus carinatum deformity. **A,** Preoperative anterior view. Note the absence of the left pectoralis muscle. **B,** Lateral view. **C,** Posterior view of the chest with the patient testing for the presence of the left latissimus dorsi muscle. Note the lateral edge of the muscle is visible with isotonic contraction. **D,** Postoperative anterior view. Note that functional transfer of the latissimus dorsi muscle to the anterior hemithorax provides contour correction and maintains latissimus dorsi function. **E,** Postoperative lateral view. The incision is concealed beneath the upper extremity. Note that the contour of the latissimus dorsi on the anterior aspect of the chest simulates the absent pectoralis muscle without contour deformity at the posterior chest donor site. **F,** A postoperative lateral view with the upper extremity abducted reveals the incision used for muscle harvest.

**TABLE 130-1**

**International Federation for Surgery of the Hand Classification System for Congenital Hand Anomalies**

1. Failure of formation
2. Failure of differentiation
3. Duplication
4. Overgrowth
5. Undergrowth
6. Congenital constriction band syndrome
7. Generalized skeletal abnormalities

***Failure of Formation*** Failure of formation is further divided into transverse and longitudinal arrest of development. Failure of formation has an incidence of 3.9 per 10,000 live births and contributes to 17.6% of all congenital hand anomalies.[67] Transverse deficiencies are congenital amputations, the most severe of which occur at the shoulder level and result in amelia. The short below-elbow defect, a common transverse deficiency, ends at the upper forearm. Prosthetic fitting should begin in infancy. Wrist disarticulation defects occur more often in girls than in boys. In this condition, the skeleton is absent beyond the distal radial and ulnar epiphyses, but pronation and supination abilities are generally maintained. In bilateral defects the Krukenberg procedure may be indicated on the dominant arm with a prosthesis worn only on the nondominant arm. The Krukenberg procedure separates the forearm bones into opposing prehensile forceps. Progressive length reduction defines longitudinal deficiencies, which may be preaxial (radial), postaxial (ulnar), central, or complete (phocomelia).[71]

**Radial Deficiencies** Radial deficiencies variably affect the radius, scaphoid, trapezius, trapezoid, and thumb, as well as associated musculotendinous, neural, and vascular structures. In the classic radial clubhand, the forearm is short, the hand is radially deviated, and the thumb is absent or floating. The defect begins in the first weeks of fetal life. Radial shaft development coincides with the development of the cardiac septum, which may explain the association of radial ray defects with the atrial septal defect found in Holt-Oram syndrome. Radial defects are also associated with vertebral defects, imperforate anus, esophageal atresia, radial and renal dysplasia syndrome (VATER or VACTERL), and blood dyscrasia such as Fanconi anemia and thrombocytopenia with absent radii (TAR) syndrome. Treatment begins shortly after birth; traditional methods stretch the hand (centralization) over the ulna by serial castings or distraction lengthening. Free fibula transfers have also been investigated.[71]

**Ulnar Defects** Ulnar ray deficiencies are rare and can be associated with defects of the fourth or fifth finger, elbow, humerus, or shoulder girdle (PS). Unlike the radius, which functions as a buttress for the wrist, the ulna may be deficient without any accompanying ulnar wrist deviation. Severity varies from hypoplasia to partial or total defects with or without humeroradial synostosis to ulnar deficiency with amputation at the level of the wrist. Prostheses such as an elbow disarticulation device can improve limb use. In selected patients, fusion of the ulnar remnant to the radius provides stability at the elbow.[71]

**Thumb Defects** The management of thumb defects depends on their severity. In total aplasia of the thumb, pollicization of the index finger is the most successful method of achieving functional opposition. Toe-to-thumb transfer is not successful because recipient nerve and tendon structures are absent and the brain lacks the motor and sensory homunculus for the thumb. Short thumbs can be lengthened by distraction osteogenesis. Widening of the first web space and tendon transfer to establish opposition may improve function. Floating thumbs are generally amputated and opposition is accomplished by pollicization of the index finger.[71]

**Central Longitudinal Deficiency** Central longitudinal deficiency, also known as *cleft hand* or *split hand,* applies to defects of the central (second, third, or fourth) rays. Typical deficiencies involve partial or complete loss of the central digit(s). Atypical deficiencies are syndactylous (the central finger remnants fuse to the second or fourth ray) or polydactylous. The polydactylous type contains supernumerary bony elements. Function determines treatment; appearance is a secondary consideration. Resection of the remnant third metacarpal assists closure of a deep cleft. Osteotomies correct rotatory deformities of the adjacent fingers. Thumb web space reconstruction is critical to overall hand function.[71]

***Failure of Differentiation*** Failure of differentiation includes soft tissue and skeletal failure of the separation of parts, as well as congenital tumors. Failure of differentiation is the most common congenital hand anomaly and has an incidence of 10.5 per 10,000 live births. It contributes to 47.2% of all congenital hand anomalies.[67]

**Syndactyly** Synostosis of the phalanges (symphalangism) is uncommon and usually occurs with syndactyly. Syndactyly itself is common and most often occurs between the middle and ring fingers. It has an estimated incidence of 5 per 10,000 live births.[72] True failure of differentiation is distinguished from the brachysyndactyly (short, webbed fingers) of PS and from acrosyndactyly with fusion of the distal digits secondary to a constriction band. Syndromes featuring syndactyly include Apert (acrocephalosyndactyly), Chotzen (cephalodactyly), Pfeiffer, and Golz; oculodentodigital; and trisomy 13.

Digits with acrosyndactyly should be separated before 1 year of age if the digits are of discrepant lengths or there is fusion of the phalangeal bones. In the absence of these features, separation can be performed at 2 to 3 years. The complexity of an Apert "mitten" hand presents a challenge to provide a functional hand with both prehensile function and fingertip sensation (Fig. 130-7). To this end, a three-finger hand is often preferable to four fingers and a thumb. The thumb and small fingers are released before 1 year of age. The remaining digits are separated within 6 to 9 months. Another feature of Apert syndrome is radioclinodactyly of the thumb (radial curvature of the thumb). Thumb osteotomy and bone graft are performed at 4 to 7 years of age, along with Z-plasty of the web space between the thumb and the index finger.[73]

**Congenital Flexion Deformities (Arthrogryposis)** Failure of soft tissue differentiation can lead to congenital flexion deformities. In the clasped thumb or thumb-in-palm contracture, the extensor pollicis longus, extensor pollicis brevis, and abductor pollicis longus muscle and tendon units are absent or attenuated. Splinting and manipulation begin in infancy, and surgical correction is delayed until 3 years of age. The clasped thumb must be differentiated from the trigger thumb, wherein a flexor pollicis longus nodule proximal to the A1 pulley interferes with interphalangeal and

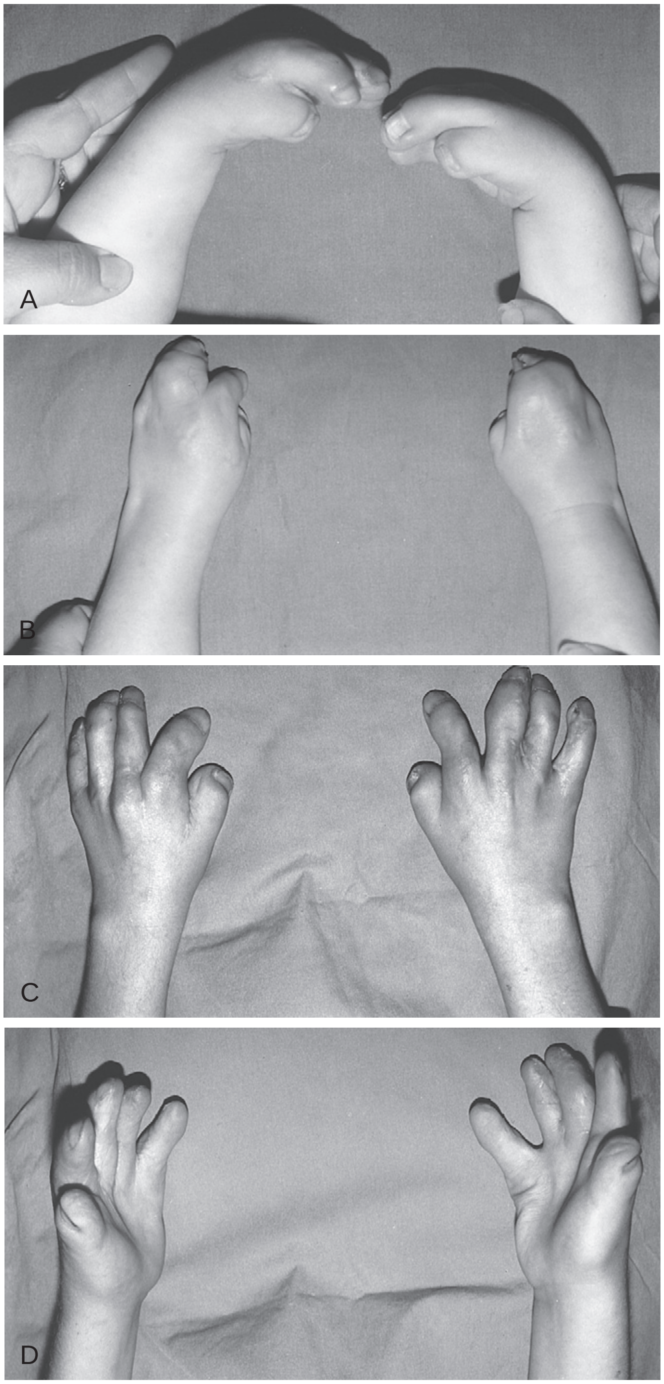

**FIGURE 130-7** **A,** Infant with Apert syndrome afflicted with the typical acrosyndactyly deformity of the hand. **B,** Complex bilateral acrosyndactyly. **C** and **D,** Postoperative appearance after release of syndactyly.

metacarpophalangeal extension. Because of a 30% spontaneous resolution rate, surgical trigger finger release is recommended for contractures that persist beyond 3 years of age.[74]

Clinodactyly most often affects the middle phalanx of the little finger and is seen in many syndromes (e.g., Treacher-Collins and Silver-Russell syndromes, orofaciodigital and oculodentodigital dysplasia). Camptodactyly refers to congenital proximal intraphalangeal flexion contracture, usually of the little finger, and is associated with such syndromes as Marfan, popliteal pterygium, and orofaciodigital and oculodentodigital dysplasia. Mild variants of camptodactyly can be found in up to 1% of the population.[75] If disabling or deforming, the contracture is released by dividing the flexor digitorum superficialis tendon and lengthening the volar skin with a full-thickness skin graft. In more severe cases arthroplasty or arthrodesis is performed. Arthrogryposis multiplex congenita features multiple congenital nonprogressive joint contractures and affects all extremities and the spine. In the upper extremity the shoulder may be flexed and internally rotated, the elbow flexed or extended, the wrist flexed and ulnarly deviated or extended and radially deviated, and the thumb and fingers flexed and ulnarly deviated.[74]

Arthrogryposis isolated to the hand manifests as the "windblown hand," with metacarpophalangeal flexion and ulnar deviation caused by malformation of the palmar fascia and retaining ligaments, with or without involvement of tendons and capsules. Thick, fibrous subcutaneous bands and shortened digitopalmar skin contribute to this malformation. Secondary metacarpal head deformation occurs with time. The thumb is flexed, and abduction is limited by a retracted volar carpal ligament and carpal skin.

Splinting and manipulation begins in infancy. If the deformity progresses, as often happens during the adolescent growth, operative intervention is indicated. Corrective procedures include release of the metacarpophalangeal joint capsule, ligament, and intrinsic tendon; relocation of the extrinsic tendon; metacarpal osteotomy; and division of palmar skin and fibrous bands followed by skin grafting for coverage.[74]

***Duplication of Parts*** Duplication of parts has an incidence of 5.9 per 10,000 live births and contributes to 26.5% of all congenital hand anomalies.[67] Duplication of parts occurs early in embryonic development. Polydactyly is a common hand malformation. Postaxial little finger duplication occurs more often than preaxial thumb duplication. Central duplications are rare. A flail, a poorly attached appendage, should be amputated early. Operative correction of preaxial polydactyly is sometimes delayed until 12 months of age, when functional evaluation is possible to identify the dominant (usually ulnar) thumb to be preserved. The collateral ligaments, even tendons and bony elements, of the ablated digit are salvaged for reconstruction of the retained digit. Alternatively, the Bilhaut-Cloquet procedure consisting of excising a central wedge from adjacent parts of both thumbs and then joining the remaining lateral portions can be performed. If the thumb resembles an index finger and cannot be opposed, treatment consists of rotational osteotomy, tendon transfer (e.g., Huber transfer of the abductor digiti minimi across the palm), and widening of the first web space.[76]

The mirror hand possesses seven or eight digits, one or two index with two ring and middle fingers, two ulnae, absent radius, absent thumb, and weak or absent extensor tendons. The hand loses its ability to pinch or grasp. An opposing digit needs to be constructed, and excess fingers should be discarded; the filleted skin is used to create a wide web space. Wrist arthrodesis may be required in early adolescence. Elbow motion may be improved by excising the olecranon off of one of the ulnae.[76]

***Overgrowth*** Congenital overgrowth anomalies are rare with an incidence of 0.4 per 10,000 live births and contribute to 1.7% of all congenital hand anomalies.[67] Digital gigantism

involves the overgrowth of bone and soft tissues. Classification has been difficult due to the wide range of etiologies for the overgrowth phenotypes and is beyond the scope of this chapter.[77] Classic type I macrodactyly is associated with lipofibromatous hamartoma of the median or (less frequently) the ulnar nerve. Phalangeal involvement is constant, and metacarpal involvement varies. Soft tissue overgrowth can affect skin and lymphatic or nerve structures, although flexor tendons and blood vessels may be spared. Gigantism of several adjacent digits is more prevalent than single-digit macrodactyly. Median nerve hamartoma can compress structures in the carpal tunnel. Type II macrodactyly is part of von Recklinghausen disease (neurofibromatosis). The distribution follows the path of a major peripheral nerve, most frequently the median nerve. Contrary to types I and II, type III macrodactyly (hyperostotic) is not associated with nerve enlargement but does follow the course of the sensory branches of the median nerve. Treatment has included epiphysiodesis, epiphyseal arrest, epiphyseal plate excision, multiple defatting procedures, longitudinal phalangeal osteotomies, soft tissue debulking, excision of distal nerves, and partial or ray amputation. Skin flap necrosis is not an uncommon complication after repair of macrodactyly.[78]

***Undergrowth*** Undergrowth malformations vary in the structures affected and the degree of the hypoplasia. Undergrowth anomalies have an incidence of 0.7 per 10,000 live births and contribute to 3.1% of all congenital hand anomalies.[67] Brachydactyly (shortened digits) is commonly seen in association with syndromic disorders, generally of autosomal dominant transmission. Ectrodactyly is the complete absence of phalanges or metacarpals. Short metacarpals are uncommon and often go unrecognized until the adolescent growth spurt; associated syndromes include pseudohyperparathyroidism, Turner, and cri-du-chat (chromosome 5p deletion). Treatment is usually unnecessary, but lengthening the affected ulnar metacarpals does increase palm size and improve grip. Lengthening procedures use either bone grafting or distraction osteogenesis.[79] Short phalanges are the major cause of brachydactyly. The middle phalanx of the little finger is the hand bone, the length of which varies the most, particularly in girls. Other than osteotomies to correct deviations, there is little role for operative intervention. Phalangeal lengthening procedures rarely improve function.[80]

***Constriction Band Deformities*** Constriction band deformities are rare (incidence of 0.3 per 10,000 live births, 1.7% of congenital hand anomalies) and occur during fetal rather than embryonic development.[67] The predominant theory is that amniotic bands wrapped around a limb cause local ischemia and necrosis. An alternate explanation proposes an intrinsic defect wherein hemorrhage or a local defect in the limb leads to necrosis of the superficial tissues. The necrotic area heals as a circumferential scar, and amniotic bands appear secondary to the limb injury. The distal regions of the extremities are more often affected than are proximal regions. Compression neuropathy distal to the constriction band scar has been reported. In the digits, acrosyndactyly results from tissue necrosis and fusion. Separations between the digits proximal to the fusion and distal transverse grooves or amputations characterize acrosyndactyly. For most constriction rings, simple or staged excision and Z-plasty suffice. Broad rings may require local flap coverage of large defects. Treatment of fused digits is individualized; separation may include cross-finger flaps, completion amputation, distraction lengthening, or free-toe transfer.[81]

## Summary

A wide spectrum of anomalies of varying severity can result from the congenital absence or alteration of tissues. Any anatomic region of the body can be affected. In determining the indications and timing for surgical correction, the severity of functional impairment, the degree of disfigurement, and the social pressures associated with the malformation must be considered. A sound plan of management relies on accurate diagnosis and analysis of the defect. Almost all defects can be systematically evaluated by the degree of malposition of normal structures, absence of tissues, and aberrations in tissue composition. Surgical correction can then be formulated to specifically address each component of the deformity. Using a systematic approach simplifies and optimizes a safe treatment plan for even the most complex malformations.

CHAPTER 131

# Conjoined Twins

Lewis Spitz, Edward M. Kiely, and Agostino Pierro

Conjoined twins can be subdivided into (a) symmetric conjoined twins, which form the main bulk of this chapter, and (b) heteropagus or parasitic twins.

## Symmetrical Conjoined Twins

### HISTORY

Although there are numerous examples of figurines depicting conjoined twins dating back to classical times, particularly among Aztec art and ancient Turkish culture, it is doubtful whether these were factual representations.

The earliest example is a 17-cm marble statuette portraying parapagus twins, "the double goddess," dating from the sixth millennium BC. The statue of sisters of Catalhoyuk is housed in the Museum of Anatolian Civilization in Ankara, Turkey.[1] Another early example that appears more authentic is a stone carving of pygopagus twins dating back to 80 BC, discovered in Fiesole and kept in the San Marco Museum in Florence, Italy (Fig. 131-1).

The earliest attempt at separation of conjoined twins took place in Kapadokia, Armenia, around 945 AD. When one of the male ischiopagus twins died at the age of 30 years, an attempt was made to save the surviving twin by separating him from his dead brother, but he died 3 days later.[1]

The first well-documented case is that of the Biddenden maids born in Kent in 1100 AD and "joined at the hips and the shoulders"[2] (Fig. 131-2). They lived together for 34 years. When Mary became ill and died, Eliza was advised to be separated but absolutely refused, saying, "as we came together we will also go together." She died 6 hours later. They amassed a vast fortune and bequeathed to the parish of Biddenden 20 acres of land with the expressed wish that proceeds from rent should be spent on the distribution of cakes, bearing an impression of their images, to be given to the poor each Easter Sunday—a practice that endures to the present day. It is impossible that they were joined as depicted in numerous illustrations at the hips and shoulders. The more plausible explanation was that they were ischiopagus or parapagus twins.

The Scottish Brothers were born near Glasgow in 1490.[3] They were two complete individuals above the waist but the lower half of their bodies was fused—one set of genitalia and two legs. They were taken to the court of King James IV, who ordered that they be carefully brought up and educated at court. They learned to sing, one tenor and the other treble bass; played various musical instruments; and became fluent in several languages. They often differed in opinions and sometimes quarreled. They died in 1518, aged 28 years.

Geoffrey-Saint-Hilaire cited an example of twin girls, born in 1495, joined at the forehead, causing them to stand face to face: "When one walked forward, the other was compelled to walk backward." They lived to the age of 10 years, and when one died an unsuccessful attempt was made at separation.[4,5]

In the sixteenth century, Ambroise Paré collected examples of six sets of conjoined twins and was one of the first to classify the different varieties of conjoined twins.[6]

The Isle-Brewer xiphopagus twins, Priscilla and Aquila, were born in 1680 joined "from the navel up to a point just below the nipples."[7] The vicar at their christening believed that the monstrous birth was a sign of impending evil. They were visited daily by hundreds of people keen to view "the monstrous work of Nature and admire so great a piece of curiosity." They were abducted by Henry Walrond and displayed but died in 1683.

The first successful separation of conjoined twins took place in 1689. The surgeon, Johannes Fatio, separated omphalopagus twins in Basel, Switzerland, by "tracing the umbilical vessels to the navel, where he tied them separately. He then transfixed and tied the bridge between the two infants with a silken cord and cut the isthmus." The ligature fell off on the ninth postoperative day, and both children survived. Koenig,[8] an observer at the procedure, published the case as his own and to him is credited the first successful separation.[9,10]

Table 131-1 lists the early history of conjoined twins dating back from the mid nineteenth century.

The most celebrated pair of conjoined twins was Chang and Eng Bunker, born on a riverboat in Siam (Thailand) in 1911. They were joined at the xiphisternum by a short band that stretched so that they were eventually able to stand side by side (Fig. 131-3). Their father was a fisherman, and the family lived on a floating houseboat on the Mekong River. They became proficient swimmers, and their peculiar movement attracted the attention of Robert Hunter, a traveling Scottish merchant, who eventually persuaded their mother to permit him to take them to the United States, where they were exhibited by Captain Coffin and later by the showman Phineas Barnum. They married sisters, lived in separate houses in North Carolina spending 3 days in each house alternately,

ELISA & MARY CHULKHURST

A 34 Y IN 1100

BIDDENDEN.

A SHORT, but conciſe account of ELISABETH, and MARY CHULKHURST, who were born joined together by the Hips and Shoulders, in the Year of our Lord 1100, at BIDDENDEN, in the COUNTY of KENT;

COMMONLY CALLED THE

Biddenden Maids.

THE Reader will obſerve by the above Plate of them, that they lived together in the above ſtate, Thirty-four Years; at the expiration of which Time, one of them was taken Ill, and in a ſhort time died; the ſurviving one was adviſed to be ſeparated from the body of her deceaſed Siſter, by diſſection, but ſhe abſolutely refuſed the ſeparation by ſaying theſe words, as we came together, we will alſo go together, and in the ſpace of about ſix hours after her Siſter's deceaſe, She was taken Ill, and died alſo.

BY their WILL, they bequeathed to the *Churchwardens* of the Pariſh of BIDDENDEN, and their ſucceſſors *Churchwardens* for ever, certain pieces or parcels of Land in the Pariſh of *Biddenden*, containing twenty Acres, more or leſs, which now lets at £.31 10*s*. *per Annum*. There are uſually made in commemoration of theſe wonderful phænomena's of nature, about 1000 Rolls with their impreſſion printed on them, and given away to all Strangers, on *Eaſter Sunday*, after Divine Service in the Afternoon; alſo about 300 Quartern Loaves, and Cheeſe in proportion, to all the poor Inhabitants of the ſaid Pariſh.

BIDDENDEN: PRINTED AND SOLD BY R. WESTON

A

THE Reader will obſerve by the above Plate of them, that they lived together in the above ſtate, Thirty-four Years; at the expiration of which Time, one of them was taken Ill, and in a ſhort time died; the ſurviving one was adviſed to be ſeparated from the body of her deceaſed Siſter, by diſſection, but ſhe abſolutely refuſed the ſeparation by ſaying theſe words, as we came together, we will alſo go together, and in the ſpace of about ſix hours after her Siſter's deceaſe, She was taken Ill, and died alſo.

B

and had 21 children between them. Physiologically and psychologically they were totally different—Chang was smaller and more feeble; what Chang liked to eat, Eng detested; Eng was good-natured, Chang cross and irritable; Chang drank heavily, but Eng appeared unaffected by the alcohol. They wished to be separated but could not persuade surgeons to carry out the operation, which was considered to be too hazardous at the time. In retrospect, according to the autopsy findings, the procedure would have been quite straightforward because the connecting bridge between them contained only a small tongue of liver.[11–13] They lived together for 63 years and died in 1874.[14,15]

In 1840 an African village was raided, and many of the residents were sold to a slave trader and transported by ship to America. During the voyage, a woman gave birth to xiphopagus twins by cesarean section by the naval surgeon Brito y Boin, who surgically separated them. The mother died the next day, and one of the twins died 2 days later. Another slave woman took the surviving twin and raised him. He had keloid scars removed at age 8 years and was still reported as being alive at the age of 66 years at that time.[16]

In 1860 a physician separated his own omphalopagus twin daughters. The incision was closed with three through-and-through sutures. One twin died, but the other was well 5 years later.[17]

The "first successful separation of conjoined twins" was performed at The Military Families Hospital in Portsmouth, England, in 1912. One twin survived, but the other died of pneumonia at the age of 4 months.[18]

The Tocci Brothers, born in 1877, were extensively united parapagus conjoined twins. They also wished to be separated, but the extent of their union dictated that surgery at the time was clearly not feasible. They lived together for 63 years and died in 1940.[19,20] Other conjoined twins have declined any suggestion of separation. Lori and Reba Schappell, craniopagus twins, born in 1961, never wanted to be separated, stating "God made us this way and He had a purpose for us and you do not ruin what God has made."[15]

In 1990 Hoyle[21] reviewed all attempts at surgical separation of conjoined twins, performed successfully and unsuccessfully, through 1987. Of a total of more than 600 publications, separation was attempted in 167 cases. The survival rate increased dramatically in the most recent decade before 1987. He concluded that "the current excellent outcomes (for separation) suggest that separation should always be considered with rare exceptions."

## ETIOLOGY AND EMBRYOLOGY[22,23]

In the absence of an experimental model, the exact etiology of conjoined twins is unknown. The uncertainty between fission and fusion theories remains. Because it seems likely that fission of a single fertilized ovum occurs in the same manner each time, the wide variety of types of conjoined twinning make fusion the more likely mechanism. Unlike identical monovular twins, conjoined twins often have remarkably different personalities. This difference in personality is clear from the early months of life and remains unexplained. The inference may be drawn that these twins may not always result from monovular pregnancies. Regardless of the mechanism, twins are always joined homologously—chest to chest, pelvis to pelvis, etc.—and are always the same sex. Spencer has

**TABLE 131-1**

**History of Conjoined Twins to 1851**

| *Yr* | *Type* | *Sex* | *Details* | *Outcome* | *Origin* |
|---|---|---|---|---|---|
| 6500 BC | Dicephalic | Female | Marble statuette “Double goddess” | Unknown | Turkey[1] |
| 500-800 BC | Dicephalic | ? | Various clay figures Figure 131-1 | Unknown | Mexico[5] |
| 80 BC | Pygopagus | ? | Stone carving | Unknown | Fiesole, Florence, Italy |
| 375 | Dicephalus | Male | One twin ate and slept, but the other did neither | Died at age 2 | Castle of Emaus, England[19] |
| 945 | Thoracopagus | Male | Attempt at separation after one twin died aged 30 years | Died at age 30 | Kappadokia, Armenia[1] |
| 961 | Dicephalus | Female | When one laughed, ate and talked, the other wept, fasted, and was silent | Unknown—both died in the space of 2 days | Gascony, France[19] |
| 1100 | ? Ischiopagus | Female | Joined at hips and shoulders | Lived for 34 years—when one died, the survivor refused separation | Biddenden, Kent, England[2] |
| 1490 | Dicephalus | Male | Scottish brothers—brought up in the court of King James IV of Scotland | Musical and linguistic—lived to age 28 | Glasgow, Scotland[19] |
| 1495 | Craniopagus | Female | Joined at the foreheads—when one walked forward, the other walked backward | Lived to age 10—when one died, attempt at separation failed | Worms, Germany[5] |
| 1533 | Omphalopagus | Female | Umbilicus to stomach Liver | Died after 8 days | Hispaniola[57] |
| 1552 | Pygopagus | ? Male | Three lower limbs | ? | Middleton Stony, Oxon. England[58,59] |

| 1576 | Ischiopagus | Male | Born in the Jewish ghetto of Venice | Impossible to circumcise—threat of anti-Semitism Died soon after birth | Venice, Italy[5,60] |
| 1664 | Pygopagus | Female | Waterman—Martha and Mary | Lived for 2 days Normal female triplet | Somerset, England[61,15] |
| 1668 | Dicephalus | Female | “Fair maidens of Foscott” | Apparently lived to a “mature age” | Somerset, England[19] |
| 1670 | Thoracopagus | Female | One twin had esophageal atresia | Died at birth | Plymouth, England[62] |
| 1680 | Pygopagus | Female | “The Isle-Brewers Twins” | Died at age 3 | Somerset, England[7] |
| 1680 | Craniopagus | Female | Voyoen-Pieternella and Barbara | One slept while the other was awake, crying, and eating | Bruges, Belgium[5,63] |
| 1689 | Omphalopagus | Female | Connecting bridge ligated at 2 days old—both survived | Both survived Surgeon—Fatio Reported by Koenig | Basel, Switzerland[9] |
| 1701 | Pygopagus | Female | “Hungarian Sisters” Helen—active and intelligent Judith—hemiplegic | Lived to age 22 | Szony, Hungary[5] |
| 1706 | Parapagus | ? | Single trunk, 4 arms and legs | 30 minutes | Hitchin, England[58] |
| 1783 | Craniopagus | Male | “Two-Headed Boy of Bengal”—separate brains | Died after being bitten by a cobra at age 4 yr | India[64] |
| 1811 | Xiphi-omphalopagus | Male | Connecting bridge contained liver only Married sisters—had 21 children | Lived for 62 yr | Mekong, Siam (Thailand)[15,14] |
| 1829 | Parapagus | Female | Parodi—Ritta (weak, cyanotic) and Christina (healthy, voracious appetite) | Died at 8 months old Ritta—severely deformed heart—2 superior vena cavas | Sardinia, Italy[15] |
| 1848 | Ischiopagus | Female | “Martha and Maria” | Lived 10 days | Copenhagen, Denmark[15] |
| 1851 | Pygopagus | Female | “Millie and Christine” McKoy. Walked at 12 mo | Lived to age 61—died 1912 | North Carolina, USA[15] |

FIGURE 131-3 Portrait of Chang and Eng from the Royal College of Surgeons of England, London.

proposed that union occurs at sites where ectoderm is absent or programmed to disrupt or fuse. The fusion theory suggests that two separate embryonic discs from a monovular pregnancy lie on the surface of a single yolk sac. At around the third week of pregnancy, fusion occurs at sites where the ectoderm is not present or where it is disrupted. Ectoderm is absent over the precursors of the septum transversum and heart. Fusion at this level results in thoracopagus and omphalopagus twins. Ectoderm disrupts at the sites of the oropharyngeal and cloacal membranes and fuses at the edge of the embryonic disc. Union at these sites results in cephalopagus, ischiopagus, and parapagus twins. Dorsal union—craniopagus, rachipagus, pygopagus—results in each twin having its own umbilicus and separate abdomen. The other types of union are considered ventral and usually share a single cord and peritoneal cavity. These cords will frequently have more than three vessels. Associated anomalies are common and predominantly affect the structures that are joined. The patterns of abnormality encountered depend on the type of union, and each of the eight types of twinning has a range of associated anatomic defects.

These abnormalities may preclude extrauterine survival and may render separation impossible. According to Spencer, thoracopagus twins always have a single heart with multiple chambers and separation is rarely an option. Others have been less rigid in their definition of thoracopagus, and there have been well-documented cases in which separation of thoracopagus with separate hearts has been successful.

## INCIDENCE

The frequency of conjoined twins has been estimated at 1:50,000 pregnancies, but because up to 60% of these twins succumb in utero the true incidence is 1:250,000 live births. With the advent of routine prenatal ultrasound, the early diagnosis of the nature of the problem will become evident early in gestation and elective termination will be an option.

Female twins predominate in the ratio of 3:1.

## CLASSIFICATION[23–25]

Conjoined twins are classified on the basis of the union's site, with the suffix pagus meaning fixed or fastened. The twins can have four (tetrapus), three (tripus), or two (bipus) legs. The classification of conjoined twins, limited to eight types with approximate percentages of frequency, is summarized in Table 131-2.

1. *Thoracopagus:* The twins lie face to face and share the sternum, diaphragm, upper abdomen wall, and liver and have an exomphalos (Fig. 131-4). In the majority of cases they share the pericardium (90%) and heart (85%). They may have a common small intestine (50%), which joins at the duodenum and separates at the ileum; the biliary tree can be joined in 25% of patients. There may be associated

**TABLE 131-2**
**Characteristic Features of Different Conjoined Twins**

| *Type of Fusion* | *Incidence* | *Extent of Union* | *Shared Structures* |
|---|---|---|---|
| **Ventral (87%)** | | | |
| Cephalopagus | 11% | Top of head to umbilicus | |
| Thoracopagus | 19% | Thorax | Liver 100% |
| | | Upper abdomen | Pericardium 90% |
| | | Conjoined hearts 85% | Cardiac defects 75% |
| | | | Upper intestine 60% |
| | | | Biliary tree 17% |
| Omphalopagus | 18% | Upper abdomen | Liver 90% |
| | | Separate hearts | Upper foregut 16% |
| | | | Cardiac 25% |
| Ischiopagus | 11% | Cloacal membrane | Pelvic bones 100%<br>Lower gastrointestinal tract 70% |
| | | | Genitourinary 50% |
| Parapagus | 28% | Cloacal membrane | Cardiac 75%<br>Intestine 100% |
| | | | Liver 100% |
| | | | Genitourinary 100% |
| **Dorsal (13%)** | | | |
| Craniopagus | 5% | Cranial neuropore | Skull, venous sinus, and meninges 100% |
| | | | Cerebral cortex 37% |
| Rachipagus | 2% | Neural tube | Vertebral column |
| Pygopagus | 6% | Caudal neuropore | Sacrum and coccyx 100% |
| | | | Lower gastrointestinal tract 25% |
| | | | Genitourinary tract 15% |

**FIGURE 131-4** Thoracopagus conjoined twins sharing a heart.

**FIGURE 131-5** Omphalopagus.

cardiac anomalies such as ventricular septal defect, atrial septal defect, and tetralogy of Fallot.

2. *Omphalopagus:* The heart is never fused; the liver is joined in 80% of cases, and there is an exomphalos (Fig. 131-5). The stomach and proximal small bowel are usually separate, and each twin has a rectum. In up to one third of omphalopagus twins, the intestine usually joins at the Meckel diverticulum, the terminal ileum and colon are shared, and a dual blood supply may exist. There is usually no union of the genitourinary tract.
3. *Pygopagus:* The twins are joined dorsally, sharing the sacrococcygeal and perineal regions (Fig. 131-6). They face away from each other—share the sacrum, coccyx, and part of the pelvic bones. The spinal cords are usually separate.[26] Twenty-five percent share the lower gastrointestinal tract and have a single anus and one or two rectums. In 15% of cases there is a single bladder. There is an increased incidence of vertebral anomalies including hemivertebrae, hemisacral agenesis, and thoracic anomalies.[27] Although the pelvic conjunction is fundamentally different than in ischiopagus twinning, the types are similar insofar as numerous other associated orthopaedic anomalies have been reported in association with pelvic conjunction such as hip subluxation or dislocation, congenital vertical talus, talipes equinovarus, Sprengel shoulder, and scoliosis. There can also be a variable degree of spinal and cord fusion. Although there may be only one anus and rectum, the remainder of the intestines are usually separate. The upper bodies are not fused, and there are four arms and four legs.
4. *Ischiopagus:* The twins may lie face to face or end to end (Fig. 131-7). They have two sacra or two symphysis pubis. They may share the lower gastrointestinal tract (70%) and/or the genitourinary tract (50%) and may have crossing

**FIGURE 131-6** Pygopagus.

**FIGURE 131-7** Ischiopagus.

ureters. The twins can be tetrapus, tripus, or bipus, although the most common arrangement is the presence of four legs. Pelvic conjunction leads to complex urogenital and orthopedic anatomy. The kidneys usually function normally but are often malrotated or ectopic in location. When two bladders are present, they lie side by side in a collateral position or they may lie in a sagittal midline location with one bladder draining into the other. The ureters frequently cross over and insert into a contralateral bladder such that they will need to be rerouted during separation. Partial urethral duplication is possible, but a single urethral orifice is typical. The distal gastrointestinal tract is often shared, with anorectal agenesis and rectovesical fistula. Contrast studies are necessary to delineate distal bowel anatomy. Urogenital sinus or cloaca may be present. In boys there is an increased incidence of undescended testes.

5. *Craniopagus:* The conjoined twins share the skull, meninges, and venous sinuses (Fig. 131-8). The brains are usually separate, although some cortical fusion can occur in 33% of cases.
6. *Cephalopagus:* The twins often have a fused thorax in addition to a fused head. The single fused head may have two faces (janiceps) facing away from each other; one face may be rudimentary. These twins are terminated or die in utero. They are nonviable.

**FIGURE 131-8** Craniopagus.

7. *Rachipagus:* The twins generally have vertebral anomalies and neural tube defects.
8. *Parapagus:* This is a relatively new term denoting extensive side-to-side fusion (Fig. 131-9). The twins share the umbilicus, lower abdomen, pelvis (single symphysis pubis), and the genitourinary tract. They can have anorectal anomaly and colovesical fistula and may be at risk of anencephaly.

## DIAGNOSIS

### Antenatal Diagnosis and Imaging

Fetal ultrasound can detect the presence of conjoined twins in almost all cases. Accurate antenatal assessment allows the parents to be counseled about the probable outcome of the pregnancy and the likelihood of successful postnatal separation. Prenatal diagnosis of conjoined twins is important for optimum obstetric management including decisions regarding termination of pregnancy and the timing and method of delivery to minimize maternal and fetal mortality.

***Fetal Ultrasound*** Prenatal ultrasonography (US) is capable of diagnosing conjoined twin pregnancies as early as 12 weeks' gestation.[28–30] Transvaginal US may also aid early diagnosis.[31] Diagnosis of conjoined twins may be straightforward when fusion of fetal parts is obvious (Fig. 131-10). In addition, the possibility of conjoined twins should be suspected in a twin

**FIGURE 131-9** Parapagus. (From Spitz L, Stringer MD, Kiely EM, et al: Separation of brachio-thoraco-omphalo-ischiopagus bipus conjoined twins. J Pediatr Surg 1994;29:477-481.)

**FIGURE 131-10** Prenatal ultrasound of conjoined twins.

pregnancy with a single placenta and no visible separating amniotic membrane. Conversely, observation of two placentas or an amniotic membrane excludes conjoining.[32] The sonographic findings in conjoined twins include inseparable fetal bodies and skin contours, an unchanged relative position of the fetuses, both fetal heads persistently at the same level, bibreech or bicephalic presentations, fewer limbs than expected, and a single umbilical cord with more than three vessels.[32] Most conjoined twins face each other and are fused ventrally, resulting in hyperextension of their cervical spines. Polyhydramnios occurs in up to 50% of conjoined twin pregnancies compared with 10% of normal twins and 2% of singleton pregnancies. Detailed US assessment at around 20 weeks' gestation should be able to define the site and extent of the conjoined area and provide a reasonable evaluation of which viscera are, and are not, shared.

Fetal echocardiographic assessment needs to be detailed because there is an increased incidence of congenital heart disease in conjoined twins overall, particularly thoracopagus twins.[33] A shared heart is seldom compatible with life and usually an indication for termination of the pregnancy. Hearts can be confirmed as separate when they are seen to be anatomically separate or when the heart rates are different. It has been the experience of many authors that fetal echocardiography underestimates the severity of cardiac anomalies.[32]

The thoracopagus heart typically has six chambers. Due to the abnormal cardiac anatomy and function, an increased nuchal translucency and subcutaneous edema have been noted in thoracopagus twins in particular.[29] Communications at the atrial and ventricular levels can often be well defined with US. However, the great vessel relationships and atrial morphology are often difficult to determine. Prenatal US does, nevertheless, provide an opportunity to accurately define the morphologic connections among the various chambers of the hearts. That is important because the state of the cardiac conjunction is the fundamental pointer to eventual outcome. Prenatal echo is made easier by amniotic fluid, particularly polyhydramnios in later pregnancy, acting as an acoustic window, and the lack of lung aeration permits US evaluation from different approaches. Prenatal diagnosis can be technically easier for the operator because it avoids the anatomic constraints of scanning fused chests postnatally, and fetal fluid-filled lungs may allow better images.[35]

Recently three-dimensional (3D) US imaging has been advocated as a new tool to demonstrate the extent of fusion in conjoined twins. 3D US may add anatomic information and thus improve the accuracy of classification of individual twins.[33,35] In some cases the category of conjoined twins is suspected by two-dimensional scanning but can be better appreciated on 3D US. It would seem sensible, however, to postpone attempts at detailed 3D US until after 14 weeks' gestation, when better views of the anatomy can be obtained.[30] Although 3D US may add more information regarding the extent of the union in utero, it is questionable whether these findings affect management prenatally.[33]

***Magnetic Resonance Imaging*** Magnetic resonance imaging (MRI) can be superior to US for overall fetal assessment. MRI, with its ability to differentiate soft tissues, provides an excellent alternative technique.[33] Ultrafast T2-weighted (T2-W) sequences of short duration such as the single-shot fast spin-echo sequence allow minimal image degradation by fetal motion and high-quality images of fetal organs without the need for fetal or maternal sedation.[36] The larger field of view of MRI permits better evaluation of the spatial relationships of anatomic anomalies or between normal structures (Fig. 131-11). Additional 3D MRI models may be useful in specific circumstances.[37]

### Postnatal Imaging

The choice of imaging study will depend to some degree on the site of fusion. All conjoined twins should have chest and abdominal radiography for an overall general assessment, as well as to help health professionals understand the extent of the conjoined area. Unexpected diaphragmatic hernia or vertebral anomalies can thus be detected early.

***Ultrasound*** All neonates should have routine cerebral US and, when indicated, a spinal US as baseline investigations.[33] In addition, abdominal US to assess the liver and to document the presence of two spleens, gallbladders, biliary systems, bladders, and four kidneys is necessary. Detailed Doppler studies to evaluate the great vessels in the abdomen and hepatic venous drainage should also be performed, but midline abdominal conjunction may make accurate Doppler assessment unreliable. Meticulous labeling of the images ensures the correct twin is consistently noted to be on the same side.

***Echocardiography*** Echocardiography (ECHO) is mandatory for every twin due to the high frequency of congenital heart disease. 3D ECHO has been advocated postnatally to make it easier to understand the cardiac connections and help plan treatment.[35] Andrews and colleagues[35] analyzed 23 sets of conjoined twins and classified twins according to the degree of cardiac fusion as follows: separate hearts and pericardium (group A, $n = 5$), separate hearts and common pericardium (group B, $n = 7$), fused atria and separate ventricles (group C, $n = 2$), and fused atria and ventricles (group D, $n = 9$). The degree of cardiac fusion was correctly diagnosed in all but one set. The intracardiac anatomy was correctly diagnosed in all cases, although the antenatal diagnosis was revised postnatally in three cases. Abnormal intracardiac anatomy was found in one twin only in two group A pairs, one group B pair, and both group C pairs. All group D twins had abnormal anatomy. Ventricular function was good in all twins scanned prenatally, and postnatally function correlated well with clinical condition. None of the twins from groups C or D survived

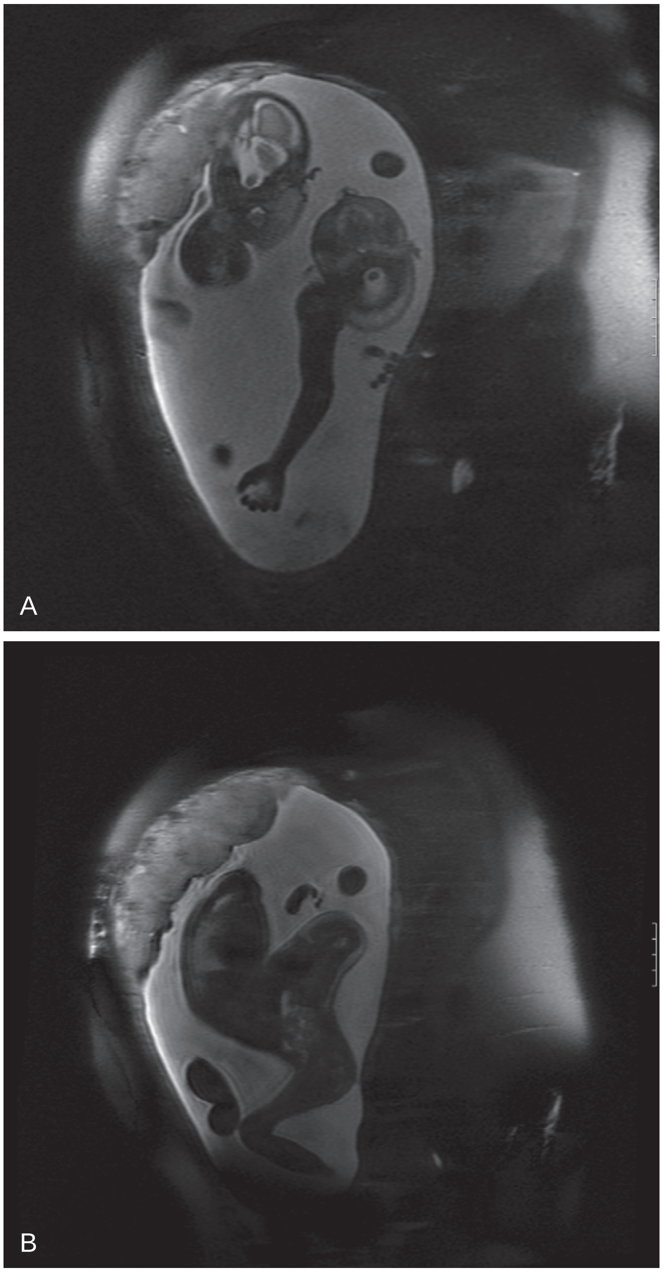

**FIGURE 131-11** **A,** Prenatal magnetic resonance imaging of conjoined twins. **B,** Scan of twins showing abdominal conjunction.

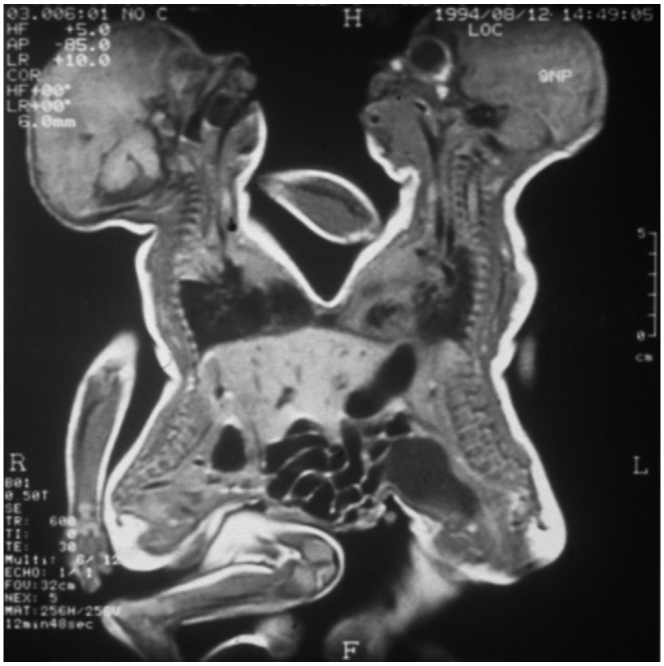

**FIGURE 131-12** Computed tomography scan of thoracopagus conjoined twins.

**FIGURE 131-13** Contrast-enhanced computed tomography showing conjoined liver and large arterial connection.

demonstrating that the outcome in twins with fused hearts remains dismal.

***Computed Tomography*** Radiologists avoid CT where possible in infancy due to the high radiation burden. Conjoined twins, even when stable and asymptomatic, are a well-justified exception. Due to the high spatial resolution and speed in particular of multidetector CT (MDCT), it is the best overall modality for evaluating conjoined twins in the postnatal setting (Fig. 131-12).

Contrast enhancement is mandatory to assess the vascular anatomy and so prior cannulation to minimize the stress of the procedure is advisable. Intravenous contrast agents (Fig. 131-13) for CT are given[33]; this can demonstrate the shared liver and vascular connections. Delayed images give very useful information on excretion by both twins' kidneys, the ureteric anatomy, and the location and number of bladders. Separate studies examining each twin's vascular anatomy on different days are recommended.[33]

***MRI*** MRI has an increasing role in the postnatal evaluation of conjoined twins, particularly those joined at the head or thorax (Fig. 131-14). MRI has the capability of producing 3D-reconstructed images in any direction with much better resolution and tissue characterization than 3D US. MRI is the optimum examination to assess for any cortical fusion in craniopagus twins. Although the ultrafast sequences such

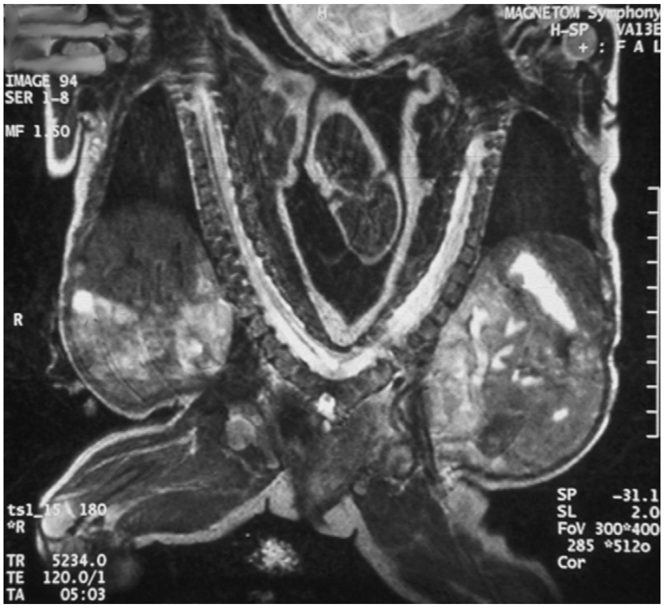

FIGURE 131-14 Postnatal magnetic resonance imaging: coronal T1 image after contrast administration to the right twin showing enhancement of that twin's liver parenchyma.

as single-shot T2-W images have advantages in the constantly moving fetus, more conventional T1-W, T2-W, and T1-W images after IV gadolinium administration are used in the postnatal imaging of conjoined twins. Intracardiac anatomy, great vessel anatomy and blood flow, and ventricular wall motion can all be accurately assessed in thoracopagus cases. Many complex fusions will inevitably get both MRI and MDCT. These modalities are often complementary with MRI showing soft tissue anatomy to best effect and CT detailing complex bony anatomy in pelvic conjunction. MRI with magnetic resonance cholangiopancreatography (MRCP) is likely to offer the best hope of assessing the biliary anatomy. Liver anatomy can be best appreciated after intravenous contrast enhancement, either via CT or MRI. Additional coronal or 3D reconstructions will provide further information. Demonstration of separate hepatic venous drainage into the inferior vena cava and right atrium of each twin is essential to plan separation as absent or severely anomalous hepatic venous drainage in one twin is incompatible with survival after surgery.

It is not unusual to find large-caliber vessels crossing the area of fusion. It is important to visualize these vessels by CT or MRI before separation to minimize blood loss and mortality during separation. It is rarely necessary to perform an angiogram before separation to clarify the vascular anatomy.

***Contrast Studies of the Gastrointestinal and Genitourinary Tracts*** Abdominal conjunction often involves fusion of parts of the intestine. In addition, there is always a common peritoneal cavity. Even in the absence of fused bowel, when contrast medium is given to one twin the bowel loops may be freely mobile across the "midline" and be seen to project into the peritoneal cavity of the other twin during fluoroscopy.[33] Pelvic conjunction leads to complex fusion and anomalies in the anorectal region. These require an individual approach with contrast studies (enemas, loopograms, and cystograms) of the distal bowel and bladder. Although performed in many cases, in practice, contrast studies provide limited information and often, particularly due to overlapping bowel loops, the anatomy can only be revealed at the time of separation.[38]

Urologic abnormalities are confined to those in whom the pelvis is joined: ischiopagus, parapagus, or pygopagus twins. Most twins share four kidneys and two bladders, occasionally with one ureter crossing from the contralateral twin to the other. The bladders are usually side by side, but they may be sagittally placed, which presents a reconstructive challenge.[39] CT scanning usually provides sufficient information regarding the upper renal tracts and bladders. Detailed urethral anatomy and possible fistulas require retrograde contrast medium examinations.

***Nuclear Medicine*** The kidneys, albeit ectopic or too few in number, usually function normally in conjoined twins.[33] Cross-sectional imaging can usually clarify the genitourinary anatomy without the need for isotope renography studies. There is an increased frequency of pelviureteric or ureterovesical obstruction in these twins, but this is seldom of major importance before separation.

Although hepatobiliary agents have been used to demonstrate separate biliary drainage, these are seldom necessary in practice. It is important to demonstrate the presence of two separate gallbladders. When two gallbladders are definitely seen in thoracopagus or omphalopagus twins, the likelihood of separate biliary systems is high.[40] When twins share the liver or have shared hepatic veins or other large shunts, then mixing of blood precludes the use of a hepatobiliary radiopharmaceutical. Despite detailed preoperative imaging, complex biliary anatomy may only become apparent at the time of surgery. MRCP may have a particular role to play in this area in the future. Individual twins raise unique individual dilemmas, and nuclear medicine studies may nevertheless be useful in specific circumstances.

## Obstetric Management

Delivery should take place at, or close to, the surgical unit where separation will be performed. Delivery must always be by classical cesarean section at 36 to 38 weeks' gestation.

## Anesthetic Management

Anesthesia involves two completely separate teams with all members being clearly aware for which twin they are responsible.[41] All drugs and intravenous fluids administered are calculated on a total weight basis with half being delivered to each twin. Because of the cross-circulation, drugs given intravenously may have an unpredictable effect and particular care must be taken to administer such drugs incrementally. Endotracheal intubation should be via the nasal passage for added security during repositioning, especially once separation has been achieved and the infants are moved into separate operating rooms or onto separate operating tables, as well as for continuing respiratory support postoperatively. Full arterial and central venous monitoring is essential and, in addition, ECG, pulse oximetry, capnography, and urine output must be carefully monitored. All lines and monitoring cables must be color coded for the individual twin to avoid confusion during repositioning. Adequate venous access is essential because brisk hemorrhage may be encountered, necessitating

rapid large-volume transfusion. Cardiovascular monitoring is particularly important because, with relative changes in position of the two infants, significant shifts in blood volume may occur.

### Separation Procedure

The key to a successful outcome is thorough preoperative planning. From the imaging, the extent of major organ union will be apparent, and the details of each phase of the procedure are planned in advance. The order in which these phases of separation will be performed is best decided during the operation itself because operative findings will often dictate a different sequence of events to what was originally envisaged.

Many anatomic variants exist for each of the different types of union. For instance, although the liver is joined in 100% of thoracopagus twins, in 50% there is intestinal union in addition. The surgeon will need to have planned for each possibility—such as what to do if there is a single duodenum or a single common bile duct.

In the most extensive forms of ischiopagus or parapagus union, the terminal ileum and the large bowel are single. Allocation of these structures cannot be planned in detail because the mesenteric blood supply is abnormal and unpredictable. As a general rule, these children have two bladders, which may lie side by side or anteriorly and posteriorly. Plans must be in place to deal with either eventuality, together with plans for dealing with crossed or uncrossed ureters. Finally, there may be a single urethra, although more commonly there are two urethras. Finally, with extensive union, there will be a substantial body wall defect after separation. The management of this problem also needs to be planned in advance. We have used tissue expanders in the past and found them to be troublesome and unhelpful in providing substantial extra tissue. With the sole exception of craniopagus twins, we would not recommend their use. We use polypropylene mesh over a plastic liner to close the defect and plicate this, as one would with any other abdominal wall defect. Even with the largest of defects, the body wall can be closed within 2 weeks.

Initially, one surgical team comprising both lead surgeons is sufficient to commence the procedure. Our preference is to start the operation posteriorly. The skin and soft tissue are divided down to muscle and fascia. The wound is then sutured closed, and the babies are turned around. We have done this with the more extensive unions; otherwise, it is difficult to allocate body wall equally and one may easily leave one with significantly less. Although this sounds cumbersome, we have never regretted taking the time for this maneuver. Once this incision has been made, it is easy to complete the separation at the final stage of the operation.

If a vestigial limb is present posteriorly, it may be bivalved and divided and the bones filleted out. This provides vascularized healthy tissue to assist in closure. Allocation of this extra tissue is decided at the time of surgery.

On opening the chest and abdomen anteriorly, it is usually best to divide the conjoined sternum to improve access. The lobar anatomy of conjoined livers is not readily discerned, and in any case it is not necessary to be precise about this. A point is chosen, midway between the gallbladders and the porta hepatis on either side, and the liver is divided in the usual manner. The use of an ultrasonic dissector combined with one of the high-energy sealing devices results in virtually bloodless conditions.

Once the liver is divided, the remainder of the gastrointestinal anatomy is easier to manage. The urologic aspects are dealt with before the decision about allocating the rectum.[39] Usually each twin has a bladder and at least a posterior urethra. Occasionally, two bladders lying fore and after are divided and the two halves are united on either side. If the bladders are side by side, the division takes place between them. In ischiopagus and parapagus twins the ureters may cross into the opposite twin's bladder. Our experience suggests that in almost all cases, it is possible to preserve at least one corpus of the penis for each twin. Occasionally, there are three or more corpora cavernosa in which case a more normal penis will result.

Once the urologic aspect has been completed, a decision is made on allocation of the rectum and anus. This will depend on the blood supply that is available. It has been our practice to leave the terminal ileum and colon with one twin while leaving the rectum with the other when conditions permit.

Once the pelvic viscera have been allocated, the posterior part of the pelvic ring is divided. Preoperative imaging will have revealed if there are substantial vessels crossing at this level. Finally, the previously sutured skin wound is opened and separation is complete.

Closure of a large body wall defect is straightforward. If the sternum is short and the heart or pericardium is exposed, a polypropylene patch is sutured to the chest wall laterally and superiorly and to the diaphragm inferiorly. This patch is left permanently in situ. The abdomen is closed by suturing two flaps of polypropylene mesh to the muscle on either side and covering the viscera with a plastic liner such as an intestinal bag.

Usually there is sufficient skin to cover the chest wall defect. The skin over the abdomen is tacked to the mesh to cover the area where the mesh is sutured to muscle (Fig. 131-15). This allows tissue to grow from the fascia through the mesh to the overlying subcutaneous fat and ensures a strong attachment of mesh to muscle.[42–46]

### Postoperative Management

Almost all these patients are electively ventilated after surgery with the usual monitoring that is used after major surgery. There are, however, two problems that are not common in other children—fluid loss and cardiac performance.

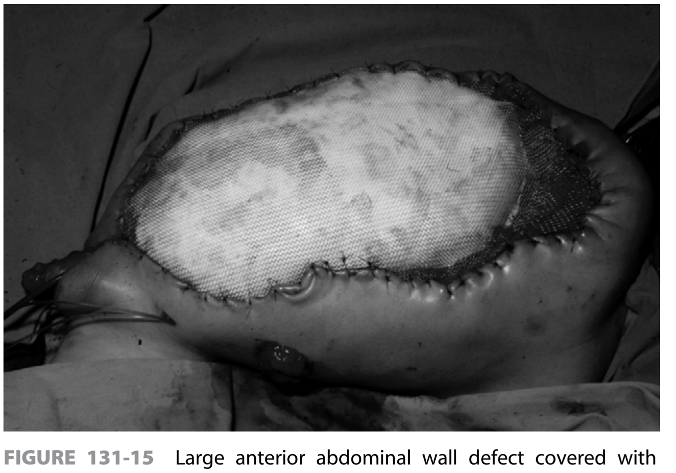

**FIGURE 131-15** Large anterior abdominal wall defect covered with polypropylene (Prolene) mesh after separation.

If the abdomen has been closed with a mesh, there will be substantial fluid losses for the first few days.

We estimate the losses by use of absorbent gauze dressings, which are weighed on an hourly basis. The fluid is then replaced milliliter for milliliter with human albumin solution. The mesh is tightened, commencing on the day after operation, although for the first few days, the degree of tension applied is limited. However, after the first 4 days, increasing tension can be applied to the mesh because it is tightened and the abdominal wall stretches and grows in an impressive fashion. It is usual to achieve abdominal wall closure within 2 weeks.

The other aspect in which conjoined twins differ is in cardiac performance. It is a feature of those who have extensive union that one circulation supports the other. In general, the thinner and more active twin has a heart that is more robust and supports the other twin's circulation. This difference in cardiac performance is not evident on echocardiography.

However, once the circulations are separated, the more dependent twin may have a compromised circulation. It is of critical importance that the lowest filling pressure possible is used and that the afterload is also reduced. We try to maintain as low a central venous pressure as possible, together with as low a blood pressure as possible, commensurate with an adequate urine output. This phase of compromised cardiac performance lasts a number of days but is usually resolved by 7 days postoperation.

The timing of enteral feeding is variable but should not necessarily await body wall closure. In the majority, complete removal of the mesh is achieved when the abdomen is closed. On occasion, it is necessary to leave some mesh, and this has not been a particular problem over the following years.

The management after birth can take one of three courses (Table 131-3):

1. **Nonoperative management** is indicated when there is complex cardiac union without the possibility of reconstructing even a single functioning heart or where there is extensive cerebral fusion. Parents faced with the prospect of a surviving twin having severe deformities may refuse consent for separation. In eight of nine cases in our series there was cardiac fusion, while in one with extensive parapagus fusion (a normal triplet survived) parents refused surgery. All nine sets died within a short period.
2. **Emergency separation** is required when one twin is dead or dying and threatening the survival of its sibling, where there is a correctable congenital anomaly incompatible with survival if left untreated such as esophageal or intestinal atresia, or where serious damage has occurred to the connecting bridge or area of fusion (ruptured omphalocele).

   Emergency separation was necessary in eight of our cases. One had a rupture of the shared omphalocele resulting in tearing of the united liver with exsanguinating hemorrhage resulting in the death of one twin. Emergency separation was undertaken in an attempt to salvage the surviving twin who unfortunately died at the end of the procedure. In three sets of thoracopagus twins, cardiac instability prompted emergency separation. Only one of these infants survived. Prenatal volvulus with necrosis and perforation occurred in a set of omphalopagus twins, necessitating emergency separation. Both twins had intestinal atresia that was repaired, but both had short bowel syndrome that required many months for adaptation to occur. They survived and eventually thrived. Another set of omphalopagus twins was transferred soon after birth because one had severe pulmonary hypoplasia needing mechanical ventilation. This twin died in the ambulance during transfer. The transport team was instructed to digitally compress the area of union to prevent exsanguination into the surviving twin and avoid applying a clamp because prior experience showed that much of the surviving twin's intestine may reside in the peritoneal cavity of its sibling. This twin did survive.

   The survival rate for emergency separation was 4 out of a possible 16 infants—25%. In retrospect, survival was not possible in six of these cases.
3. **Planned separation—**if the twins are stable and healthy at birth, they should be allowed to feed normally and thrive with the intention to separate at around 2 to 3 months. This allows time to carry out investigations to define as accurately as possible the nature and extent of shared organs. The operative procedure can then be planned with involvement of all the relevant staff.

Fourteen sets underwent planned separation, of whom three died (two at home 6 months after successful separation) and 25 survived (89%) (Table 131-4).

## Follow-up

The extent of the union will determine whether the infants will have minor or major residual problems. One or both twins may have congenital cardiac abnormalities that may require surgical correction. Residual scars or contractures may require plastic surgical correction. Short bowel syndrome occurs when each twin is allocated 50% of the shared intestine. There will be a need for parenteral nutrition and meticulous dietary support for a period of time pending intestinal adaptation, which generally occurs. Intestinal stomas may be temporary or permanent and will require the input of a stoma therapist. Imperforate anus will need reconstruction if possible. Prolonged urinary follow-up is essential, particularly in the cases of ischiopagus and pygopagus twins. Shared bladder, cross ureters, vesicoureteric reflux, and renal abnormalities will require regular monitoring to prevent further damage and to diagnose early and treat urinary calculi. Lifelong orthopedic follow-up will be necessary for limb deformities, deletion of lower limbs, and scoliosis and chest wall deformities.

Psychologic support should commence preoperatively when separation is undertaken at a later age and is essential following separation, especially when one twin dies. When the separation has involved prolonged periods of hospitalization (some of our twins have been discharged within 2 weeks of separation), there may be developmental and behavioral problems that require attention.

## Ethics

If separation is possible with the expected survival of both twins, we strongly recommend that the surgical procedure be performed. If the hearts of the twins are fused, the chances of survival of one or both twins is so remote that surgery should be declined and nature allowed to take its course.

If one twin has a lethal abnormality and cannot survive independently from his or her "normal" twin, and without separation both twins would die, then separation should proceed, even though it is at the expense of the abnormal twin.

**TABLE 131-3**

Yet twins can survive joined together for many years. Alice D. Dreger, PhD, a professor in medical humanities and bioethics, contends that "when it comes to cases in which one twin must be 'sacrificed,' it is ethically wrong to take one life so another may live."[46a] She further states that "not in a single case has the twin chosen to survive ever actually survived to go home." This is clearly incorrect as borne out in our and other series.

# Heteropagus (Parasitic) Twins

Heteropagus or parasitic twin is a grossly defective fetus, or fetal parts, attached externally, with or without internal connections, to a relatively normal twin (the autosite) in one of the same eight areas in which symmetrical twins are united.[23] They are usually composed of externally attached supernumerary limbs but may also contain viscera or visceral parts and only rarely a beating heart or intact brain.

Fetus in fetu is a fetiform mass enclosed within the body of the autosite, usually the abdominal cavity, rarely within the brain, with grossly recognizable fetal parts including an axial skeleton, attached to the autosite by a pedicle containing a few large blood vessels. Its growth rate is similar to the host within which it is discovered.

## INCIDENCE

The estimated incidence of heteropagus twins is much less than for symmetrical twins—1 per 1 million births or less. The female preponderance seen in symmetrical twins is not evident in heteropagus twins where there is an equal distribution of the sexes.

## EMBRYOLOGIC CONSIDERATIONS

The most plausible theory for the occurrence of heteropagus twins was proposed by Dönitz in 1866.[47] He postulated that heteropagus twins originated from symmetrical twins, one of which suffered secondary damage as a consequence of vascular compromise. The affected "twin" would then have to rely on collateral blood supply from the autosite while ischemic damage occurred in various parts of the affected "twin." In support of this theory, hypoplastic umbilical vessels have been found in the heteropagus twin and vascular connections from the autosite to the heteropagus twin may be found during surgical separation. Others have disputed this theory because it cannot account for all the abnormalities found in these twins and particularly cannot explain the acephalic occurrence. It is generally accepted that the heteropagus twin is genetically identical to the autosite, and this has been substantiated by DNA analyses.

## ANATOMIC TYPES

Reports of 157 cases of heteropagus twins have appeared in the literature until 2003. Recently, Sharma and colleagues[48] reviewed 39 cases reported in 23 publications since 2003. In six cases the specific variety was not defined.

Table 131-5 provides a breakdown of these cases:

*Dipygus* or *caudal duplication* (Fig. 131-16)[49] is a rare abnormality comprising two sets of accessory lower limbs sited between the autosite's limbs and including accessory external genitalia.

*Omphalopagus* (Fig. 131-17) or *epigastric heteropagus* accounts for the majority of cases—more prevalent in recent series, in which almost 60% of cases were in this region.[50–52]

*Fetus in fetu*[53–55] occurs most commonly within the abdominal cavity with 57 reported cases with only 9 having a brain and 6 a heart, both always small and rudimentary. In most cases a pedicle of vessels arises from the retroperitoneal region and attaches to the umbilical area of the parasite. In the cranial region the majority of fetuses in fetu are epignathi attaching to the posterior pharynx near the Rathke pouch. Only seven cases of intracranial fetuses in fetu have been reported.

Sacral parasite is a rare variety of heteropagus twin and needs to be differentiated from sacrococcygeal teratoma.[56] Some authors consider fetus in fetu and fetiform teratomas within the spectrum of teratomas, but this remains controversial.

FIGURE 131-16 Dipygus with prolapsed intestine.

FIGURE 131-17 Parasitic omphalopagus twins.

## DIAGNOSIS

Prenatal identification of heteropagus twins has been documented on at least seven occasions at gestational ages ranging from 9 to 28 weeks. The importance of recognition of the nature of the abnormality is evident in that the condition is entirely benign and compatible with normal development. The diagnosis in utero should not be considered an indication for termination of the pregnancy provided that it is not causing gross deformity of adjacent structures.

## OBSTETRIC CARE

Depending on the size and extent of the parasitic twin, delivery can be by normal vaginal route. If there is a suspicion of expected obstructive delivery, then cesarean section at around 38 weeks of gestation would be indicated.

## INVESTIGATION

Sharing of organs and vascular connections are infrequent in heteropagus twins. As a result, preoperative imaging has usually been restricted to CT, ultrasound, and MRI scans, which reveal bony and soft tissue structures. Occasionally angiography has been undertaken to show vascular communications, but in recent years magnetic resonance angiography, which is safer and noninvasive, has replaced the invasive conventional angiography. Echocardiography of the autosite is mandatory in thoracopagus parasitic twins because more than 25% have congenital cardiac defects.

## SURGERY

Separation of the parasite from the autosite is generally undertaken in early infancy. As mentioned earlier, sharing of organs and major vascular connections is unusual in heteropagus twins. Therefore the surgical procedure is generally straightforward and uncomplicated. The initial skin incision should be carefully planned to take sufficient skin and subcutaneous tissue from the parasite to ensure tension-free closure of the wound following separation. One of the common complications following separation is wound breakdown or infection, and this can be avoided by careful planning and meticulous closure of the incision. A thorough search of the autosite at the site of attachment must be carried out to exclude any retained abnormal or extraneous tissue and to correct possible anomalies in the autosite such as associated congenital intestinal abnormalities.

## OUTCOME

The prognosis for the autosite is generally excellent except for cases with severe cardiorespiratory problems. Wound complications can be avoided by careful preoperative planning and meticulous attention to detail in the operative procedure.
